* The numbers in parentheses indicate the number of determinations; ± *S.E.*

was freely movable on the 10th day but quite firm by the 34th day. The animals in general lost weight between the first and second test but tended to regain this loss prior to the 34th day.

From the data of Table 1, it can be concluded that by the 34th day an increased rate of proline utilization accompanies callus formation; the serum proline level is abnormally low at both 30 min and 1 h after injection of proline. In contrast, after only ten days of healing when callus is small, there is no significant difference in proline 'tolerance'; 30 min after an injection of proline the average value is higher and more variable in the fracture animals than in the controls. Furthermore, the increase in proline 'tolerance' during the period of growth of callus is a relatively constant response. These observations suggest that increased proline tolerance recently reported in patients with osteogenesis imperfecta should be interpreted with caution; many patients hospitalized with this disease are recovering from fractures, both clinical and non-symptomatic microfractures. It should be emphasized, however, that fracture healing effects do not necessarily disprove the relation between osteogenesis imperfecta and increased proline 'tolerance'. But because of the potential importance of that relationship, it must be investigated further in patients having no visible fractures.

In any event, that proline disappearance from the blood is accelerated by fracture healing suggests the proline 'tolerance' test might be used as an indicator of bone formation. Whether the effect on proline 'tolerance' specifically reflects callus formation or, non-specifically, either a phase of tissue repair or an aspect of metabolism associated with a phase of recovery from injury, is a question to be settled by additional experiments. A proline 'tolerance' test would have the advantage of not involving radiation, permitting its daily repetition with minimal discomfort or hazard.

This investigation was supported by research grants from the U.S. National Institutes of Health (grant No. A-3793), the Squibb Institute for Medical Research, National Society for Crippled Children and Adults, and Ayerst Laboratories, Inc.

HISTOLOGY

Hypogastric Nerve of the Dog

EXPERIMENTS attempting to distinguish between the effects of reserpine on sympathetic ganglia and on post-ganglionic fibres were carried out on the inferior mesenteric ganglia and the hypogastric nerves of the dog. Analysis of the tissues showed such large and variable amounts of both noradrenaline and adrenaline in the hypogastric 'nerves', coupled with a high degree of resistance to the depleting effect of reserpine, that it was obvious that these 'nerves' were complex in structure. Langley and Anderson's detailed analysis[1] of the hypogastric nerves of the cat and the rabbit had shown these to consist of about 90 per cent non-medullated and 10 per cent (afferent) medullated fibres. As these authors pointed out later[2], a proportion of the non-medullated fibres are preganglionic and are interrupted in ganglia situated usually near the innervated organ, such ganglia being more frequent in the rabbit than in the cat. This analysis did not, however, explain the chemical findings on catecholamines in the dog, since these strongly suggested the presence of chromaffine tissue in the nerves.

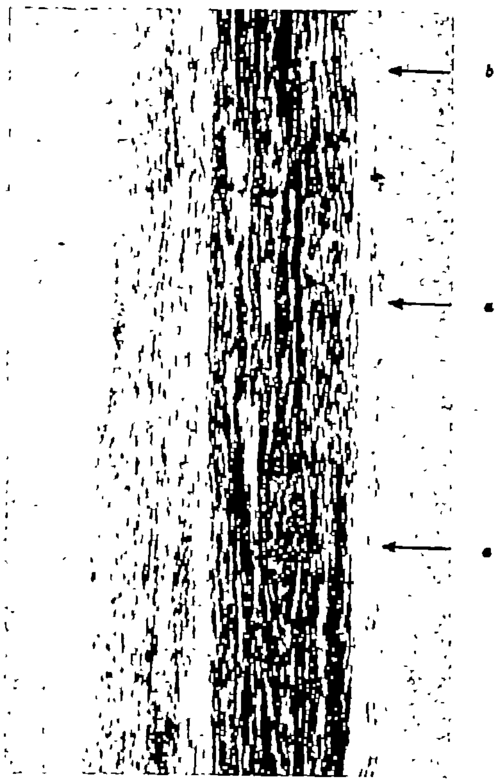

Fig. 1. Longitudinal section through dog's hypogastric nerve about midway between inferior mesenteric ganglion and pelvic plexus. Clusters of (*a*) chromaffine, and (*b*) nerve cells in the core of the nerve

The occurrence of chromaffine tissue in sympathetic ganglia, particularly those of the abdomen, and in the preaortic nerve plexus of cat and man was known since the work of Kohn[3]. However, whereas in man there is only a hypogastric plexus and no hypogastric nerve, the dog has distinct hypogastric nerves, which are 4–8 cm long and have very few branches and no macroscopic swellings. The question, therefore, arose where chromaffine tissue, if such was present, might be localized in such a nerve.

Longitudinal serial sections were made of the inferior mesenteric ganglia and the hypogastric nerves of 4 dogs, 2 adult and 2 puppies of either sex. The dogs were bled to death under anaesthesia. The tissue was stretched out and tied on a glass plate and fixed in a solution containing, per 100 ml., 10 ml. 40 per cent formaldehyde solution, 2·5 g potassium bichromate and 1·0 g sodium sulphate. After washing overnight it was embedded in paraffin, sectioned at 6μ and stained with cresyl violet. As expected, large chromaffine bodies were found inside the inferior mesenteric ganglia, but these did not extend into the hypogastric nerve. However, small elongated groups of 5–50 chromaffine cells occurred either within the very core of the nerve (Fig. 1), or along its surface underneath the epineurium. These groups were usually found in the middle part of the nerve, 2 or more cm away from either the lower pole of the mesenteric ganglion or the beginning of the pelvic plexus. They were not necessarily in the vicinity of nerve cells. Nerve cells were abundant in the meshes of the pelvic plexus, but were also present, though scarce, within the hypogastric nerve proper, and were usually arranged like a string of beads in the core of the nerve. They were found in larger clumps at the origin of the hypogastric nerves near the lower pole of the inferior mesenteric ganglion.

So far as can be judged from this small material there was no difference in the amount of chromaffine tissue in the nerves of young and of adult dogs. Similarly, Kohn[3] found that chromaffine tissue does not degenerate in adult cats and rabbits.

In view of the present interest of pharmacologists in the hypogastric nerve–vas deferens preparation of the guinea pig devised by Huković[4], the fact should be kept in mind that this 'nerve' is a complex structure and varying in composition from species to species, and not just a bundle of postganglionic fibres.

I thank Mr. B. S. C. Hollands for preparing the sections.

These investigations were sponsored in part by the Air Force Office of Scientific Research, *OAR*, through the European Office, Aerospace Research, United States Air Force.

PATHOLOGY

Ineffectiveness of Autotransplantation on Growth of the Methylcholanthrene Sarcoma in Rats and Mice

RECENTLY, Ishibashi *et al.*[1] reported that the subcutaneous autotransplantation of a patient's own tumour slices was effective against the growth of the original tumour and sometimes caused its regression. It seems, however, that experimental evidence on the effectiveness of autotransplantation is not sufficient to try it against human cancer. Attempts were made in this laboratory to examine whether autograft of tumour induced by methylcholanthrene could increase the survival days of the host after appearance of a tumour.

The animals consisted of 100 virgin female Wistar strain rats weighing about 105 g and of 100 mice of *A1* strain[2] of both sexes, 15–20 g in weight. They were injected subcutaneously in the interscapular region with 3 mg in rats and 1 mg in mice of 20-methylcholanthrene (California Corp. Biochem. Res., Los Angeles) in olive oil, and were fed a synthetic cube diet (Central Laboratory for Experimental Animals, Tokyo) and given tap water *ad libitum*.

Subcutaneous autotransplantation. Seventy rats in which tumours (fibrosarcoma) developed in 100–130 days after methylcholanthrene injection were subjected in this experiment. When the tumour attained a diameter of 20–25 mm, two-thirds of it was excised from 40 animals. Twenty (group 1) of them were transplanted surgically with their own tumour (2 slices, 3 × 3 × 3 mm) into the subcutaneous tissues of the dorsal surfaces apart from the indigenous tumour. Twenty other rats (group 2) were subjected to an identical procedure as the animals of group 1, without tumour implantation. Thirty animals as control (group 3) were maintained freely without surgical excision or implantation of the tumour. After surgical operation, maximum diameter and its right-angled one in all tumours were recorded at least once a week.

Growth rates of tumours in rats of each group are presented in Fig. 1*a*. The growth curve of group 1 has almost the same as that of group 2. Average survival after tumour occurrence was 50·6 ± 10·1 in group 1, 46·9 ± 7·0 in group 2 and 47·0 ± 13·1 days in group 3, respectively. Statistical analysis revealed that there were no significant differences in survival days among three groups.

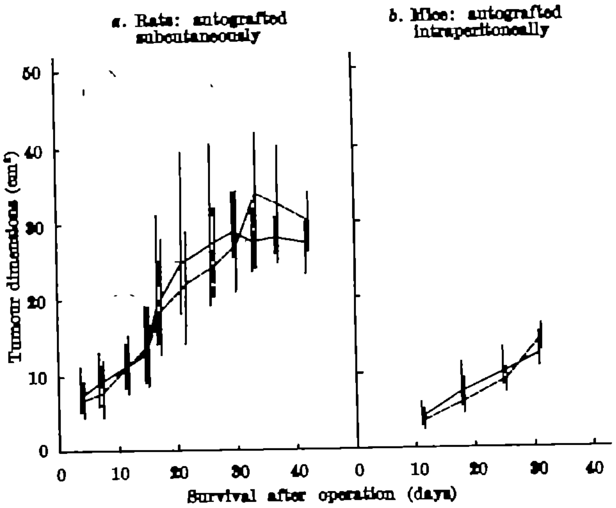

Fig. 1. Growth rate of the methylcholanthrene sarcoma in the autografted (——) or the non-autografted (- - - - -) rats (*a*) and mice (*b*). The length of the longitudinal lines denotes the range of tumour sizes

Intraperitoneal autotransplantation. When the tumour reached a size of 12–15 mm in diameter, mice were autotransplanted with tumour (2 slices, 2 × 2 × 2 mm) into the peritoneal cavity by 13-gauge trocar. Sixty mice in which tumour developed (fibrosarcoma) 70–100 days after injection of the carcinogen were subjected to the following experiment. In 20 mice, two-thirds of the tumour was excised and the tumour was inoculated intraperitoneally (group 4). The tumour in 20 other animals was excised similarly with group 4 and the abdominal wall was inserted by the trocar without tumour transplantation (group 5). The remaining 20 mice were maintained freely without any operation (group 6).

Growth rates of the tumours of each group are presented in Fig. 1*b*. The curve of group 4 has almost the same configuration as that of group 5. Average survival days after tumour occurrence was 39·3 ± 3·3 in group 4, 38·2 ± 5·5 in group 5, and 35·8 ± 5·4 in group 6, respectively, and differences among three groups were of no significance.

The results of the present experiments showed no convincing effect of the immunological treatment on malignancies, although the negative results might mean that the materials or the techniques were inadequate. After preparation of this paper, we read Rhodes's experiment[3] in which the tumour (the spontaneous tumour of the $c+$ strain) was autografted subcutaneously with Freund's adjuvant and tetanus toxoid into autochthonous mice. He found also no significant difference in the life-span between autografted and non-autografted animals.

We thank Dr. K. Sugiura, Sloan-Kettering Institute, for the gift of the trocar, and Prof. T. Nagayo and Dr. K. Kojima of this Department for their advice. This work was supported in part by research grants from the Ministry of Education and the Japan Cancer Society.

Hepatitis in African Monkeys

INFECTIOUS hepatitis is thought to be caused by a virus which is transmissible to man[1–4] but not to monkeys or other laboratory animals[5–9].

The present communication is a preliminary report on work carried out to determine the susceptibility of West African monkeys to infectious hepatitis. For this purpose, young animals were inoculated subcutaneously with suspensions of human tissues and fæces from fatal cases of this disease. The livers of these monkeys were examined in serial biopsies taken at intervals of 2–3 days for six weeks after inoculation. All biopsies were divided into two portions; one stored in the frozen state to preserve virus, the other examined by cytological and cytochemical methods for changes similar to those occurring in the human liver[10–12].

Following inoculation, young patas monkeys (*Erythrocebus patas patas*) showed liver changes during the period 3–6 weeks after inoculation. The parenchymal changes (Fig. 1) consist of occasional small foci of liver cells showing a slight increase in nuclear and nucleolar size and a concurrent increase in nucleolar and cytoplasmic ribonucleoprotein. Occasional necrotic cells and mitotic figures also occur. Some of the portal tracts exhibit an infiltration with inflammatory cells and swelling of the connective tissue fibroblasts. The stored portions of biopsies showing such changes were inoculated into further young patas monkeys. These animals showed similar, although more pronounced, parenchymal and stromal alterations during the same period.

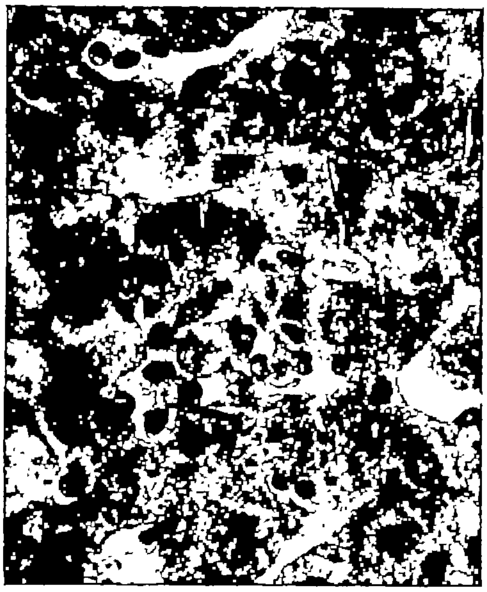

Fig. 1. Early parenchymal focus in patas monkey liver 23 days after inoculation (× 600)

Although the livers of all infected monkeys show focal parenchymal and stromal changes, in many third and later passage monkeys, these alterations afterwards spread to involve the entire liver. In these cases, parenchymal changes are diffuse throughout the lobule (Fig. 2) but necrosis is limited to a few individual or small groups of liver cells. In viable liver cells (Fig. 3) the nuclei and nucleoli are usually slightly enlarged and the latter shows an increased amount of ribonucleoprotein. The cytoplasm is partly or completely filled with ribonucleoprotein but swelling of the cells does not occur. There is no increase of lipids but glycogen is reduced or absent. The mitochondria appear increased in number in viable cells but are swollen in degenerating or necrotic cells. The sinusoids are often dilated, especially near the central veins, and contain an increased number of lymphocytes and granulocytes. The Kupffer cells are swollen. The portal tracts show a moderate to marked infiltration with inflammatory cells and a variable degree of degeneration. Occasionally complete necrosis of the portal tract occurs. The capsule and intercalated veins also show localized areas of infiltration and degeneration.

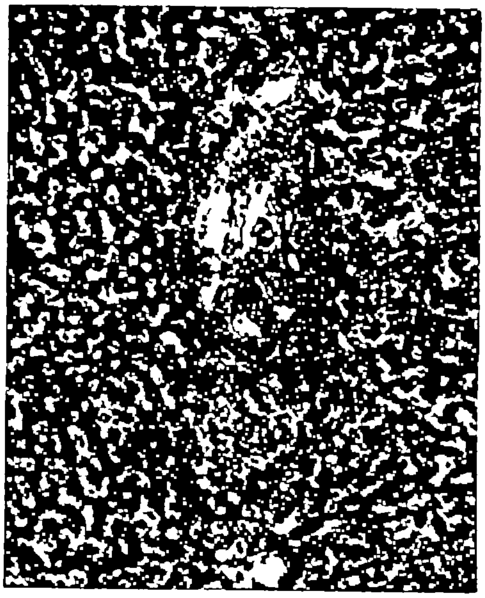

Fig. 2. Liver of patas monkey dying 29 days after inoculation (× 125)

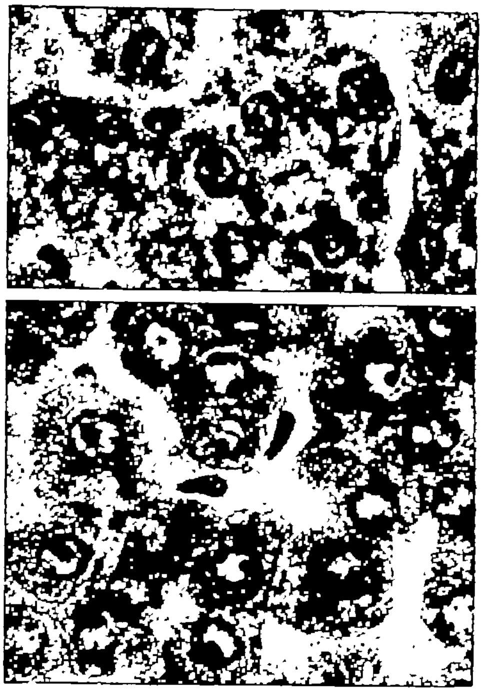

Fig. 3. Liver cells of healthy (above) and infected (below) patas monkeys (× 1,000)

Subcutaneous inoculation of a variety of African monkeys with infected patas liver suspensions has given rise to similar changes in the livers of five other species of Cercopithecoid monkeys, but not in baboons, drills or mangabeys. Though the majority of infected monkeys exhibit no clinical manifestations of disease, young animals with widespread changes in the liver usually show anorexia and become emaciated. In these instances, death frequently ensues. There is never any clinical evidence of jaundice.

Changes in the liver similar to those in infected animals have not been seen in the livers of 223 uninfected African monkeys, neither have they been induced by inoculating pooled biopsies from uninfected into healthy monkeys. Inoculation of infected patas liver suspensions into white mice and white rats has not given rise to disease or changes in the livers in these animals. No virus has been isolated in monkey kidney tissue cultures. Attempts to isolate bacteria from infected monkey livers in a variety of artificial media have been unsuccessful. No micro-organisms have been seen in stained liver sections. The agent passes a Seitz filter and withstands a temperature of 56° C for 30 min. These findings suggest that the hepatitis occurring in young patas monkeys is caused by a relatively thermostable virus. At the time of writing, this virus has been isolated on eight separate occasions following the inoculation of suspensions of liver, spleen, colon and faeces from these cases. All isolations have been maintained in serial passage through the subcutaneous inoculation of infected patas monkey liver suspensions.

The results reported here suggest that hepatitis may be induced in young patas monkeys through inoculation of material from human cases of infectious hepatitis. Although the liver changes in infected animals parallel those in the human liver in this disease, further studies are necessary to determine whether the virus causing the hepatitis in monkeys is the same as that causing human infectious hepatitis.

IMMUNOLOGY

Properties of Phage-neutralizing Antibodies produced by New-born Rabbits

The new-born rabbit is known to show an immunological reactivity which differs in several respects from that of the mature animal. We have found that rabbits injected at birth with coliphage T_2 show, after a short delay, phage-neutralizing activity in their sera which appears to be antibody. These antibodies, however, differ in several aspects from the phage-neutralizing antibodies produced by adult animals immunized with the same bacteriophage.

For the work reported here rabbits were injected in the foot-pad, within 24 h of birth, with 2×10^9 plaque-forming units of *E. coli* T_2 bacteriophage purified by differential centrifugation[1] suspended in 0·1 ml. saline. At 7 days of age the animals were killed and their serum assayed for phage-neutralizing activity following the procedure of Barlow *et al.*[2], the titration being performed either immediately or after storing the serum for a few days at 4° C. All the sera examined showed activity ranging from 4 to 64 phage-neutralizing units (50 per cent p.n.u.) per ml.; no activity at all was found in the fresh serum of control 7-days-old rabbits not injected with phage at birth. We then examined the effect of various treatments on the phage-neutralizing activity found in the serum of immunized baby rabbits; for comparison we also examined the normal serum from a non-immunized adult rabbit and the serum from an adult rabbit repeatedly immunized with coliphage T_2. This last serum was diluted with serum from untreated 7-days-old rabbit in order to give a titre of 50 per cent p.n.u./ml. comparable with that of the immunized new-born animal. The results of a typical experiment are presented in Table 1.

Table 1. T_2 PHAGE-NEUTRALIZING ACTIVITY OF RABBIT SERA, MEASURED AS 50 PER CENT P.N.U./ML.

Treatment	Normal adult	Immunized new-born	Immunized adult
None, dilution for titration in buffer as indicated by Barlow *et al.*[2]	8	64	64
None, dilution for titration in 1:10 fresh serum from untreated 7-days-old rabbit	8	250	64
Heating at 56° C for 30 min	0	0	64
Heating at 56° C followed by dilution in 1:10 fresh serum from untreated 7-days-old rabbit	0	0	64
With 0·01 M sodium EDTA	0	0	64
Absorption with 'Zymosan' at 17° C	0	0	50
Ultracentrifugation* activity in the central part of the sector	−	−	+
Ultracentrifugation* activity in the peripheral part of the sector	+	+	+

* Spinco Model *E* analytical ultracentrifuge, cell equipped with an Yphantis–Waugh moving partition centrepiece. One central and one peripheral fraction were collected after the passage, into the peripheral part of the sector, of a peak sedimenting at about 19*S*.

The results suggested that the phage-neutralizing substances produced by the immunized new-born rabbit might be similar to those naturally present in the adult and often included in the properdin system. We tested our sera against a phage antigenically unrelated to that used for immunizing the new-born animal, namely, coliphage T_5, and we found no activity whatever.

The simplest interpretation of the results is that the phage-neutralizing activity found in the sera of rabbits immunized at birth with T_2 phage was indeed due to antibody. Thus it fulfilled the requirement of appearing as the consequence of a given antigenic stimulation and of being specifically directed against the same antigen; the phage-neutralizing activity appeared 4–5 days after the antigenic stimulation, a latent period not dissimilar from that of many primary antibody responses, and also was associated with the 19*S* globulins, a serum fraction known to include many kinds of antibodies.

On the other hand, the phage-neutralizing substance produced by immunized new-born rabbits has many of the properties once ascribed to properdin[3]. This is perhaps not so surprising in view of the possibility that properdin may represent a family of somewhat peculiar antibodies[4], arising as the consequence of natural stimulation with a number of antigens, a possibility also borne out by the recent observations[5] that the phage-neutralizing activity of normal (human) sera appears to be due to a combination of molecules with different specificity. Indirectly our results give support to the hypothesis that these are indeed antibodies elicited by 'natural' contact with minimal amount of each phage against which a neutralizing activity is found in 'normal' serum. So it would appear that heat-labile and complement dependent 19*S* antibodies are formed by the new-born rabbit as a consequence of immunization with sufficient amounts of phage, and by the adult animal as a product of basal stimulation with what might be the minimal amounts of antigen that penetrate the intestinal tract.

Perhaps our observations may be interpreted on the basis of recent results which show that the antibodies produced by different animals in the early stages of the immune response usually are 19*S* [6–8] and may be complement dependent[9] and more heat-labile than those produced later on in the course of immunization[10]. Thus the new-born rabbit would respond to immunization with phage in a more sluggish way than the adult, the 'early' antibodies being the only ones produced for a period of about two weeks (which is the age at which we first observed the production of 'classical' heat-stable anti-phage antibodies). This situation might not be valid for species other than rabbit because, for example, heat-stable anti-phage antibodies may be produced by the new-born guinea pig[11] or even by the opossum embryo[12]. In the rabbit, heat-stable antibodies (but mainly 19*S*) may be produced by 10–16 days old animals immunized at birth with some bacterial antigens[13] or with antigens plus adjuvant[14].

ANATOMY

Periodic Acid–Schiff-positive Component of the Medullary Bone of the Laying Domestic Fowl

INVESTIGATION of avian medullary bone in this laboratory led to the observation of a substance therein which gave a very strong positive reaction with the periodic acid–Schiff technique. In some instances this took the form of branching homogeneous strands or fibrils of irregular thickness distributed in a less-strong periodic acid–Schiff-positive matrix; in other instances it was more dispersed and less distinctly fibrillar. Variation in the amount of this substance was also noted in different stages of the egg-laying cycle and, as a loss of chondroitin sulphate from the cartilage is known to precede endochondral bone formation, an attempt was made to determine the nature of the periodic acid–Schiff-positive substance in avian bone and to correlate the variations in appearance and amount with the alternate absorption and deposition known to occur in this bone during the egg-laying cycle[1].

Specimens of medullary bone were obtained from forty laying hens of the Thornber 505 hybrid strain, varying in age from 1 year to 18 months, specimens being taken from about the middle of the shaft of humerus, femur, tibia and fibula of each bird within a few minutes after death. Specimens from each block were fixed in absolute alcohol, or in Heidenhain's susa containing twice the prescribed quantity of trichloroacetic acid to initiate decalcification. Alcohol fixation tissues were decalcified in N acetate buffer at *p*H 4·5; decalcification of susa-fixed tissues was completed in 'Permutit' ion exchange resin ('Zeo-Karb 225') in 10 per cent formic acid. After decalcification the tissues were dehydrated, cleared, embedded in paraffin and sectioned at 5μ.

Sections from each specimen were stained with periodic acid–Schiff technique[2,3] either alone or following preliminary treatment by one or other of the following: (1) salivary amylase (saliva) for 30 min at 37° C; (2) bovine testicular hyaluronidase (L. Light and Co.) for more than 16 h at 37° C (ref. 4); (3) ribonuclease (L. Light and Co.) for more than 16 h at 37° C (ref. 5); (4) methanol–chloroform for 16 h at 37° C (ref. 6).

All sections were stained with nuclear fast red[7] and acriflavine[8], toluidine blue *p*H 3·8 (ref. 9), and 0·01 per cent azure *A*[10], amido black 10*b* (ref. 11), alcian blue[12] and gallocyanin chromalum[13] and hæmatoxylin eosin. The methylene blue extinction test[14] and the gentian violet reaction[15] were used to estimate basophilia.

All the long bones of the birds in this series contained medullary bone, though this was generally scanty in the humerus, due to the intrusion of the calvicular air-sac. In one case, however, larger amounts than usual were found. Variations in the amount of medullary bone were noted in different birds, but the variations appeared to be random and could not be correlated with the position of the egg in the tube. This confirms the finding of Bloom *et al.*[1]. Variations in the quantity and appearance of this intensely periodic acid–Schiff-positive material were also observed, but again no correlation between this and the position of the egg could be distinguished. It was noted, however, that the diffuse non-fibrillar phase was characteristic of the second half of the period of shell deposition, although not confined to this phase.

A strong periodic acid–Schiff-positive reaction indicates the presence of complex polysaccharides with the 1,2-glycol linkage, including glycogen, mucopolysaccharide, mucoprotein and glycolipoid and, possibly, also nucleic acids. The unlikely presence of the latter in this material is negatived by the fact that the intensity of staining is not reduced by prolonged pre-treatment with ribonuclease, which results in hydrolysis of both RNP and DNP[5] and also by the failure of the material to stain with gallocyanin chromalum. Glycolipoids and glycogen are eliminated by pre-treatment with methanol–chloroform and diastase respectively and it would seem, therefore, that this material is a mucopolysaccharide or mucoprotein. Because of its high protein content, the latter might be expected to stain with amido black, and failure to obtain a reaction with this dye suggests that the substance is a mucopolysaccharide. This receives confirmation from the finding that it exhibits metachromasia with toluidine blue and azure *a*. Under the conditions of this latter staining technique metachromasia is exhibited mainly by sulphated mucopolysaccharides but also by hyaluronic acid (through its carbonic acid radical) and by nucleic acids (through phosphoric acid radicals). The latter are eliminated by their lack of response on treatment with ribonuclease and hyaluronic acid by the continuing periodic acid–Schiff response without change after 16 h hydrolysis in hyaluronidase. Furthermore, there is a positive reaction with alcian blue, specific for acid carbohydrates[12]. There is thus evidence that the periodic acid–Schiff-positive substance in avian medullary bone is a sulphated mucopolysaccharide. The failure to respond to hyaluronidase despite prolonged incubation is interesting, in view of the report by Meyer and Rapport[16] that testicular hyaluronidase is capable of hydrolysing the chondroitin sulphate component of cartilage.

This substance stains also by the nuclear fast red and by the acriflavine techniques, reactions which are regarded as being specific for sulphated mucopolysaccharides[7,8]. Again, basophilia with methylene blue at a *p*H of less than 2·5 tends to confirm this suggestion. However, there is evidence against the view that this basophilia necessarily indicates sulphated mucopolysaccharides[17]. Further confirmation with regard to the nature of this substance is found in the fact that a reaction is obtained in alcohol-fixed material stained for 24 h in a solution of gentian violet at a dilution of 1 : 1,280,000. Harada[15] has claimed that only sulphated mucopolysaccharide will respond at this dilution, the carboxylated mucopolysaccharides failing to respond to dilutions greater than 1 : 250,000. It is interesting, however, to note that this response is obtained only with alcohol-fixed material, the susa-fixed tissue

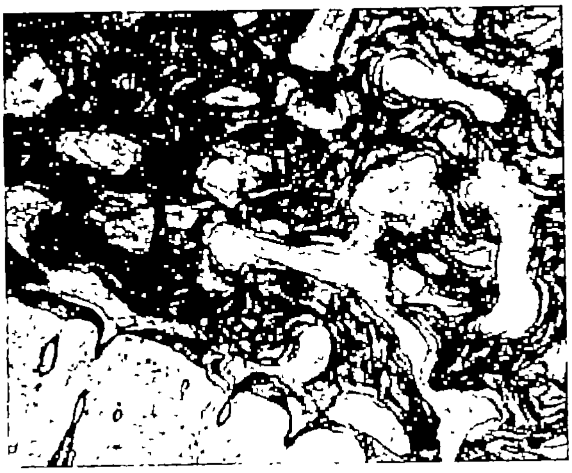

Fig. 1. Section showing cortical and medullary bone from the femur shaft of a laying hen. The specimen was taken shortly after an egg had been laid and prior to the next ovulation. Note the strongly periodic acid–Schiff-positive strands of sulphated mucopolysaccharide incorporated in the medullary bone matrix. (Hæmatoxylin and periodic acid–Schiff)

failing to react at dilutions greater than 1 : 250,000. The significance of this is not understood.

Irving[18], using sudan black following pre-treatment with pyridine, alcohol or benzol, has demonstrated the presence of a line of sudanophil material (calcification line) at the surface of developing intramembranous bone. This substance is periodic acid–Schiff-positive and metachromatic and thus appears to be an acidic mucopolysaccharide. In formalin-fixed material, however, it could not be stained with methylene blue at low *p*H values (2·5) without pre-treatment in one or other of the foregoing reagents and it is thus distinguished from the mucopolysaccharide of avian medullary bone. Moreover, the sudanophil material described by Irving[18] fails to stain with alcian blue and is, in any event, confined to surfaces at which appositional growth is occurring, being separated from the bone only by a thin layer of pre-osseous matrix. Clearly, therefore, this substance is not identical with the periodic acid–Schiff-positive material of the labile avian medullary bone and, although there is evidence that the latter substance varies in amount and appearance at different stages of the egg-laying cycle, it does not appear to be associated with calcification in the same way as the sudanophil material of developing mammalian bone.

Investigation of the cell picture in the medullary bone (predominance of osteoblasts or osteoclasts) is continuing in an attempt to correlate more accurately the changes in the appearance of the periodic acid–Schiff-positive substance with the phases of shell deposition.

RADIOBIOLOGY

Alkaline Earths in Heparin

Heparin is widely used as a blood anticoagulant. In the determination of calcium, in plasma, for example, it is commonly assumed that heparin has no effect on the assay. We have recently found, however, that the strontium content of heparin could be a very substantial correction in the determination of the strontium content of heparinized plasma. This result stimulated us to determine the calcium, strontium and barium content of five different preparations of heparin which were available here.

The heparin for assay was taken as solid (when possible from an unopened ampoule) prepared by Boots Pure Drug Co., Ltd., or Evans Medical, Ltd. Calcium was determined directly by flame spectrophotometry. Strontium and barium were determined by neutron activation analysis. The results are shown in Table 1.

Table 1. Calcium, Strontium and Barium in Heparin in p.p.m.

Heparin batch No.	Calcium	Strontium	Barium
64373	2,930	92	4
64373/1	2,810	84	—
68424	390	5	2·5
66306	700	7·5	12
D 25200	300	9	8

It will be seen that there was a considerable range in calcium, strontium and barium depending on the particular preparation. If, for example, 20 mg of heparin (batch No. 64373) equivalent to about 2,400 units were added to 100 ml. of human blood, the adventitious calcium would be approximately 60 μg per 50 ml. plasma or 1·2 per cent. The strontium in the heparin would be nearly 2 μg and the barium 0·1 μg or about 100 per cent and 10 per cent respectively of the normal strontium and barium content of the plasma.

The results given in Table 1 are sufficient to show the importance of analysing each preparation of heparin when it is to be used as an anticoagulant for the estimation of alkaline earths in plasma and that the amount of heparin used should not be appreciably greater than that required to prevent clotting of the blood.

BIOLOGY

Relation between Carcass Composition and Live Weight of Sheep

A re-examination of the work of Hammond[1], Wallace[2,3], Pálsson and Vergés[4,5], and Wardrop[6], suggests that the carcass composition of a sheep, in terms of dissected bone, muscle and fat, is more closely related to its live weight than to its age. Using all the available data from these papers, including ewes and wethers irrespective of breed, age, stage of pregnancy and nutritional history and ram lambs up to the age of 2 weeks, the following regression equations have been computed for estimating the body composition of sheep from empty live weight (that is, the weight of the live animal at slaughter minus the contents of its alimentary tract):

$$\text{(i)}\ \frac{\text{Weight of carcass bone } (y_1)}{\log y_1 = 0\cdot722 \log x - 0\cdot706} \tag{1}$$

$$\text{(ii)}\ \frac{\text{Weight of dissected carcass muscle } (y_2)}{\log y_2 = 1\cdot018 \log x - 0\cdot554} \tag{2}$$

$$\text{(iii)}\ \frac{\text{Weight of dissected carcass fat } (y_3)}{\log y_3 = 1\cdot539 \log x - 1\cdot843} \tag{3}$$

Equations (1), (2) and (3) account for 96·1, 98·0 and 88·3 per cent, respectively, of the variance of the dependent variable ($\log y_1$, $\log y_2$, $\log y_3$) contributed by its relation to the independent variable ($\log x$). In each case, x and y are in kg, x being empty live weight. The data on which these regression equations are based, together with the regression lines, are shown on a log–log grid in Fig. 1. Data on individual sheep have been used, where available, but otherwise it has been necessary to use group means.

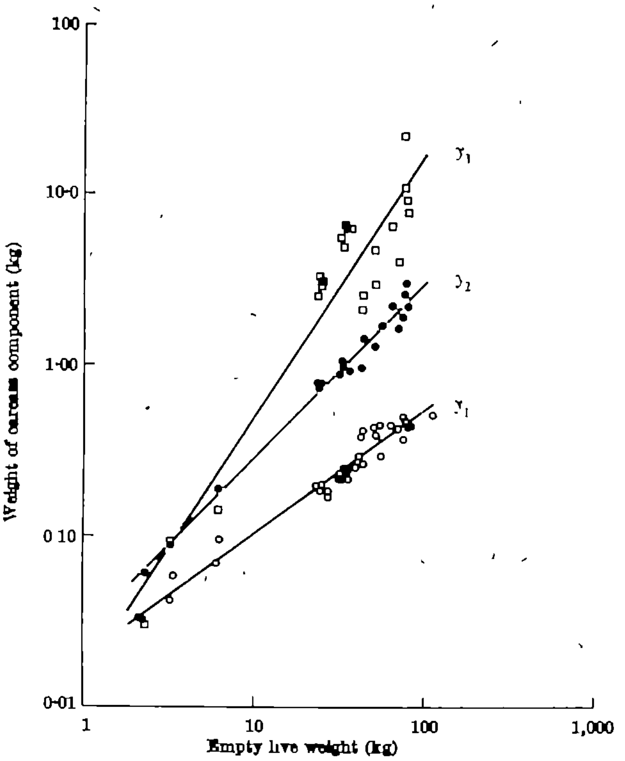

Fig. 1. Weight of dissected carcass bone (○), muscle (●) and fat (□) compared with empty live weight of sheep. The regression lines have been plotted using the equations given in the text

These equations are of the same form as Huxley's[7,8] allometric equation. They indicate that, as a sheep increases in empty live weight, each of these tissues also increases in weight. However, the slopes of these lines show that, as empty live weight increases, the percentage of carcass fat also increases, but the percentage of carcass bone decreases, whereas the percentage carcass muscle remains almost constant. The equations imply also that as a sheep loses weight, changes in body composition will result from the loss of all three tissues, the losses being given by these equations.

These equations all suggest that there is a constant differential growth ratio[7,8] between each carcass tissue and empty live weight. However, pooling of mass observations, as has been necessary here, may obscure changes of slope[9] which could occur within individual animals. In Fig. 1 the deviations from the regression lines are large enough to suggest that no equation is likely to be sufficiently accurate in its predictive value to adequately represent all sheep for any one carcass component. It will be necessary to investigate breeds and strains of sheep within various environments to establish more accurate regression equations.

By growing sheep at different rates and killing them at the same live weight, Pálsson and Vergés[4,5] were able to demonstrate the profound effects of plane of nutrition on the shape of young sheep. However, as indicated here, these various planes of nutrition had small effects on carcass composition. In addition, these treatments did not affect the weights of the commercial cuts of meat in the carcasses of these sheep. This evidence suggests that the shape of a sheep is of doubtful importance from a commercial point of view.

Similar conclusions have been reached following an examination of published data on cattle and pigs. It is proposed to publish this work in detail elsewhere.

I thank Mr. R. Seebeck for computing the regression equations.

This work forms part of a research programme financed by the Reserve Bank of Australia (Rural Credits Development Fund).

A Secondary Induced Thiamine Deficiency in Mink

NUMEROUS reports attest to the occurrence of thiamine deficiency in fur-bearing animals due to destruction of the dietary source of the vitamin by thiaminase activity. Fresh-water fish were first implicated as sources of the thiaminase enzyme, and their presence as major diet ingredients for foxes led to the definition of characteristic thiamine deficiency symptoms as 'Chastek paralysis'[1–3]. Ranch mink fed similar rations developed corresponding symptoms[4,5]. Extension of the diet sources used with mink led to the recognition that marine fish might also be troublesome as contributors of thiaminase activity[6] and at present a number of different fish species are listed as containing significant amounts of thiaminase. These have been assembled by Harris[7], who reports 28 fresh-water and 8 salt-water fish species as thiaminase-active.

Another distinct deficiency disease in mink, termed 'cotton-fur', has been shown by Stout *et al.*[8] to occur when two other fish species, Pacific hake (*Merluccius productus*) and Atlantic whiting (*M. bilinearis*), were fed as ingredients in an otherwise satisfactory basal mink diet. This condition has been identified as an induced iron deficiency and has been shown to respond to parenteral iron therapy[9]. Mink fed raw hake have characteristically become progressively anaemic and emaciated, but have retained a fair appetite and normal muscular activity. Hake has never been implicated as a thiaminase-containing fish species, yet there has been some controversy as to whether whiting contains thiaminase activity[10,11].

This communication describes a situation wherein mink placed on a hake diet formulated to produce the 'cotton-fur' anomaly developed typical symptoms of Chastek paralysis, and relates the thiamine deficiency to the feed consumed by the hake just prior to their being caught.

A group of 34 standard dark mink housed individually in wire pelter cages were placed at weaning in mid-July on a diet composed as shown in Table 1. This diet was formulated on the basis of past experience as causative of the 'cotton-fur' condition, due to its content of Pacific hake.

In marked contrast to previous 'cotton-fur' studies, mink in this instance evidenced early anorexia. Within 3 weeks of first receiving the test diet, they refused the major portion of their daily diet offering. Concurrently animals became extremely emaciated and loss due to death occurred. Since the ration was known to induce iron-deficiency, five mink were each injected with 25 mg of iron ('Armidexan', Armour Veterinary Laboratories) intra-

Table 1. Composition* of Experimental Ration

	%
Pacific hake	50·00

Alfalfa meal	2·34
Skim milk powder	1·44
	100 00

* Calculated on an 'as fed' basis.

muscularly; of these, three died indicating no therapeutic value of iron. Death losses continued and necropsy revealed complete depletion of internal fat stores and livers which appeared mottled and pale pink to bright orange in colour.

Individual mink exhibited signs of tetany when handled and showed other symptoms of Chastek paralysis. In checking the possibility of thiamine deficiency, four animals which showed varying degrees of paralysis were each given an intraperitoneal injection of 5 mg of thiamine hydrochloride. A rapid response to this treatment was noted and mink regained control of their muscles and several commenced eating within about 0·5 h of administration of thiamine.

Since Pacific hake had not previously been listed as a thiaminase-containing fish and since the remaining diet ingredients were known to be innocuous relative to production of thiamine deficiency, it was presumed that some alteration of this particular lot of hake had occurred. Examination of the viscera showed the stomachs of the hake to be distended and filled with anchovies (*Engraulis mordax*). No reference as to thiaminase activity of this latter small fish species is available; however, the striped anchovy of the Gulf of Mexico (*Anchoa hepsetus*) does contain the thiaminase factor[12]. A number of the hake stomach contents were removed, weighed and calculated to constitute approximately 14 per cent of the weight of the entire fish. As hake made up 50 per cent of the test diet, the anchovies were present to the extent of about 7 per cent of the total diet, as fed. Apparently this level was sufficient to destroy the dietary thiamine with the result that Chastek paralysis occurred. Afterwards, stomach contents of hake were removed, remaining animals were given 5 mg of thiamine hydrochloride intraperitoneally and the experiment was successfully continued to completion. Growth curves (Fig. 1) illustrate weight loss and subsequent improvement (following thiamine administration and anchovy removal) of mink fed contaminated hake rations as compared with growth of animals fed hake free of anchovies or an adequate control ration.

This experience is further confirmation of the potency of thiaminase in rendering biologically inactive the thiamine content of other dietary ingredients. More significant, however, it provides evidence of a secondary induced thiamine deficiency and demonstrates that not only the primary fish components of the diet, but also the stomach contents of such fish need to be considered as potential sources of thiaminase activity. In this regard it is notable that Neilands[13] found that stomach contents of two perch species showed considerable destruction of thiamine *in vitro* while the fish tissue *per se* was devoid of such activity.

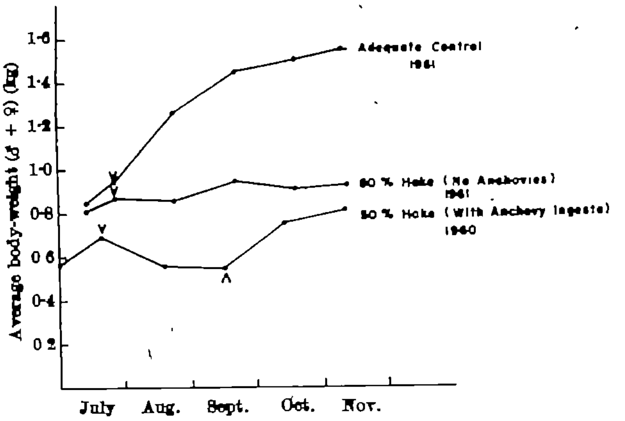

Fig. 1. Growth curves of mink fed fish diets with and without anchovy contamination. V, On test ration; Λ, injection of B_1 and removal of anchovies

This incident may help to explain the disparity between observations of thiaminase activity appearing in previous literature. Green *et al.*[14] observed that whiting caused Chastek paralysis in foxes fed this fish as part of their ration whereas others[10,11] were unable to demonstrate thiaminase activity of whiting *in vitro*. Quite possibly the whiting in the former case had ingested enough thiaminase-containing fish to be harmful while the latter fish were free of such contaminants.

Circadian Adrenal Cycle in C Mice kept without Food and Water for a Day and a Half

CERTAIN rodents (as also is the case with man) show circadian (about 24-h; *circa, dies*[1-3]) rhythms in many body functions. Prominent among these rhythms is the adrenal cycle, gauged indirectly by observations on functions influenced by corticosteroids[4,5] and directly by determinations of corticosterone in serum[6-9] and in the adrenal gland itself[10]. Investigations of an indirect index, the blood eosinophil rhythm, suggested that the adrenal cycle persists in mice kept under conditions which gravely alter the œstrus cycle, such as the prolonged 50 per cent reduction in dietary calories[11]. This communication summarizes shorter-term work with a more direct index, that is, the level of corticosterone in serum and adrenals. Circadian periodic changes in these indices as well as in rectal temperature and pinnal mitoses continue in *C* mice deprived of all food and water for 36 h.

Two experiments were performed on a total of 192 female *C* (Bagg albino) mice, 3–4 months of age. This strain has been maintained at the University of Minnesota Medical School by brother-to-sister mating for more than 12 years. For each experiment, the mice were housed singly in temperature-controlled 'periodicity rooms', illuminated only by fluorescent lights for a 12-h period each day (0600–1800). All the animals were standardized for 6 days on this regimen and, thereafter, groups of mice were killed at 4-h intervals. At each of these time points rectal temperature was measured and immediately thereafter the mice were killed for collection of blood, adrenals and ears.

Sampling in a first experiment started at 0400 and ended 24 h later. In this experiment the animals had food and water available throughout the sampling period. In another experiment begun at 0800 of one day and completed at 2000 of the next, food and water were removed about 3 h prior to start of sampling.

The times indicated with the results are mid-points; actual sampling at any one time-point extended over a period of about 1 h. At intervals of several minutes cages were removed from the periodicity room to an adjacent laboratory in which temperature measurements by thermistor-bridge circuit and other procedures were carried out. Following decapitation by scissors, the blood was allowed to drain from the neck into a centrifuge tube. Blood from 6 animals was pooled and the serum obtained. Corticosterone in serum pools and in pairs of adrenals from individual mice was determined according to the fluorometric method of Silber, Busch and Oslapas[12]. This method has been qualified elsewhere as to specificity, and the usefulness of data transformed into a percentage of series mean (relative values) particularly for periodicity analysis also has been documented[7]. Data were subjected to analysis of variance.

In keeping with earlier work on other species[13,14], the circadian rhythm in rectal temperature stood out clearly in starving and thirsting mice, as well as in mice kept with food and water available *ad libitum*. As further anticipated in the light of earlier less-extensive unpublished work from this laboratory, the circadian rhythm of pinnal mitoses also was maintained in *C* mice deprived of all food and water for 36 h.

Fig. 1 demonstrates the extent of agreement in absolute values of serum corticosterone between the two pools from each of the groups investigated (left half), and the group means expressed as relative values, namely, as a percentage of the mean of the first 6 values, the latter being equated to 100 per cent (right half). A rhythm in animals that had food and water available *ad lib.* until death is readily seen. The peak value at 1600 agrees well with that recorded earlier for mice of the *C* strain and of other inbred stocks studied under similar conditions, notably a regimen of light from 0600 to 1800, alternating with darkness[4,7,10].

The results of starved animals show a progressive increase in level of corticosterone during the 36-h period of examination. Whether dehydration underlies this trend is not known. In any event, the trend does not obscure two peaks separated by about 20–24 h from each other, peaks that stand out more clearly in the relative values. The statistical significance of these rhythmic changes is supported by the results of an analysis of variance. Time is indeed a significant source of variation in the serum corticosterone-levels of both groups ($P < 0{\cdot}01$).

The persistence during a 36-h period of food and water deprivation of the rhythm in adrenal corticosterone, in turn, is demonstrated in Fig. 2 by the average values per gland pair and the *S.E.*, plotted against time.

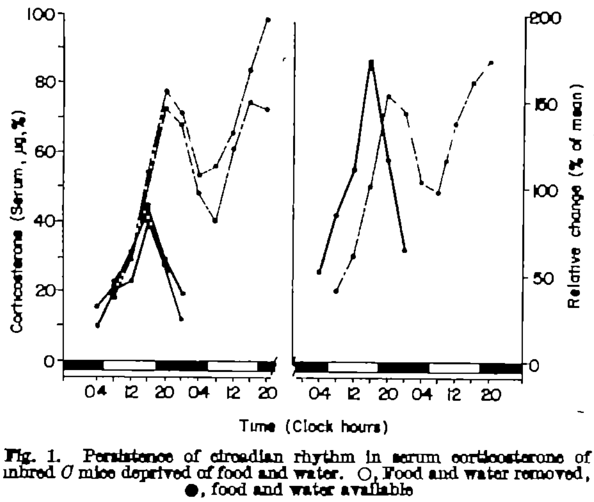

Fig. 1. Persistence of circadian rhythm in serum corticosterone of inbred *C* mice deprived of food and water. ○, Food and water removed, ●, food and water available

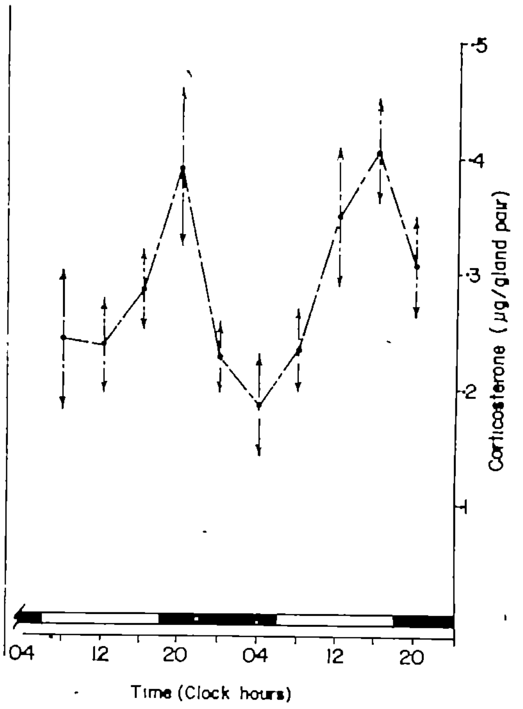

Fig. 2. Persistence of circadian rhythm in adrenal corticosterone of inbred *C* mice deprived of food and water (means and *S.E.*)

Figs. 1 and 2 as a whole, summarizing an examination of 192 mice, can be interpreted to suggest that the adrenal cycle[1,4,11], gauged by hormone contents of blood and gland, persists, at least for a while, in *C* mice subjected to starvation and water deprivation. To discuss a possible difference in the timing of circadian rhythms in the two groups of mice studied is not justified without added data over more extended periods.

Awaiting further study is also the question whether the overall serum hormone-level around which rhythmic changes recur undergoes a consistent change during longer periods of thirsting and starving.

On the practical side, the present results serve to re-emphasize[1] objections to a not uncommon assumption made in the design of many experiments, tacitly if not explicitly. In certain endocrine and metabolic investigations, among others, it has been presumed that circadian rhythms can be 'eliminated' by starvation. Common designs in these fields involve the removal of food, with or without the removal of water for a period of 12–24 h. Such designs have their uses for aims other than the 'elimination of rhythms'. For further comments on this point, the reference should be made to a study summarizing about twenty years of work by Chossat[15], awarded the prize for physiology by the French Academy of Sciences in 1843. This author demonstrated the persistence of circadian periodic behaviour in the cloacal temperature of pigeons until the day of their death from food and water deprivation. In a mammal, the mouse, a circadian susceptibility rhythm also has been shown to persist in animals deprived of food or water, at least for 36 h[16]. This point of methodological and theoretical interest must be kept in mind in work on the adrenal cycle of *C* mice as well as on their circadian rhythms in rectal temperature and pinnal mitoses. Periodicity analysis is required for a safe description of changes in periodic functions, including studies made from the point of view of starvation *per se* or with the view of other conditions studied in starved animals, as was suggested and practised already by Chossat[15]. Moreover, the basic nature of a circadian temporal co-ordination in physiological function is further supported by documentation of the persistence of rhythms at various levels of organization in a thirsting and starving mammal.

This work was supported by grants from the U.S. Public Health Service, the American Cancer Society (E–145), and the Department of Public Welfare, State of Minnesota.

Transmission of anti-*Brucella abortus* Agglutinins across the Gut in Young Mice

IT has been recorded[1] that antibodies from hyper-immune anti-*Salmonella pullorum* sera prepared in various species were absorbed from the gut of young rats at significantly higher rates than antibodies from hyper-immune anti-*Brucella abortus* sera. The absorption rates of these antibodies depended more on the antigen used in their production than on their species of origin. A similar conclusion was thought to apply to young mice when it was observed that the absorption from the gut of antibodies from hyper-immune anti-*Brucella abortus* serum prepared in a rabbit was markedly less than that of other rabbit γ-globulins. If the relative rates of absorption of antibodies from the gut are expressed in concentration quotients which are the ratios of the concentrations of antibodies in the serum of the animals fed and in the immune serum fed, the maximum concentration quotients obtained after feeding 11-day hybrid $C_{57}Bl \times A_2G$ mice with rabbit anti-sheep red cell agglutinins[2] or with rabbit normal γ-globulin[3] were 1/64–1/128, whereas the maximum concentration quotients obtained after feeding with rabbit anti-*Brucella abortus* agglutinins were < 1/1,024. This phenomenon was investigated further, and preliminary results are presented here.

The concentration quotients for feeding to 11-day $C_{57} \times A_2G$ mice or to 12-day albino rats 0·01 ml. of rabbit anti-*Brucella abortus* serum per gram body-weight are given in Table 1. Agglutination titres of the immune serum administered and of the sera of the experimental animals, killed 4 h after feeding, were determined by the saline dilution technique and by a modification of the Coombs test[4] using a high-titre goat anti-rabbit-serum-proteins serum. Since the latter test measures the total amount of complete and incomplete antibodies in the test sera, it is evident that the antibody in the immune serum administered is mostly of the complete type. Complete antibody could not be detected in the sera of the fed animals, whereas the incomplete antibody could be measured easily and, in the mice, gave concentration quotients equal to those for feeding rabbit normal γ-globulin or anti-sheep red cell agglutinins.

The sedimentation behaviour of the antibodies in the immune serum used, and in the pooled serum of mice fed with the immune serum, was investigated in the ultracentrifuge by the method described by Hemmings and Jones[5]. The test sera were diluted to a protein concentration of 2 per cent and layered on to a 20–12 per cent sucrose gradient in a tube of the *S.W.* 39 head of a 'Spinco' model *L* centrifuge and spun for 18 h at 30,000 r.p.m. This resulted in the separation of the heavy and light components of the test serum in the sucrose gradient, which was afterwards fractionated into a series of 40 samples. Alternate fractions were titrated against *Brucella abortus*, while the remaining fractions were used for protein determinations by the method of Lowry *et al.*[6]. The sedimentation profiles of the sera with the distribution of the anti-*Brucella* titres superimposed are shown in Fig. 1, which indicates that the distributions of the antibody titres of the test sera are all very similar with medians in the 7*S* region.

Rabbit anti-*Brucella* serum was injected intravenously at doses of 0·01 ml./g body-weight to each of four 11-day $C_{57} \times A_2G$ mice, two of which were killed 5 min later, and their sera pooled and titrated. The others were killed after 4 h and their sera pooled and titrated. The results (Table 2) show that the titre of the complete anti-

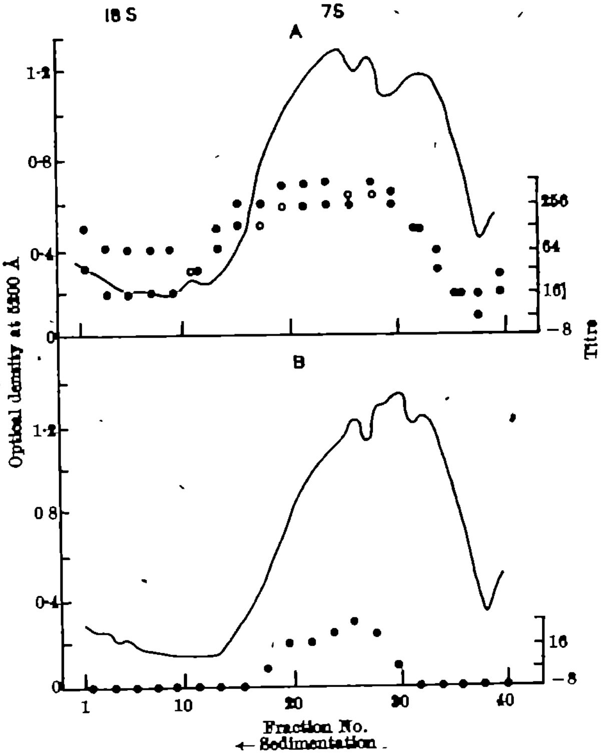

Fig. 1. Profile of sedimentation of (*A*) rabbit anti-*Brucella* immune serum and of (*B*) the serum of young mice fed with the immune serum. The continuous line represents relative protein concentrations expressed in optical density. ○, Saline agglutinating titres; ●, Coombs agglutinating titres

Table 1. CONCENTRATION QUOTIENTS FOR YOUNG MICE AND RATS FED WITH RABBIT ANTI-*Brucella* AGGLUTININS

Animals fed	Agglutinin titration	Titre of serum fed	No. of experimental animals having serum concentration quotients of:			
			1/32	1/64	1/128	1/1,024
Mice	Saline	4,096	0	0	0	6
	Coombs	4,096	1	4	1	0
Rats	Saline	4,096	0	0	0	2
	Coombs	4,096	0	2	0	0

body in the sera of young mice remains unchanged during the 4-h test period. Consequently, differences, if any, in the nature of the antibodies fed to young mice and those measured in their circulations 4 h later will have been effected in the absorptive cells of the gut rather than in the circulation.

Table 2. ANTIBODY ACTIVITY OF THE SERA OF YOUNG MICE INJECTED INTRAVENOUSLY WITH RABBIT ANTI-*Brucella* SERUM

Interval after injection	Serum titre	Dilution of antibody in serum
5 min	Saline = 512	1/8
	Coombs = 512	1/8
4 h	Coombs = 512	1/8
	Saline = 512	1/8

It has been established that the activity of the immune serum used is due primarily to 7*S* and 18*S* complete antibodies, and possibly to 7*S* and 18*S* incomplete antibodies, whereas the activity of the sera of young mice fed with the immune serum is due to 7*S* incomplete antibodies. Consequently, the transmission of rabbit anti-*Brucella* agglutinins across the gut may involve any or several of the following possibilities:

(1) During transfer across the absorptive cells the 18*S* antibodies may be degraded into the 7*S* incomplete type. An analogous change *in vitro* would be the decomposition of 18*S* saline agglutinating Rh antibody by the action of mercaptan into 7*S* Coombs sensitizing antibody[7].

(2) A configurational rather than a degradational change from the 7*S* complete antibody into a 'more acceptable' 7*S* incomplete type may be effected by the absorptive cells. A similar explanation has been suggested to account for the observation that bovine γ-globulin, which had reached the circulation from the gut of young rats, entered the circulation in relatively larger amounts when fed a second time to other young rats[8].

(3) The absorptive cells may exhibit selection between 7*S* complete and incomplete antibodies and exclude the former from the circulation. If this were the case, such a high degree of selection between two antibodies prepared in the same species would be hard to reconcile with the much lower degree of selection exhibited between antibody molecules of different antibody activities prepared in different species[8], unless the effect of variation in the configuration of the antibody reactive portions[9] of 7*S* antibody molecules on selection overrides that of the species-specific parts.

The inability to measure the incomplete antibody activity of the immune serum used, due to the higher concentration of the complete antibody, precluded hitherto any assessment of the relative importance of these possibilities. Further investigation of the problem is desirable, especially in view of the light it might throw on the mechanism of the transmission of Rh antibodies across the human placenta.

I thank Prof. F. W. R. Brambell for his advice and Mr. W. A. Hemmings for carrying out the ultracentrifugal run. We are indebted to the Rockefeller Foundation for providing the Spinco ultracentrifuge.

An Anomalous Infection of Mice with *Schistosoma mansoni*

MICE exposed percutaneously to cercariæ of *S. mansoni* develop an infection which can be well standardized. For the past three years we have exposed albino mice, kept in identical conditions of diet and housing, to about 200 cercariæ of a Venezuelan strain[1] which led to the development of a bisexual infection in the portal and mesenteric veins and the deposition of eggs in the liver, intestinal walls and occasionally in the lungs.

In one experiment on a group of ten mice, in spite of a normal bisexual development of the trematodes, no eggs could be found in any of the organs of the hosts. In this experiment all cercariæ were shed by a single snail, *Australorbis glabratus*. The total number of cercariæ shed by the snail, which died the following day, was about 2,000, much higher than the usual number encountered in the average experiment, that is, to 600–700 a day. The snail itself was infected with 5–10 miracidia.

Eight mice were autopsied 55–140 days following infection and no ova were found in any of their organs. Perfusion of the liver and the mesenteric circulation[1] revealed that the 33–83 (average 65) schistosomes counted per mouse were of normal size, many of them copulated, with a ratio of 42–63 per cent (average 52 per cent) males. Slides of the fresh livers and intestines examined under microscope showed no eggs, nor did the trypsin–pepsin digestion of the organs followed by exposure to intense light in river water liberate miracidia[2]. The reproductive organs of the schistosomes stained with 0·005 per cent methylene blue solution were normal in size and number in the males, as were the ovaries and the vitelline glands in the females. However, in the uterus at the site where normally the ovum is located an irregular mass without shell was noted. Two of the mice of this group infected ten months ago are still alive, though animals infected with the same inoculum usually do not survive more than two months.

It has already been shown that induced nutritional deficiencies in guinea pigs[3] and in mice[4] may cause variations in the sexual organs of the schistosomes, and that in certain hosts[5–8] hermaphroditism of the male occurs; but we cannot find a precedent for complete sterility in mouse, a species allowing the development of a bisexual infection with deposition of eggs. We exclude nutritional influences in the present case and we think that the sterility, presumably due to the anomaly noted in the female schistosomes originated from cercariæ shed by the same snail, may have been determined by the miracidium. It is known that the sex of the parasite is predetermined in the miracidium, which forms the cercaria[9], and it could be assumed that the deformation resulting in sterility may depend on a genetic variation in the parent miracidium, which may have been the same individual for all the (female) cercariæ of the infection.

We thank Dr. Eugenio Gerulewicz, Ministerio de Sanidad y Asistencia Social, Caracas, for the *Australorbis glabratus* strain.

Effect of Dietary Calcium Lactate and Lactic Acid on Fæcal *Escherichia coli* Counts in Pigs

CERTAIN strains of *E. coli* have been isolated[1] from pigs which have died from bowel œdema. Strains of the same organism are involved[2] in certain baby pig scours. It has been reported[3], in investigations of the intestinal flora of growing/fattening pigs, that the count of *E. coli* was inversely related to those of lactic acid producing bacteria, chiefly *Lactobacillus bifidus*. Significant growth increases with pigs were obtained[4] with milk inoculated with *Lactobacillus* sp. when compared with that inoculated with *Streptococcus* sp.

Two trials were conducted in the present work. The first trial was carried out during November–December 1961 over a four-week period. Three pairs of pigs from three separate litters, and weighing initially 70–80 lb. live-weight, were housed in one pen which was equipped with individual feeding accommodation. The pigs were fed the same basal diet which had the following composition: 7½ per cent fish meal, 5 per cent soya bean meal, 5 per cent bran, 15 per cent pollard, 25 per maize, 42 per cent barley, 0·5 per cent vitamin/trace mineral premix. Three pigs, one from each pair, were fed the basal diet which had 2 per cent of the barley replaced with 2 per cent calcium lactate, Bow-Calac., Ltd., Widnes. The basal diet for the three control pigs was adjusted to the same calcium content as the lactate diet by the addition of ground limestone, again in place of barley. The pigs were fed twice daily on a scale of feeding which was related to their live-weights[5]. Freshly voided fæces were collected after the morning feeding and transported as soon as possible to the laboratory. *E. coli* counts were made daily for 5 days each week, on 1-g samples of the wet fæces for a four-week period. During the third and fourth weeks dry matters and *p*H were also recorded on the fæces. The mean weekly *E. coli* colony counts/g wet fæces, with the mean percentage fæcal dry matter, and daily live-weight gains, are given in Table 1.

Table 1. MEAN *E. coli* COUNTS ($\times 10^6$) PER G OF WET FÆCES, DAILY LIVE-WEIGHT GAINS, AND MEAN PERCENTAGE FÆCAL DRY MATTER (IN BRACKETS)

	Pig No.	Week 1	Week 2	Week 3	Week 4	Daily light-weight gain (lb.)
Control	1	1·08	9·03	46·44 (25·7)	21·03 (25·5)	1·14

* Pig 2 scoured during third week

A second trial was conducted, for an 8-week period, during April–June 1962, using three pairs of pigs from each of three litters and weighing initially 60–70 lb. *E. coli* counts were made as in the first trial for five days/week for the first two weeks. This was reduced to twice weekly for the remainder of the trial. The pigs were housed in the same pen and fed twice daily as in the first trial. Since small but variable amounts of lactic acid were found in the calcium lactate used, and because only one pig seemed to be responding to the lactate in this trial, lactic acid (B.P.), 2 g/lb. of diet, was given to the lactate pigs from the fifth to eighth weeks. The data are given in Table 2.

Unidirectional Response to Angular Acceleration recorded from the Middle Cristal Nerve in the Statocyst of *Octopus vulgaris*

YOUNG[1] suggests that the three orthogonally arranged sections of the crista of the statocyst of *Octopus vulgaris* could function as detectors of angular acceleration in a manner similar to the semicircular canals of vertebrates. He also suggests that the macula could provide continuous information about the position of the head. That the statocyst in cephalopods indeed participates in the control of equilibrium and posture has been shown behaviourally[2,3]. Now we have recorded from the middle cristal nerve of the statocyst the activity of single units of the longitudinal crista that respond unidirectionally to angular acceleration.

We suspended a disarmed octopus in a tank with circulating sea-water, removed the left eye and cut the cranial cartilage down to the statocyst nerves, leaving a thin layer of cartilage on top. Next, we removed mantle and viscera, leaving attached to the aorta only the cranium with the statocysts, brain and right eye, and perfused aerated sea-water through the aorta. The preparation and the micro-electrode holder were mounted on a turntable which allowed smooth rotation and tilting while recording. The statocyst was placed in the centre of rotation. The electrodes were thick-walled micropipettes filled with Wood's metal and plated with platinum black.

We recorded from the left statocyst of thirteen animals and studied more than 60 units, isolated or in groups.

In the absence of stimulation the electrode passes through the nerve without recording spontaneous activity until the surface of the sac is reached and some cells are killed. Otherwise, if one taps the table gently while penetrating the nerve, one finds units that respond with a series of 4 or 5 bursts with 3–4 spikes per burst for each tapping, at a frequency of about 30 bursts/sec. If several units are recorded simultaneously their responses appear phased. These units are highly sensitive to low-frequency vibrations transmitted through the ground but do not respond to air-borne sounds. These same units responded with a large discharge (100 spikes/sec) to a counter-clockwise rotation in the horizontal plane (as seen from above) and with a smaller discharge (45 spikes/sec) at the end of a clockwise rotation. A sinusoidal movement elicited a response that extended from the end of the clockwise through part of the counter-clockwise phase. Increasing the frequency of the sinusoidal movement caused a rise in the frequency of discharge and the recruitment of new units. Recruitment also occurs with vibrational stimulation. That different units have different thresholds is apparent from the recruitment. All this is illustrated in Fig. 1. (1) The absence of resting activity; (2) the response to the counter-clockwise rotation that subsides before the end of the swing (*B*); (3) the response to the end of the clockwise movement which begins before the stop or reversion of the swing (*A* and *C*); (4) the complete adaptation at the cessation of movement (*A*). It is apparent that the effective stimulus was angular acceleration in the counter-clockwise direction. A cinematic analysis considering the phase relation of the response to the angular displacement (θ), the angular velocity ($\dot{\theta}$) and the angular acceleration ($\ddot{\theta}$) makes this obvious. These experiments, however, do not prove that these receptors respond to angular acceleration only. They could also respond to unidirectional linear acceleration. If this were the case the two accelerations could be distinguished by comparing the activity in the two statocysts.

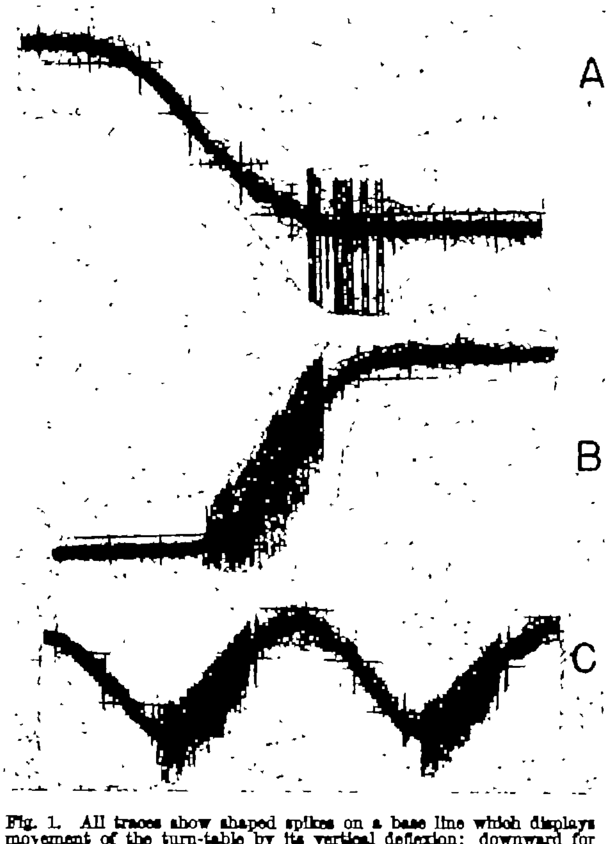

Fig. 1. All traces show shaped spikes on a base line which displays movement of the turn-table by its vertical deflexion: downward for clockwise and upward for counter-clockwise rotations

Young[1] expected the longitudinal crista to detect rotations around the longitudinal axis through a vertical deflexion of the horizontally placed cupula. Our recordings from the middle cristal nerve issuing from it indicate that this crista at least responds to rotation around the vertical axis and that these rotations can cause an adequate movement of the endolymph and cupula (whichever this movement is). However, we have not examined rotations around the other axes and we do not yet know which is the optimal stimulus for this section of the crista, nor if we can deem the responses of each section of the crista distinct enough for each of them to indicate rotations in one plane only.

We do not know which cells we recorded from, but we presume that the most likely are the large hair cells, which have the largest axons[1]. In the crista there are also some second-order neurones that send their axons to the brain[1]; but we are inclined to believe that these perform a more complex function and that we did not record from them. Whichever is the case, two facts stand out: (1) That the same unit responds to two modes of stimulation, namely, to low-frequency vibration and to angular acceleration. These differences in response pattern could be used for their central distinction. A similar duality of response is found in statocyst receptors of crustaceans[4]. (2) That there is no resting activity and that the response to angular acceleration is unidirectional. Whether this unidirectionality is due to a mechanical property of the statocyst, the cupula or the hair cells or to the interaction of the latter with local neurones, we do not yet know, but this property and the absence of resting activity make this system different from the known equilibrium systems of vertebrates[5] and crustaceans[4].

This work, done at the Stazione Zoologica, Naples, was supported by grants from the U.S. Air Force Office of Scientific Research, the Office of Naval Research and the National Science Foundation.

Vectorcardiogram of *Anguilla anguilla* L. and *Pleurodeles waltlii* Mich.

PREVIOUS investigations[1–4] on the epicardial electrocardiogram of fishes (*Anguilla anguilla* L., *Ameiurus nebulosus* Raf., *Cyprinus carpio* L., *Salmo irideus* Gibb., *Acipenser sturio* L., *Scyliorhinus canicula* L. and *S. stellare* L.), of larval Urodeles (*Ambystoma tigrinum* Green) and adult Urodela (*Pleurodeles waltlii* Mich., *Triturus cristatus* Laur. and *Salamandra maculosa* Laur.) showed that the general activation front in the epicardial layers moves approximately from the heart basis towards the apex in the fishes and in *Ambystoma tigrinum*, and from the apex towards the basilar region in *Pleurodeles waltlii*, *Triturus cristatus* and *Salamandra maculosa*.

Furthermore, it was observed by the simultaneous recording of epicardial and intracardiac leads that the stimulus spreads at the same time into all layers of the cardiac muscle and not from the sub-endocardial layers outwards, as in the mammalian heart.

In order to confirm the aforementioned results an investigation of the direction of the cardiac vectors in the different planes was undertaken. For this purpose frontal and sagittal plane QRS vectorcardiograms were recorded in a fish, *Anguilla anguilla*, and in a Urodele, *Pleurodeles waltlii*; from these tracings the spatial direction of the stimulus was reconstructed.

The investigations were carried out on 12 specimens of *Anguilla anguilla* and on 4 of *Pleurodeles waltlii*. The animals were narcotized with 20 mg/kg of amobarbital sodium intramuscularly, and put into an earthed Faraday cage.

For the recording of the vectorcardiogram the cube arrangement developed by Grishman[4] and at present used for human beings was utilized; according to this system the electrodes are placed so as to represent four of the corners of a cube having the dipole centre at its centre.

The electrodes were placed as follows:

(*A*) Vertical bipolar lead: the electrodes were located cranially and caudally to the heart.

(*B*) Horizontal bipolar lead: two symmetrical plates were placed subcutaneously laterally to the heart.

(*C*) Sagittal bipolar lead: two plates were placed subcutaneously dorsally and ventrally to the heart.

The composition of *A* and *B* gave as a result the vectorcardiogram in the frontal plane, while from *A* and *C* the vectorcardiogram in the sagittal plane was obtained. Care was taken, so far as possible, to apply the statement of Gillard *et al.*[5], according to whom the electrodes are regarded as ideally placed when they are located at the same distance from the heart—the distance between each pair being the same—and the distance between heart and electrode about five times the heart's radius.

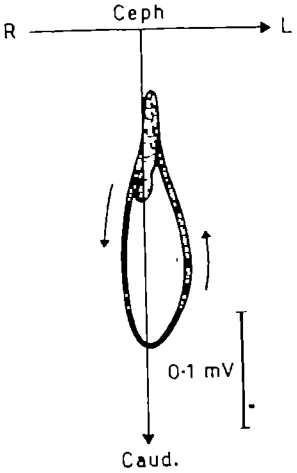

Fig. 1. QRS vectorcardiogram of *Anguilla anguilla* L. in the frontal plane. *R*, right; *L*, left; *Ceph.*, cephalic extremity; *Caud.*, caudal extremity

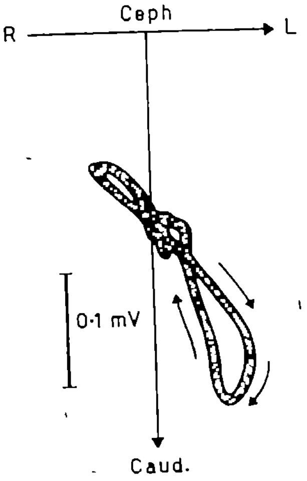

Fig. 2. QRS vectorcardiogram of *Anguilla anguilla* L. in the sagittal plane

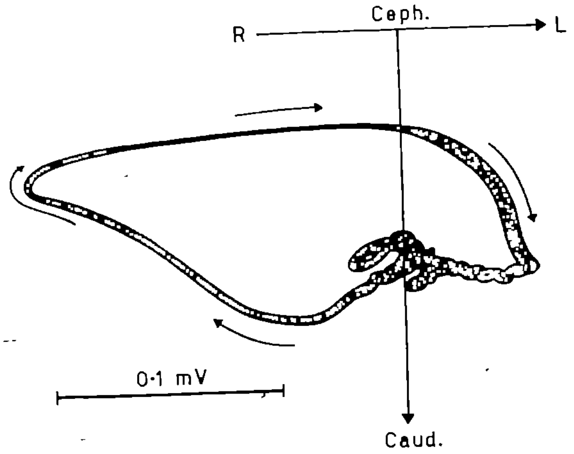

Fig. 3. QRS vectorcardiogram of *Pleurodeles waltlii* Mich. in the frontal plane

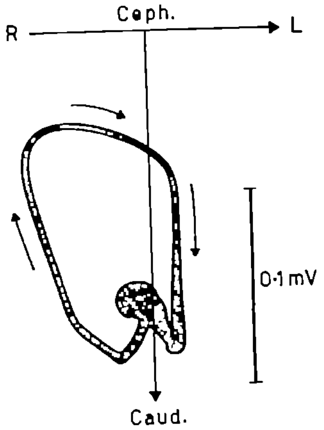

Fig. 4. QRS vectorcardiogram of *Pleurodeles waltlii* Mich. in the sagittal plane

The electrodes were made of stainless steel needles and silver plated; the diameters varied from 5 to 10 mm in conformity with the size of the animal.

All the recordings were performed by a dual-beam oscilloscope Tektronix 502.

In Figs. 1–4 the morphology of the QRS vectorial loops in the frontal and sagittal plane for each of the species examined is illustrated.

As well as the morphological characteristics of the vectorial loop itself, the spatial direction of the excitation wave, as can be ascertained by the analysis of the different tracings, must be stressed. In the case of the eel it can be seen that the stimulus starts in the base of the heart and spreads into the apical region, moving from right to left and from back to front.

In Pleurodeles, on the contrary, the excitation wave starts from the apical region, moves backwards and rightwards, spreading at last into the basal region leftwards and forwards.

Thus, these vectorcardiographical investigations confirm what has been established by scalar electrocardiography concerning the activation of the epicardial layers.

It can therefore be admitted that the general action of the fishes' heart is clearly different from that of Pleurodeles, where the activation front is approximately directed from the apex to the base, thus resembling the behaviour of several mammals.

The patterns observed in Pleurodeles is very likely the same for all the Urodela: in fact, either the epicardial electrocardiograms or the frontal and sagittal vectorcardiograms recorded on few specimens of *Triturus* and

Salamandra allow us to postulate the existence of a general apico-basilar direction of the activation front.

ENTOMOLOGY

Incorporation of ^{14}C-Acetate into Scent Constituents by the Green Vegetable Bug

THERE is rapidly growing interest in the nature and functions of the hypodermal glands of insects, which produce not only pheromones but also chemicals which are used in defence. Short-chain aldehydes, both saturated and unsaturated, the paraffin tridecane[1-4] and possibly furans and quinones[2] have been identified in the repugnant secretion (scent) of a number of species of the hemipterous super-family Pentatomoidea. In this group the scent is believed to play a defensive part[1,4]. Nothing is known of the precursors of the scent nor whether the constituents are synthesized by the insect or merely concentrated from the sap which many species pass through their digestive tract in quantity. It has been pointed out that some of the scent substances are present in low concentration in the plants on which the bugs feed[1]. The present experiments were carried out in order to determine whether acetate, the main building unit in lipid metabolism, is involved in the production of the scent constituents.

The contents of the scent storage sac of the green vegetable bug, *Nezara viridula* var. *smaragdula* (F.), consist of a mixture of two liquid phases, one almost colourless (actually a very light yellow) and the other a distinct yellow. The phases are easily separated by centrifugation. The yellow phase has the higher density and has been shown by gas chromatography to contain some 13 volatile constituents, not all of which need be present in any one sample of scent. Since most of the constituents have not yet been identified, we have numbered them in order of increasing retention times on an 'Apiezon-*L*' column. Peak 12 is always a prominent constituent in both phases, and has been identified as *n*-tridecane[1]. Peak 10 has the same retention time as *n*-dodecane. Peak 11 is *n*-dec-2-enal[1] and peak 5 is *n*-hex-2-enal[1]. Peak 6 forms a dinitrophenylhydrazone with properties resembling those of α,β-dicarbonyl compounds[1].

In an experiment designed to detect utilization of acetate for the biosynthesis of scent, 42 adult bugs (both sexes) were each injected with 4 μc. of sodium acetate-1-^{14}C (specific activity 32 mc./mM) in 1 μl. of water. Thirty-six of these had been previously depleted of scent by electric shock stimulation (exposure for two brief periods to 50 V with 5 pulses/sec of duration 50 msec); 13 survived for 8 days. Of the 6 unshocked bugs, 4 survived. After 8 days the living bugs were dissected and scent collected by inserting a fine glass capillary into the scent storage sac which lies ventrally between the metathoracic legs. The capillaries were sealed and stored at −40° C for several months. The depleted sacs, the paired accessory glands and a little adjacent cuticle and fat body were stored in a test tube in 1 ml. pentane under the same conditions.

The capillary collected scent was transferred into 1 ml. of pentane and an aliquot counted in an Ekco scintillation counter. The total count (2,000/sec) showed that only 0·2 per cent of the injected carbon-14 had been incorporated into the scent. A 0·25-ml. aliquot of the pentane solution was evaporated at room temperature in a stream of air to a volume of about 25 μl. Counting of a 1 μl. aliquot of the concentrate showed that about 80 per cent of the carbon-14 had been lost during the evaporation. Four microlitres of *n*-tridecane and 25 μl. of the pentane solution of capillary drawn scent were added and the sample injected into a Pye Preparative Argon Gas Chromatograph run at 100–125° with a column of 10 per cent 'Apiezon-*L*' on 'Celite'.

The effluent gas from the gas chromatograph was passed through 9-mm. diameter glass U-tubes packed with about 7 cm. of 2-mm. diameter glass beads and containing 0·5 ml. of toluene at room temperature. Tests with *n*-hexanol-1-^{14}C have shown that this system is as efficient (about 50 per cent) as one cooled in dry ice and ethanol for trapping quantities of 30 μg or more, although quantities of less than 1 μg are trapped with only about 5 per cent efficiency. Each peak indicated by the gas chromatograph was collected in one or more tubes, and valleys between peaks were also sampled. All collections gave some increase in count above the background count, but peaks 6, 7 and 8 gave counts 4 × to 7 × background, and peak 12 (tridecane) was 100 × background. Two later gas chromatographic runs of the same radioactive material with the addition of several microlitres of non-radioactive scent to improve the trapping efficiency of minor constituents showed significant radioactivity in peaks 5, 6, 7, 8, 9, 10, 11, and 12.

Broadly comparable results were obtained with the pentane solution from the residual scent sacs and associated tissues. This initially had a total activity of about 5,000 counts/sec, but, when vacuum distilled into a liquid air trap, 90 per cent of the activity proved to be non-volatile. The pentane distillate was concentrated by slow evaporation at room temperature, which caused 25 per cent loss of the carbon-14 content, and several microlitres of cold scent were added to improve trapping efficiency. Significant radioactivity was found in peaks 4, 5, either or both of 6 and 7 (which did not separate clearly), 9, 10, 11, 12 and 13.

Scent was collected in a capillary from a total of five bugs which had been injected 9 days previously with 1 μc. of either sodium decanoate-1-^{14}C, sodium caproate-1-^{14}C or sodium propionate-1-^{14}C. The pooled scent gave significant counts (greater than 1·5 × background) in peaks 5, 6, 12 and 13 and barely significant counts (between 1·2 × and 1·5 × background) for peaks 7, 8, and 11.

Significant radioactivity has thus been found at one time or another in all peaks except 1, 2 and 3, which each contain so little material that significant activity would not have been detected unless these constituents had been particularly 'hot'. It is, therefore, clear that *Nezara* is capable of incorporating acetate into the major components of the scent (including hexenal, the unknown dicarbonyl, decenal and tridecane) and does not rely on concentrating unchanged, preformed materials from the sap of the various plants on which it feeds in order to produce its characteristic scent.

MICROBIOLOGY

Effect of Chilling on Bacteria in Aqueous Suspension

CERTAIN bacteria in the logarithmic growth phase become non-viable when chilled in aqueous suspension. The phenomenon has been observed with strains of *Escherichia coli*[1], *Pseudomonas pyocyanea*[2] and *Aerobacter aerogenes*[3]. Loss of viability of logarithmic phase *A. aerogenes* suspended in chilled phosphate-saline is accompanied by the leakage of endogenous solutes, and the leakage products, in sufficient concentration, protect the bacteria against the lethal effect[3]. Thus, loss of viability is greater the sparser the population and is insignificant in chilled suspensions containing more than 5 × 10^8 organisms/ml. Correlation between loss of viability and leakage of endogenous solutes has now been obtained by observing the effects of chilling on three Gram-negative bacteria.

Escherichia coli strain Jepp, *Aerobacter aerogenes* NCTC 418 and a laboratory strain of *Serratia marcescens* were used. Cultures growing exponentially were obtained by seeding flasks (1·5 litre) containing 100 ml. of either a defined mannitol–ammonia–salts medium[4] or tryptic meat broth with 4 ml. of a 16-h culture in the same medium, and shaking for 2–3 h at 37°. Bacteria were separated from the culture and washed twice with phosphate-saline (0·11 M sodium chloride and K_2HPO_4 + KH_2PO_4 (0·02 M —PO_4), *p*H 6·5) by centrifugation, then resuspended in this diluent (about 10^{10} bacteria/ml.). The effect of chilling on viability was assessed by adding washed bacterial suspension (0·1 ml.) to cold phosphate-saline (10 ml.) held in a temperature-controlled bath at 0° ± 0·25°; samples were removed at intervals for determination of viability by slide culture[5] on tryptic meat broth agar. Denser suspensions were used to examine the leakage of substances from chilled bacteria: washed suspension (4–5 × 10^9 bacteria/ml.) was rapidly cooled to near 0° by contact with brine at −10° and placed in the bath at 0°; at intervals, samples (5 ml.) were quickly filtered through well-washed Oxoid filter membranes (grade *AP*). Filtrates were analysed for ultra-violet absorption at 260 mμ, adenosine triphosphate with the firefly luminescence technique[6] and ninhydrin-reacting substances[7]. As controls, filtrates separated from similar suspensions at 20° were analysed.

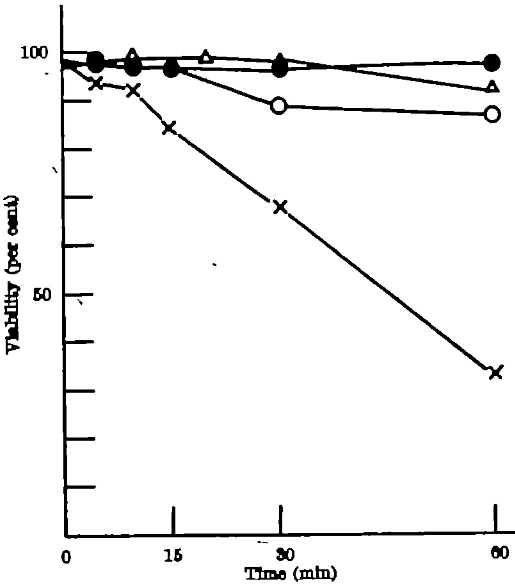

Fig. 1. Changes in viability of bacterial suspensions at 0°. Washed exponential phase bacteria were held in cold phosphate-saline, *p*H 6·5 (about 10^8/ml.). *A. aerogenes* NCTC 418 grown in a defined medium (×) and tryptic meat broth (○); *E. coli* Jepp grown in both media (●); *S. marcescens* grown in tryptic meat broth (△). Viabilities were determined by a slide culture technique (ref. 5)

Fig. 1 shows changes which occurred in the viability of suspensions containing about 10^8 exponential phase bacteria/ml. during 1 h at 0°. When grown in the defined medium, *A. aerogenes* were markedly susceptible to chilling whereas the organisms were more resistant when grown in tryptic meat broth; *E. coli* grown in either medium or *S. marcescens* grown in tryptic meat broth were almost completely resistant. The viabilities of similar suspensions of these organisms at 20° remained unchanged during 1 h.

At concentrations of about 5 × 10^9 bacteria/ml. of phosphate-saline no loss of viability of these organisms occurred during 1 h at 0°. However, when compared with similar suspensions at 20°, there was a considerable leakage of ultra-violet-absorbing substances (including adenosine triphosphate) and ninhydrin-reacting substances from *A. aerogenes* grown in the defined medium, much less from this organism grown in tryptic meat broth (Table 1). Leakage from *E. coli* at 0° was less than 20° (Table 1) and about the same at these temperatures from *S. marcescens*. Thus, on chilling bacteria in relatively dense suspension, the extent of leakage was related to the loss of viability which occurred in more dilute suspension (Fig. 1). Since the adenosine triphosphate concentration in filtrates of chilled *A. aerogenes* reached a maximum in 30 min and then decreased (Table 1), resorption, adsorption or breakdown of this substance must have occurred.

Loss of endocellular constituents on chilling bacterial suspensions may be a cause but is not an effect of bacterial death since leakage occurs from bacteria in relatively dense suspensions which remain viable. Presumably, in dilute suspension, the concentration of leakage products in the suspending fluid is too low for resorption to occur and loss of bacterial viability results. It is of interest that exponential phase *Aerobacter aerogenes* grown in a complex medium were more resistant to chilling than organisms grown in a defined medium.

Nuclear Size of Live and Dead Bovine Spermatozoa

THE size distributions of spermatozoan nuclei are of interest from two points of view. On one hand there is the question of the identification and separation of X and Y chromosome bearing spermatozoa, and on the other hand the relation of nuclear size to total content of chromatophilic substances measured by the plug or core method of microspectroscopy. We do not wish to become involved in the former question; but are interested in the latter in connexion with work on the DNA content of bovine spermatozoa being examined in this laboratory.

We have adopted the van Duijn[1] formula for determining nuclear areas. This method has been shown to yield a high correlation with areas determined by planimetry[2]. The regression of optical density of Feulgen-stained bovine spermatozoa on nuclear area is negative and highly significant[3]. Under some experimental conditions 51 per cent of the variation in optical density could be explained by this regression. Suspecting that dead cells might be an important factor in this regression, an experiment was designed to determine the size and Feulgen staining characteristics of live and dead spermatozoa. This communication reports the nuclear size relationships.

Live and dead spermatozoa were differentiated by the eosin method of Lasley, Easley and McKenzie[4] but omitting the background stain. Areas on each slide containing 10 or more live (eosin-negative) and 10 or more dead (eosin-positive) cells were mapped so that the individual cells could be relocated. The slides were then fixed, hydrolysed and stained by the Feulgen method following normal procedure[5]. The process of fixation in acetic alcohol and hydrolysis in 1 N hydrochloric acid effectively removes all the colour from the eosin-stained spermatozoa as determined by visual inspection, but there is an effect of eosin treatment on the apparent DNA content of the cell. After relocating the fields, length, maximum width and base width of the Feulgen-stained, mapped sperm heads were measured with an ocular micrometer. Twenty-eight slides were examined, representing three different semen samples, with sub-samples ranging in age from fresh to 13 days old (stored in yolk-citrate at 5° C).

The dead cells were found to be larger than the live cells in all the dimensions studied. These differences were significant at the 0·001 level of probability, except for base width which was significant only at the 0·05 level. The means and standard deviations are given in Table 1. With the exception of the standard deviations for maximum width, all the means, standard deviations and ranges were larger for the dead cells than for the live ones. Nuclear areas were likewise larger for the dead than for the live sperm. The difference in area amounted to 9·78 per cent of the area of the live cells, and was significant at the 0·001 level of probability.

The distributions of live and dead cell nuclear areas are depicted in the histograms in Fig. 1. While the modes are distinctly different, there is a large overlap of areas in the two arrays. The sampling method used does not permit any exact statements with regard to bimodality of the sperm populations studied, but if the two distributions are pooled on the assumption of a single population containing 53 per cent live cells, no evidence of bimodality can be shown.

Thus it can be seen that nuclear area of a spermatozoon cannot be taken as *prima facie* evidence that the cell was live (or dead) at time of fixation. However, the large differences between mean areas and the larger standard deviations of dead cells may account for some of the differences in DNA and the greater variability in DNA content reported in the spermatozoa of infertile as contrasted to fertile males[6,7]. Certainly such studies in the future should include some estimate of the live cells present in the sample at fixation, for such differences in fertility may be due entirely to the paucity of live spermatozoa in the semen of infertile males and not to intrinsic differences in DNA content of those live cells which are capable of penetrating the vitelline membrane.

Table 1. MEANS AND STANDARD DEVIATIONS OF NUCLEAR DIMENSIONS AND AREAS OF LIVE AND DEAD BOVINE SPERMATOZOA

	Live	Dead	Difference (%)	Significance
No. of cells	300	279		
Length	8·53 ± 0·50µ	8·93 ± 0·55µ	4·69	***
Maximum width	3·98 ± 0·32µ	4·19 ± 0·28µ	5·28	***
Base width	1·80 ± 0·24µ	1·84 ± 0·27µ	2·22	*
Area	27·51 ± 2·06µ²	30·20 ± 2·73µ²	9·78	***

* Indicates significance at the 0·05 level of probability. *** Indicates significance at the 0·001 level of probability.

VIROLOGY

Measles Virus

COOPER[1] placed measles virus in the deoxyvirus group. There is now considerable evidence which is contrary to this view. The appearance of acridine-orange stained inclusions in measles virus infected cells under ultraviolet illumination suggests the presence of a ribovirus[2].

This is in agreement with the observations of Atherton[3]. Waterson *et al.*[4] reported similarity of measles virus to myxoviruses, under the electron microscope. Waterson[5] further showed that the three serologically related viruses, measles, canine distemper and rinderpest, are structurally identical with Newcastle disease virus (NDV), representative of a myxovirus sub-group. Further support for the similarity of measles virus and NDV is that these viruses undergo identical morphological changes during ether treatment, and the ability of measles virus to cause hæmagglutination.

Recent reports have shown that halogen derivatives of deoxyuridine interfere not only with normal deoxyribonucleic acid (DNA) synthesis in animal and bacterial cells but also specifically inhibit viral DNA synthesis and hence the multiplication of such deoxyviruses as herpes, vaccinia and polyoma. Cooper[1] suggested that 5-fluorodeoxyuridine may be useful in distinguishing deoxyviruses from riboviruses. In the present investigation of the nature of measles virus three derivatives of deoxyuridine, 5-fluoro-, 5-bromo- and 5-iodo-2′-deoxyuridine were used separately at a concentration of 20 μg/ml. in a study of plaque production in monolayers of *H.Ep2* cells by a known deoxyvirus (herpes strain *HFE* 253228–32), a ribovirus (arborvirus *AMM*2354) and measles virus.

Significant plaque reduction was recorded with herpes virus while no such effect was seen on plaque counts of arborvirus or measles virus, under the same conditions (Table 1). This is taken as evidence that measles virus is a ribovirus.

Table 1. PERCENTAGE PLAQUE REDUCTION IN THE PRESENCE OF HALOGEN DERIVATIVES OF DEOXYURIDINE

Inhibitor (20 μg/ml.)	Herpes virus	Arbor virus	Measles virus
5-Fluoro-2′-deoxyuridine	93	0	0
5-Bromo-2′-deoxyuridine	56	0	0
5-Iodo-2′-deoxyuridine	79	0	0

The internal component of measles virus has not been identified chemically; however, there is now a strong possibility that it is a ribonucleoprotein. If this were the case measles virus then falls into the NDV sub-group of myxoviruses.

This investigation was supported by University of Queensland Research Grant No. 438.

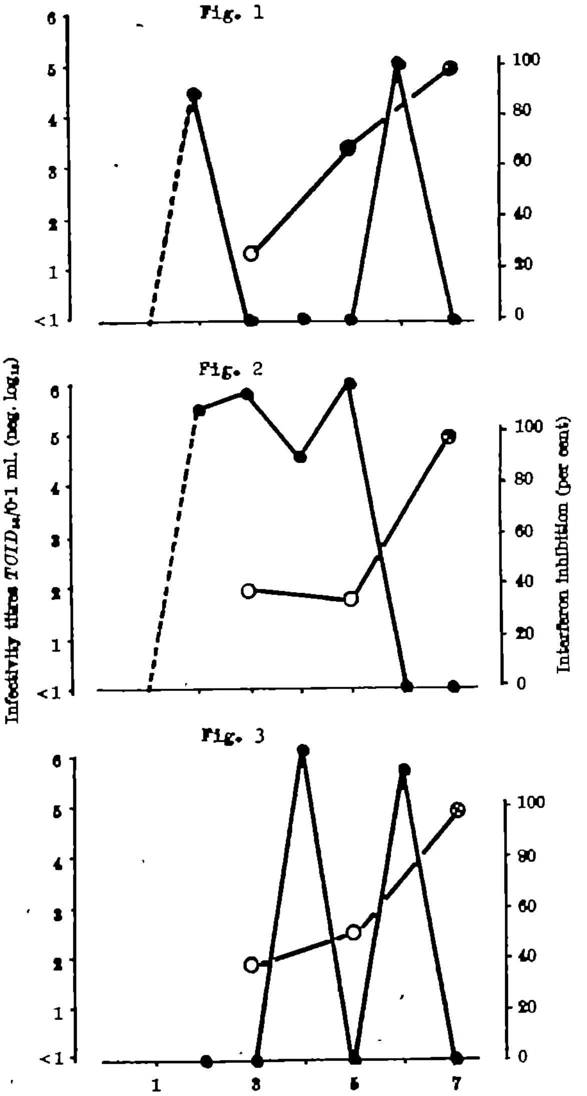
Effect of an Exogenous Interferon on Experimental Influenza Virus Infection and Interferon Production in White Mice

WE have investigated the effect of an exogenous interferon obtained from inbred albino mice (*asw* strain) after infection with a mouse-adapted influenza virus (strain *Em2*, type *A*1) on the dynamics of the influenza virus infection, in parallel with interferon production.

Exogenous interferon was obtained from lungs of mice infected intranasally with influenza virus containing allantoic fluid (50 per cent egg infective dose (EID_{50}) = 10[illegible]/0·1 ml.; dose = EID_{50} in 0·05 ml.) as described by Isaacs and Hitchcock[1]. Exogenous interferon was then concentrated according to Žemla and Vilček[2], lyophilized and resuspended in buffered broth (*p*H 7·2). Four drops of the resulting solution corresponded to yield of exogenous interferon from one mouse lung.

A control group and two test groups, each consisting of 18 inbred albino mice (*asw* strain) weighing 14–16 g, were inoculated intranasally under light ether anæsthesia. The control group was inoculated only with 2 EID_{50} of infected allantoic fluid, whereas the first test group of mice was treated 4 h prior to infection (2 EID_{50}) with four drops of exogenous interferon intranasally, and the second test group with the same dose of exogenous interferon 4 h prior to and 24 and 48 h after infection respectively. Starting with the second day after infection, 3 mice were killed from each group daily, and from their lungs 10 per cent suspensions were prepared in Horváth's[3] medium. The suspensions were clarified by centrifugation at 2,500 r.p.m. for 10 min and serial ten-fold dilutions of them inoculated into suspended chorioallantoic membrane tissue cultures according to Horváth[3]. The cultures were incubated at 35° C for 72 h and the reproduced virus detected by hæmagglutination test on plastic plates[4]. The presence of produced interferon was tested according to Isaacs and Lindenmann[5] in the corresponding lung suspensions of the third, fifth and seventh day after infection.

The results are shown in Figs. 1, 2 and 3. The titre of virus is expressed on the left in log $TCID_{50}$ values, the



Figs. 1, 2 and 3. ○, Non-significant interferon activity ($P > 0·05$), ●, significant interferon activity ($P < 0·01$)

activity of the interferon in percentage lowering of the control hæmagglutinating titres on the right scale of the diagram. It can be seen that the virus in the control group (Fig. 1) was first detected on the second day after infection. It disappeared on the third day and was not detectable up to the sixth day, in order to disappear again on the seventh day. The lack of the virus in lung suspensions on days 3, 4 and 5 is to be explained by the presence of an interferon on the fifth day[1-8].

In the first test group (Fig. 2) virus was found in the mice lungs from the second up to and including the fifth day. As an interferon could be found in the corresponding lung suspensions only on the seventh day we suggest that exogenous interferon suppressed the interferon production in comparison with the control mice and, as a consequence of it, virus multiplication could occur in the absence of interferon in the mice treated with exogenous interferon to a significantly larger extent than in controls.

In the second test group (Fig. 3) both virus multiplication and interferon production were delayed in comparison with the control group: virus was first detected in the lung suspensions on the fifth day, whereas significant interferon activity could be demonstrated only on the seventh day.

As has been seen in our experiments, exogenous interferon given in a single dose 4 h prior to infection suppressed the interferon production and, consequently, enhanced the virus multiplication, while the same dose of exogenous interferon, when given three times (that is, 4 h prior to, 24 and 48 h after, infection, respectively), suppressed not only the interferon production but also delayed the virus multiplication in the mice lungs.

There arises the question of whether exogenous interferon should have a similar effect also in human beings, and, if applied for a sufficiently long period, would be able to eliminate the virus multiplication at all.

CYTOLOGY

Structure of Red-Cell Ghosts and the Effect of Saponin Treatment

The molecular organization of the various components of cell membranes, a frequent topic for theoretical speculation[1], is a difficult problem to approach by experimental methods. Little, if any, structural detail has been convincingly demonstrated in the plane of the membranes until the recent electron microscope investigations of Dourmashkin, Dougherty and Harris[2]. These workers discovered regular hexagonal patterns in membranes of various origin (Rous sarcoma virus, human and guinea pig erythrocytes, chicken liver cells), treated with saponin.

We have recently observed similar, and unexpected, hexagonal structures among the liquid-crystalline phases of lipid–water systems (lipids extracted from human brain)[3,4], and we have developed our own conclusions about the possible biological implications of non-lamellar organization of membrane elements. We thus welcomed the work of Dourmashkin *et al.* as a confirmation of our ideas, and thought it worth while to carry out similar experiments using X-ray diffraction techniques. Some preliminary results of this work are reported here.

Human erythrocytes, washed and suspended in phosphate buffer, pH 7·2, were hæmolysed either in hypotonic phosphate (0·01 M) or in the presence of saponin (0·05 per cent in water, 30 min at 37° C). The ghosts were then washed and centrifuged (30 min, 40,000*g*) several times and freeze-dried. We ascertained in a few experiments that freeze-drying had no drastic effect on the structures.

The X-ray diffraction experiments were carried out in a small-angle camera of the Guinier type[5] at various concentrations and at two temperatures: 22° C and 37° C. The samples were made by mixing fixed amounts of dry ghosts and water concentrations (c = weight of dry ghosts per gram of sample) were determined by dry-weight after the X-ray experiments.

With 'intact' ghosts, that is, not treated with saponin, two main concentration-ranges could be distinguished. From $c = 0·30$ to $c = 0·42$ a lamellar structure was present, characterized by 3–4 sharp reflexions, integral orders of a fundamental spacing : 170 Å at 22° C, 205 Å at 37° C. At higher concentrations, $0·42 < c < 0·70$, a second lamellar structure was found, in equilibrium with the previous one; the repeat distance was 64 Å. Samples at concentrations higher than 0·70 were not examined; at low concentration ($c < 0·30$) the scattered intensities became very weak.

In saponin-treated ghosts one type of X-ray diffraction diagram was observed, which varied very little with concentration and temperature. It was composed of a few sharp lines, the spacings of which were typical of a two-dimensional hexagonal lattice (ratios $1 : \sqrt{3} : \sqrt{4}$) (ref. 3), and of some fairly broad bands at spacings close to 58, 40 and 30 Å. The unit cell side of the hexagonal lattice was 165 Å.

The sharpness of the reflexions of the lamellar and hexagonal phases shows that the ordered regions must be fairly large in the three dimensions.

The results of the X-ray diffraction analysis were very similar to the electron microscope observations of Dourmashkin *et al.*[2]. With both techniques hexagonal structures were observed only in saponin-treated ghosts. The parameter of the hexagonal cell was almost identical : 140–160 Å in the electron microscope preparations, 165 Å in the X-ray samples.

The most exciting suggestion of the observations of Dourmashkin *et al.* is that intact membranes are hexagonal mosaics of various elements (lipids, proteins, cholesterol, water). The fact that this structure becomes visible in the electron microscope only after the action of saponin could be explained by assuming that saponin removes some of the membrane elements, leaving 'holes' accessible to negative staining. But such an interpretation can scarcely be reconciled with the X-ray observations: if a hexagonal structure were present in the 'intact' ghosts, it should be detected by the X ray diffraction techniques. We therefore find it difficult to escape the conclusion that the hexagonal structures are artefacts produced by the treatment with saponin.

It should be emphasized that our results are still preliminary. A detailed analysis of the phase diagram[3] and of the structure of 'intact' ghosts must await more complete experimental data. Furthermore, the effect of the various preparative procedures must be carefully investigated.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, February 25

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. B. Ackner: "Stress and Psychosomatic Disorders".*

British Society for the History of Science (in the Council Room of the Science Museum, Exhibition Road, London, S.W.7), at 5.30 p.m.—Dr. M. J. S. Rudwick: "The Foundation of the Geological Society of London (1807)".

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Dr. F. N. L. Poynter. "On Collecting Books for a Library of the History of Medicine".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. George Pendle: "Latin American Culture". (Second of three Cantor Lectures on "Latin America—World of Tomorrow".)

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.15 p.m.—Prof. D. B. DeLoach (California): "Agricultural Technology and the Management of Surpluses".* (Fifth of eight lectures on "The United States of America".)

Institut Français du Royaume-Uni (at Queensbury Place, London, S.W.7), at 8.15 p.m.—French Scientific Films.

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. W. W. Herbert: "In the Footsteps of Roald Amundsen".

Monday, February 25—Tuesday, February 26

Institution of Electrical Engineers, Power Division (at Savoy Place, London, W.C.2)—Symposium on "Transient, Fluctuating and Distorting Loads and their Effect on Power Systems and Communications".

Tuesday, February 26

Institution of Mechanical Engineers, Hydraulic Plant and Machinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Use of Plastics in Hydraulics".

Society for Analytical Chemistry, Physical Methods Group (in the Cuthbert Wallace Lecture Room, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2), at 6 p.m.—Meeting on "Fractionation of High Molecular Weight Compounds".

Royal Institute of Chemistry, London Section (joint meeting with University College Chemical and Physical Society, at University College, Gower Street, London, W.C.1), at 6.30 p.m.—Prof. A. D. Walsh: "The Electronic Spectra of Small Molecules".

Society of Chemical Industry, Plastics and Polymer Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. A. Sharples: "Recent Studies of the Crystallization of Polymers".

Society of Instrument Technology, Systems Engineering Section (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Dr. A. E. Mitchell, Mr. H. H. Glaettli and Mr. H. R. Mueller: "Fluid Logic Devices and Circuits".

Royal Society of Edinburgh (in the Auditorium of the Station Hotel, Perth), at 7.30 p.m.—Mr. Arthur R. Wannop, O.B.E., F.R.S.E.: "More Food from Our Hills" illustrated by coloured lantern slides. (Meeting to inaugurate the Royal Society of Edinburgh Fund for the Promotion of Interest in Science and Technology in Scotland. Chairman: Prof. E. L. Hirst, F.R.S.)

Wednesday, February 27

Geological Society of London (joint meeting with the Institution of Water Engineers, at the Institution of Civil Engineers, Great George Street, London, S.W.1), from 2 p.m. to 7 p.m.—Symposium on "Groundwater".

Society of Chemical Industry (joint meeting with the Microbiology and Food Groups, at Queen Elizabeth College, Campden Hill Road, London, W.8), at 2 p.m.—Meeting on "Aseptic Filling".

Institution of Electrical Engineers, Power Division (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. T. Norris: "High-Voltage Power-Transformer Insulation".

University of London (at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 5.30 p.m.—Dr. J. R. Anderson: "Auto-Immunity and Oral Pathology".* (Second of three lectures on "The Scientific Basis of Dentistry" organized by the British Postgraduate Medical Federation.)

British Institution of Radio Engineers, Television Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. A. V. Lord: "The Present Position of the N.T.S.C. and SECAM Colour Television Systems".

Thursday, February 28

Royal Society (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion Meeting on "The Scientific Results of the Expedition to Tristan da Cunha, 1962", organized by Prof. W. Q. Kennedy, F.R.S.

Chemical Society (in the Large Chemistry Lecture Theatre, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Prof. A. R. Battersby: "The Biosynthesis of Alkaloids" (Tilden Lecture).

Institution of Mechanical Engineers, Applied Mechanics and Automatic Control Groups (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Joint Discussion on "Are Mechanical Engineers Slow in Adopting the Use of Computers ?"

Royal Institute of Chemistry, London Section (at the West Ham College of Technology, Romford Road, London, E.15), at 7 p.m.—Dr. T. S. West: "Modern Methods of Analysis—a Survey of Methods Based on Reagent Chemistry".

Friday, March 1

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 11 a.m.—Symposium on "The Experimental Taxonomy of the Pteridophytes".

Institution of the Rubber Industry (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5 p.m.—Mr. W. A. Tandy and Mr. F. Woods: "Some Aspects of Reclaim Technology". 6.15 p.m.—Dr. C. C. McCabe and Mr. R. H. Walsh: "A Sulphur Vulcanizable Ethylene Propylene Copolymer".

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. J. H. Beynon: "The Use of Mass Spectrography".

Society of Chemical Industry (joint meeting of the Food Group and the Manchester Section, at the Manchester Literary and Philosophical Society, 36 George Street, Manchester), at 6.30 p.m.—Dr. E. C. Bate-Smith: "Thoughts on Meat" (Jubilee Memorial Lecture).

Royal Institute of Chemistry, London Section (joint meeting with the Brighton Technical College Chemical Society, at Brighton Technical College), at 7 p.m.—Prof. H. N. Rydon: "The Active Centres of Enzymes".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. F. A. Vick: "Harwell".

Saturday, March 2

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. Michael Sullivan: "Chinese Painting".*

Monday, March 4

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. A. Morgan Jones: "The Coronary Collateral Circulation".*

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. Peter Haggett: "Coastal Deforestation in Brazil".

Institution of Electrical Engineers, Electronics Division P.G.E3 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Evaluation of Technologies for Fabricating H.F. Transistors" opened by Dr. J. R. Tillman, Mr. P. Beale, Mr. P. Charman and Dr. R. W. A. Scarr.

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. H. G. Conway and Mr. M. Hartland Thomas: "Engineering Problems of the Decimal and Metric Systems".

University of London (at the School of Pharmacy, 29–39 Brunswick Square, London, W.C.1), at 5.30 p.m.—Dr. P. W. Brian: "Two Biologically Active Fungal Metabolic Products. 1: Griseofulvin".

Institution of Mechanical Engineers, Railway Engineering Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "New Materials Which Could Play an Important Part in Railway Engineering".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Dr. B. K. Blount: "Science in Latin America". (Last of three Cantor Lectures on "Latin America—World of Tomorrow".)

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. J. Pickthall: "About Perfumery"; Dr. B. Dudley Sully: "Perfumery Chemicals from Pinene".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturers (men or women graduates) in Physical and Inorganic Chemistry—The Assistant Secretary, Westfield College (University of London), Kidderpore Avenue, London, N.W.3 (March 1).

Assistant Lecturer in Physics; and an Assistant Lecturer in Sociology—The Secretary, University of Exeter, Northcote House, The Queen's Drive, Exeter, Devonshire (March 2).

Assistant Lecturer in Zoology—The Registrar, Queen Mary College, Mile End Road, London, E.1 (March 4).

Lecturer (with research experience in nuclear physics) in Physics—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (March 4).

Assistant Lecturer in the Department of Psychology—The Secretary, The University, Aberdeen (March 9).

Assistant Lecturer (with a good honours degree) in Applied Mathematics—The Registrar, King's College (University of London), Strand, London, W.C.2 (March 9).

Junior Research Fellow in Physics—The Registrar, The University, Sheffield (March 9).

Lecturer in Zoology—The Secretary, The University, Aberdeen (March 9).

Chair of Veterinary Physiology—The Secretary of University Court, The University, Glasgow (March 15).

Lecturers (2) in Theoretical Chemistry—The Secretary of University Court, The University, Glasgow (March 15).

Research Assistant in Mathematical Statistics in the Department of Applied Mathematics—The Registrar, The University, Liverpool, quoting Ref. No. CV/254 (March 15).

Lecturer in Animal Health; and a Lecturer or Assistant Lecturer in Animal Physiology in the Department of Agriculture (Animal Husbandry)—The Registrar, University College of Wales, Aberystwyth (March 16).

Lecturer (preferably with Ph.D. or equivalent experience in metallurgy) in Metallurgy—The Registrar, The University, Sheffield (March 16).

Senior Lecturer in Physics; and a Senior Lecturer in Metallurgy—The Registrar, The University, Sheffield (March 16).

Lecturer or Assistant Lecturer (with a good honours degree in zoology or agricultural zoology and a special interest in agricultural entomology) in Agricultural Zoology at Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 19).

Demonstrator in Inorganic Chemistry—The Secretary, Department of Inorganic Chemistry, The University, South Parks Road, Oxford (March 23).

Demonstrator in Pathology—The Registrar and Secretary, The University, Bristol (March 25).

Lecturer in Pathology (Morbid Anatomy)—The Registrar and Secretary, The University, Bristol (March 25).

Professor of Agriculture at the University of Queensland, Australia—The Secretary Association of Universities of the British Commonwealth (Branch Office), Marlborough House; Pall Mall, London, S.W.1 (Australia and London, March 29).

Lecturer in Mathematics at Fourah Bay College, The University College of Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 30).

Lecturer (with an honours degree in physics and an interest in some branch of optics) in the Physics Department—Prof. W. D. Wright, Physics Department, Imperial College of Science and Technology, London, S.W.7 (March 31).

Senior Lecturer or Lecturer in Metallurgy at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 8).

Reader in Theoretical Physics—The Secretary of Faculties, University Registry, Oxford (April 15).

Master to teach Mathematics to Scholarship standard—The Headmaster, Ipswich School, Ipswich, Suffolk.

Postdoctoral Fellow in the Department of Physics, to investigate the acceleration of plasma to high velocities—The Registrar, University College of Wales, Aberystwyth.

Research Assistant (preferably with experience in cytology) in the Department of Genetics, to take part in a programme designed to study human chromosome abnormalities and associated disorders—The Secretary, Genetics Department, The University, Sheffield 10.

THE ADVISORY COUNCIL ON SCIENTIFIC POLICY IN BRITAIN

THE fifteenth annual report of the Advisory Council on Scientific Policy* is on the whole a disappointing document. Its main interest lies in the discussion of international co-operation in science, and particularly the recommendations regarding an International Institute for Science and Technology, as proposed by a Working Group of the North Atlantic Treaty Organization over which Dr. J. R. Killian presided, and in its discussion of a report on biological studies from the Biological Research Committee of the Royal Society. This report is appended, as are some notes on the scope and methods of an inquiry into research and development expenditure which are also considered by the Advisory Council. Scientific libraries, however, are cursorily dismissed in a paragraph which shows no awareness of how important a contribution the Advisory Council might make, if it were so minded, to the development of the new National Reference Library of Science and Invention, or to the shaping of the national library system to which the Minister of Education is immediately committed. Further, once again the question of research into natural resources is deferred, pending the report of the Slater Committee, while that of the organization of scientific research is postponed pending the report of Sir Burke Trend's Committee reviewing existing organization for the promotion of civil science by Government agencies. Of any progress, meanwhile, in implementing the recommendations of either the Plowden Committee or the Zuckerman Committee on the management and control of research and development there is no mention.

Two other matters are briefly considered in the report. First, the arrangements described in the Advisory Council's last report for the supply of costly equipment such as computers for research appear to have proved their value. In 1961 a total of £2·1 million was allocated for computers to universities through the University Grants Committee, and when two universities applied for the very large *Atlas* computers that Committee took the view, endorsed by the Treasury, that provision must be made on a national basis. As a substantial requirement for time on such a computer was foreseen by the Atomic Energy Authority, it was decided to establish an *Atlas* computer of the most advanced design at the Rutherford Laboratory of the National Institute for Research in Nuclear Science at Harwell. This would manage the computer and allocate a defined minimum of computer time to the Atomic Energy Authority, and the rest to the Meteorological Office or other Government departments and to universities, on the advice of a committee of computer experts. Three universities have also decided to use their resources as contributions to a larger machine and propose to meet part of their computer needs by *Atlas* machines or *Atlas* components. Needs over the next five or six years should be adequately met by the arrangements now made.

Secondly, during the year the Council considered a report, endorsed by the Royal Society, from the British National Committee on Astronomy, proposing the establishment of an Institute of Theoretical Astronomy, if possible at the University of Sussex, and providing facilities generally for encouraging research in theoretical astronomy as well as a centre of teaching and for the exchange of ideas and research workers. The Advisory Council is satisfied that steps ought to be taken to strengthen, co-ordinate and stimulate such studies in the United Kingdom and to provide satisfactory facilities for collaboration with astronomers overseas. A plan of the kind and on the scale proposed would, in the Council's view, be a good way of meeting these needs, and it is understood that the University of Sussex is considering this project in conjunction with the Royal Society and the British National Committee on Astronomy. The Council also reports that, in accordance with its recommendations in their report for 1959–60, effective arrangements have now been made for expanding seismological studies at the University of Edinburgh. Conditions for seismological work at its station at Eskdalemuir are as favourable as anywhere in the United Kingdom; the Department of Scientific and Industrial Research has made a grant of £43,100 over three years for staff and equipment, while a further grant of £10,480 over three years has been made to the University of Durham for researches in seismology of the Earth's crust.

The Advisory Council was invited by the Minister for Science at the end of 1961 to consider the whole question of international scientific activities and to advise on the issues of policy which arise. While welcoming the growth of international consultation through the numerous agencies of the United Nations, the North Atlantic Treaty Organization, the European Nuclear Energy Agency and the International Atomic Energy Agency, the Advisory Council sees some danger of duplication between these activities where the Agencies have similar objectives or functions. This can be largely avoided by forethought, and accordingly the Council has invited its Sub-committee on Overseas Scientific Relations to review from time to time the various consultative international activities.

International collaborative research projects, such as the International Geophysical Year, have proved highly rewarding and the scientific results have been substantial. The Advisory Council welcomes the increase in international collaboration of this type. The expenditure involved is usually small, and programmes can be organized in a way that permits results which could not otherwise be achieved. It is an added advantage that much of the expenditure is likely to be incurred in the currencies of the countries concerned. Several of these projects have been organized under the auspices of the International Council of Scientific Unions, and the Council refers particularly to the forthcoming International Quiet Sun Year and the International Biological Programme, and to the International Cell Research Organization which it is proposed to set up under the auspices of the United Nations Educational Scientific and Cultural Organization.

The United Kingdom is also participating in four centralized international schemes, in which research facilities are provided and controlled internationally. One of these, the European Space Research Organization, to which the United Kingdom is expected to contribute £7·6 million in 1962–67, is still in the formative stage. The others are the European Organization for Nuclear Research, to which Britain's contribution is estimated at

* Annual Report of the Advisory Council on Scientific Policy, 1961–1962. (Cmnd. 1920.) Pp. vi+45. (London: H.M. Stationery Office, 1963.) 3s. net. See also p. 851 of this issue of *Nature*

£10·4 million, the Halden reactor experiment (£140,000) and the *Dragon* reactor project (£7·2 million), all over the same period. Although these schemes differ widely in type, they all involve centralization on a regional basis and they share the calls on high-grade scientific man-power.

The Advisory Council stresses the importance of the principle that, in centralized international schemes providing facilities for fundamental research, national teams, working in their own laboratories, should have a major share in the use of the facilities provided. Proper use of very advanced equipment provided internationally is, however, only possible by member countries in which a substantial measure of activity already exists and, in the Council's view, it is important to ensure that national research teams from universities can use the opportunities in the very advanced fields of research which the European Organization for Nuclear Research and the European Space Research Organization will provide. While in schemes such as the *Dragon* reactor project, economic and technological considerations may be the determining factors in the decision to participate or not, in reaching decisions regarding participation in scientific schemes, which are usually very costly, it is important that strictly scientific considerations should be given full weight and that all should be satisfied that, from Britain's national point of view, the enterprise is worth the heavy cost involved.

While the Council agrees that the development of international co-operation in science is, in principle, desirable, it is not induced by the success which has hitherto attended the participation of the United Kingdom in such schemes to conclude that any and every international scientific collaborative arrangement has merit simply because it is international. Each scheme must be considered on its scientific merits and there are limits to the cost which a country can incur on scientific activities. Moreover, it is essential to maintain reasonable balance between national and centralized international activities, and it should be noted that the Council attaches great importance to a close relation between the two. It also suggests that one of the most useful ways of assisting international co-operation in science would be to review and improve the existing arrangements for international exchange of scientists.

This recognition that international co-operation is no substitute for national excellence in science does not lead the Advisory Council to overlook the element of assistance to smaller countries or to the 'larger objectives' —objectives such as strengthening European economy or union which may be served by participation. Due weight is given to these factors; but the Advisory Council rightly holds that it is a mistake to resort to international activities, whenever possible, simply because it is politically desirable to extend the area of co-operation. Ultimately, the political value of co-operation is proportional to the extent to which there are real scientific advantages for all the participants.

It is from this pragmatic point of view that the Advisory Council then considers the particular proposals for an International Institute for Science and Technology, recently discussed in these columns (196, 1127; 1962). While the Council is in sympathy with the basic aims and objectives which inspire the proposals for such an institute and considers the basic objectives sound, the majority of the Council believes that these ends can be attained more readily and economically by alternative methods. It questions the soundness of the analogy drawn between an international institute and international research facilities, such as are provided by the European Organization for Nuclear Research. In most fields of science it believes that the nucleus around which work of the highest quality can be developed is the exceptional individual and not a research facility, and this view is supported by the policy which the Carnegie Institution of Washington and the Nuffield Foundation have consistently followed. Moreover, it doubts whether it is wise to ignore the value of existing equipment and stimulus such as are to be found in the great existing centres of research at universities and elsewhere. Most of the Council doubts whether it would be possible to attach research leaders of the highest quality to a new multi-discipline organization to be built up from the beginnings in Europe at the present time, though others believe that, given the necessary backing of Governments, this would be possible.

The Advisory Council suggests, therefore, that in place of a new institute, international agreement should be sought on the selection in Europe of individual centres in existing universities, etc., in particular fields of science and technology which could readily and economically be developed into a nexus of the kind of international centres envisaged. It gives as examples the Imperial College of Science and Technology, which already draws a high proportion of its postgraduate students from overseas, and the National Physical Laboratory. Such international agreement would cover international recognition of the research degrees conferred by these centres as having parity with the research degrees of the participating countries. International and national support for these centres would then be channelled to develop them as rapidly as possible into inter-disciplinary postgraduate centres recognized as the leading institutions in their field in Europe. Besides provision of international research fellowships and visiting professorships, an essential element would be short-period exchanges or visits to maintain close contact and co-ordination by members of the various institutes to other similar centres.

The Advisory Council believes that the benefits of such an arrangement would ultimately spread to the whole of the universities, etc., of which the centres were part and that in this way it would be possible to go far towards truly international universities. It suggests that such proposals could suitably be put forward to the North Atlantic Treaty Organization as the basis of an alternative both to the plan for a single institute and to the proposal for an international research fund. Subsequent to these recommendations, the possibility of establishing an institute which would comprise, in one country, a central 'core' of perhaps two centres, together with a headquarters and with associated centres in other countries, has been considered and the Advisory Council does not regard such a scheme as contrary in its essential principles to its earlier advice.

It might be remarked that Dr. Killian and his colleagues on the Working Group fully recognized the value of the exceptionally gifted individual as a nucleus for research schools of outstanding merit, and the Group laid considerable stress on the importance of flexibility to cope with this situation and its implications. The Advisory Council scarcely seems to do justice to this aspect, nor does it comment on a further draft proposal for an international foundation for the development of science and technology. Since, however, Sir John Cockcroft is a member of the Advisory Council as well as of the Working Group, it may be assumed that the proposals of the Working Group were fairly considered. The broad comments of the Advisory Council are unexceptional and should receive full weight in considering any proposals for international co-operation in research and in decisions as to the organization of Britain's scientific effort generally.

On biological studies, the Advisory Council does not necessarily accept at every point the views expressed in the report of the Biological Research Committee of the Royal Society, but in its present report it is concerned essentially with the diagnosis of the state of biological studies in the United Kingdom. Consideration of the institutional changes which may be desirable to deal with the problems revealed by the diagnosis is deferred until the Committee under Sir William Slater concludes its examination of the case for a research council dealing with research into natural resources. In view of the overlap, this decision is reasonable enough. However, at the same time, it must be pointed out that here once again the Advisory Council scarcely shows the drive and sense of urgency that are desirable. Granted that rapid action is not necessarily precluded when the Slater Committee reports, this means that the Advisory Council is unlikely to contribute further to informed public discussion of an issue of immediate importance within the next twelve months.

It is such circumstances that foster doubts as to the adequacy of the existing structure and the real effectiveness of the Advisory Council and such criticism is not invalidated by the very sound discussion of the state of biological studies in the present report. In fact, that discussion, and the report on which it is based, bring out the imperative need for some further consideration of the respective functions of the University Grants Committee and the Research Councils in fostering biological research. That is a first step towards remedying on any permanent basis the relative neglect of biological research which is emphasized by the present report.

That neglect is attributed primarily to the failure within the universities to recognize the need for developing biological studies. It is generally agreed that biology at present is in a state of transition. With a continuing change of emphasis from descriptive studies to the analysis of living matter and the interactions of biological systems, traditional branches of biology are being increasingly infiltrated by other scientific disciplines: the interaction of these subjects has been responsible for many of the most promising new developments. Such interaction is at present occurring at a wide range of levels, and, as the Advisory Council for Scientific Policy frankly recognizes, implies the need for major changes in the organization of biology departments especially in universities. The plans for an International Biological Programme, concerned with biological productivity and human welfare, are designed to deal specifically with one aspect of this situation, but more generally the proposal for an International Institute of Science and Technology is intended to deal with this problem of inter-disciplinary relations and overcome the difficulties which the rigidity of departmental organization in universities often offer.

In the universities at present the situation is far from uniform. In some there are large and well-equipped centres for biological research, but in others there are small traditional departments with relatively modest equipment and insufficient space for expansion. In many branches of biology adequate progress is only possible with first-rate modern equipment and facilities and inter-disciplinary co-operation. For this co-operation to be achieved, the Advisory Council considers much greater financial support to biology should be provided. Besides this, however, leaders in research will have to face much more severe administrative and managerial problems, and in all but the newest schools recently equipped by the University Grants Committee, there is a critical shortage of space for research equiment, accentuated by the growth in new directions which cut across the traditional structure of faculties.

Special measures may be required to meet the situation, but the Advisory Council recognizes that the establishment of new universities presents special opportunities for creating biological departments embodying a multi-disciplinary approach. It is vital, it holds, for the proper evolution of biological studies in the United Kingdom that centres where the necessary conditions exist, or can be established, should be developed and provided with staff and resources comparable with the best centres in the world. It gives a broad hint, though no more than a hint, that this will not be possible with the level of support for the universities which is at present contemplated by the Government. Even with a substantially higher level of support for university research, some selection of céntres of biological research for development will be unavoidable, especially in the creation of new departments.

The Advisory Council has several times during the past ten years directed attention to weaknesses in the traditional pattern of university education in the biological sciences, pointing, for example, to the importance of basic training in mathematics, physics and chemistry. These comments are the more pertinent in the light of the new developments just noted, and the Advisory Council hopes that throughout biology departments there will continue to be developments in both established and new universities in training biologists with adequate knowledge of the physical sciences and mathematics. It suggests also that more senior and responsible posts are required particularly to meet inter-disciplinary needs if facilities are to be provided which will attract the younger men who might otherwise be tempted to emigrate to centres abroad providing such conditions. While the Advisory Council recognizes that Britain may be limited in the scale on which expensive facilities of this kind can be provided, it strongly insists that such additional resources as can be made available should be channelled with vigour and foresight into the chosen centres.

In these comments and recommendations the Advisory Council follows broadly the conclusions of the Royal Society's Committee. The latter concluded specifically that insufficient biologists are being trained even to meet present-day needs and that the present expenditure must be at least doubled if Britain is to exploit the present possibilities in biological research. Little would be gained by redistributing the funds at present available, but if additional resources are provided the means for distributing Government grants should be modified so as to permit more positive planning. The need for biologists has been underestimated and a reassessment of the need by the Committee on Scientific Manpower is recommended. The opinion is expressed that previous estimates were based largely on a survey of the needs of industry and took insufficient account of the needs of agriculture, veterinary medicine, fisheries, forestry, etc., in which biologists tend to find employment, while in borderland subjects it is necessary to match with biological recruits those coming from the physical sciences.

Reference is also made to a number of particular deficiencies. It is questioned whether the Advisory Committee on Fisheries of the Development Commission is in a sufficiently strong position to finance and expand work on many aspects of physiology, biochemistry and the physical sciences where marine and fresh-water organisms and their environment offer exceptionally favourable subjects for study. The position of the centres for fundamental research in marine and fresh-water biology in Central and East Africa and in Malaya is noted as calling for immediate investigation. It is curious, however, that neither here nor in the specific references to the role of the Research Councils is the Overseas Research Council mentioned. In terrestrial ecology and general zoology the main specific deficiency in the present organization is considered to be the lack of adequate means of financing biological expeditions. Moreover, in economic microbiology it is submitted that the Microbiological Research Establishment at Porton should be freed from Service control and expanded so as to act as a national institute of microbiology, with its own governing body, suitably attached to an appropriate Research Council and with close liaison with university departments.

The almost unlimited possibilities in the development of research on marine and fresh-water animals while the present restricted work is hampered by lack of funds is again stressed in this report, as is the inadequacy of the grants which the Nature Conservancy is at present able to make for biological or botanical research. Certainly there is firm criticism of the present departmental structure in the universities for teaching and research in biological sciences. Obviously the time is ripe for reform, apart from the opportunities for experiment which the creation of new universities offer, and there is a note of urgency which the University Grants Committee can scarcely ignore. In particular, greater flexibility is required if the universities are to be enabled to foster precious talent. In the absence of sufficient senior research posts, with security of tenure, and more post-doctoral fellowships Britain is losing too many trained scientists abroad. Whereas nine-tenths of the research personnel engaged in the earliest research in a new field were provided by the United Kingdom, this rapidly changed to a situation where three-quarters of the research workers engaged in its further exploitation were in the United States.

The reluctance of the Advisory Council to commit itself to any reassessment of the role of the Research Councils in the organization of research in advance of the report of the Trend Committee is understandable; but it is clearly of the utmost importance that the whole system should be reconsidered as a matter of urgency, but in relation, for example, to the University Grants Committee and to the universities themselves, and in respect of the scale of Britain's whole effort. In particular, it is once more apparent that the place and functions of the Overseas Research Council are of significant importance and that the Nature Conservancy requires much greater resources at its disposal. The urgency derives only in part from the opportunities provided by university expansion; it arises equally from the pace of development in Britain, the productivity campaign and the position of research in the emergent countries overseas. The report of the Royal Society's Biological Research Committee demonstrates the urgency in one particular field, but it is clear enough from the whole report of the Advisory Council how imperative it is that it and the Minister for Science should be thinking urgently and constructively about the whole scale and balance of the research effort. The present report is scarcely less tentative than that for 1960–61, and another successive report of the same character must seriously prejudice the position of the Advisory Council itself as an effective element in the national structure for advising on and planning the development of Britain's research effort.

FUTURE OF BRITAIN'S NATIONAL PARKS

THE thirteenth annual report of the National Parks Commission*, covering the year ended September 30, 1962, is noteworthy for its unequivocal criticism of Government policy in regard to the national parks. This is most clearly expressed in regard to the Government's failure to indicate when a place will be found in the legislative programme for what the Commission regards as the essential amendment of the 1949 Act. It is no less obvious, if implied rather than expressed, in the Commission's remarks on coastal preservation, the closure of railways and on development questions, such as electricity supply, water supply, aerial masts and disused Service sites.

The magnitude of these latter issues is sufficiently illustrated by the simple fact that during the year some 471 proposals for development affecting landscape beauty in national parks, in areas of outstanding natural beauty, or elsewhere were referred to the Commission by Government departments, by park and other local planning authorities, or by amenity organizations. There were, however, several encouraging features of the year which may be briefly noted before discussing the major issue. In the ten national parks a number of creative projects were proposed by the Park Planning Authorities. Some progress is reported in dealing with the litter problem, and on Dartmoor and elsewhere encouraging examples are cited of co-operation with local people in preserving and enhancing the countryside. In the Lake District and on the Pembrokeshire coast particular attention was directed to problems arising out of caravan camping and the increasing congestion of roads by motorists, while in the Exmoor National Park particularly difficult problems arose in the conflict of interests in the enclosure of open country and in the reconciliation of the need for landscape preservation with the demands of forestry. An Order designating East Hampshire an 'area of outstanding beauty' was confirmed by the Minister on September 26, 1962, and a proposal to designate an area to be known as the Forest of Bowland is to be submitted for confirmation shortly, but there was a disappointing further delay in the confirmation of an Order designating the Sussex Downs such an area. However, some progress was made towards completing proposals for the South Downs Long Distance Route, the first such route to be proposed as a bridle way, and for a route in Yorkshire from near Filey northwards along the coast to Saltburn and thence inland along the escarpment to Helmsley. Proposals for solving the problem of the route of the Pennine Way in Northumberland were submitted to the Minister, who has now approved proposals submitted for the variation of three other sections of the Pennine Way.

---

* National Parks and Access to the Countryside Act, 1949 Thirteenth Report of the National Parks Commission for the year ended September 30, 1962. Pp. vi+80+8 plates. (London: H.M.S.O., 1962.) 6s. 6d. net.

Turning now to the major issue of development, the Commission views with grave apprehension the large-scale plans which the Electricity Board has in mind, although it fully appreciates that the Board is giving increasing attention to its statutory duty to pay due regard to the impact of its schemes on natural beauty. For the Commission's part, it recognizes the need for more generating stations and transmission networks, but nevertheless maintains its objection to particular schemes such as those for for Edern in Lleyn in North Wales and Hamstead in the Isle of Wight. It again points to the dangers of a piecemeal approach to these problems and has urged both the Board and the Minister of Power to consider as a whole the proposals for extending a new high-voltage transmission line westwards as far as Fraddon in Cornwall. While it welcomes evidence that water supply is likely to receive more deliberate consideration, it is disturbed at the absence of a central body to ensure that there is no unnecessary multiplication of aerial masts and that any new proposal utilizes an existing tower or mast if possible. At present, any one of eight Government departments may satisfy itself that no existing mast can be used, and it is understood that unless it issues a certificate to this effect the Government will not clear the proposal.

The National Parks Commission suggests that the Planning Authority should likewise be in a position to require, in respect of any new proposal, a certificate from the appropriate sponsoring department that no existing mast, tower or building can be made to serve. The point has been put to the Ministry for consideration, but a reply is awaited on this and also on the further submission that it should be accepted as Government policy that a site for a new mast within a national park, or in any area of special scenic value, should be considered only when a site outside such areas is not capable of serving the purpose. The Commission considers that the sponsoring department responsible for examining the project should at the same time consider alternative sites outside the special scenic areas; such departments should refuse to put forward for planning approval any project involving a site in a national park or in any area of special scenic value unless it can certify on Government authority that sites outside such areas cannot be used for the project in question.

The National Parks Commission has already provided Government departments with maps showing the areas which, in its view, need special protection. Clearly the argument applies with no less force to the scientific interests of nature reserves, and the Nature Conservancy and the National Parks Commission are equally affected by this whole development problem. Meanwhile, however, the National Parks Commission is alarmed at the prospects implied in the Government's statement on the development of broadcasting as to the need for many more transmitting stations. This again is not entirely removed by the Government statement that all new ultra-high-frequency programmes for the same area will be transmitted from the same mast and site, and the Commission is seeking further information from the Ministry.

Government indifference or negligence appears also over the disused Service sites and in regard to fresh proposals for training areas. Once again the Commission directs attention to the way in which land and buildings acquired in good faith for what seemed to be essential defence requirements have afterwards become redundant and have been left derelict, and to a tendency to disregard the duty to clear up before disposing of a site. Often the development was only allowed in the particular area because it was imposed on the planning authority as being in the national interest. Sometimes attempts have been made to dispose of the sites for private development—sites which the planning authorities would never have sanctioned in such areas—and hence to saddle others with the costs of clearance or restoration. The Commission rightly argues that it is indefensible that one Government department should refuse to carry out clearance operations when, under other legislation, in fulfilment of a statutory duty laid down by Parliament, another department will be meeting most of the cost.

The Commission is constantly urging Government departments to take what is manifestly the right and reasonable action, but it has become necessary for it to raise the whole subject with the Minister, as it may be necessary to do also over new proposals concerning training areas. The Government's whole 'policy' here appears to be based on entirely wrong priorities and values, and in particular on a refusal to accept Mr. Harold Macmillan's own view, in 1952, that national parks are areas in which amenity and access are to be given an overriding position. That is persistently refused. There is no evidence of determined effort to find military training areas outside national parks. Requests for impartial inquiry into the persistent retention or misuse of areas, such as Dartmoor, which should have been the first to be relinquished, are refused and the Services are never forced to consider either the pooling of requirements or to recognize that if a particular request is granted, further requests elsewhere are *ipso facto* excluded.

Coastal preservation and the closure of railways provide further examples of Government indifference to the essential issues. While it is true that the National Parks Commission has made some positive contribution to coastal preservation in that about 30 per cent of the coastline of England and Wales is included within the areas established as national parks or as areas of outstanding natural beauty, it follows from what has already been said that the effectiveness of this protection is still in doubt. The Coastal Preservation Committee of the Council for the Preservation of Rural England suggested the appointment of a Committee, similar to the Minister of Transport's Committee on Landscaping of Trunk Roads, to advise him on problems relating to the development of land around the coast. The Minister was unable to agree to this suggestion, and referred to the general duty of the National Parks Commission to advise him on all questions relating to natural beauty. The Commission believes that the Minister of Housing and Local Government recognizes the need for a proper coastal preservation policy, but it is disappointed that he has not yet issued a promised circular to local planning authorities on the review of Development Plans, and asking them to make special surveys of the coast with the view of deciding where facilities for holiday-makers should be concentrated while safeguarding the rest of the coast so that its attractions might be enjoyed to the full.

As regards railways, the national parks lie in the rural areas where drastic curtailment of services has occurred or is most likely. Proposals to withdraw services from all railway lines into Brecon were strongly opposed locally, and the Commission believes that if the purposes for which the Brecon Beacons National Park was established are to be achieved, access by train from the heavily populated industrial centres of South Wales is important. The Newport to Brecon and Neath to Brecon lines are regarded as worthy of special treatment because of the exceptional beauty of the landscape which can be seen from them. These lines have now been closed, however, and the Commission is equally disturbed about the implications of this policy of closure for the Exmoor National Park, and generally the Commission insists that railways provide an important means of public access to national parks and are in themselves facilities from which the scenery can be enjoyed.

Apart from this, of course, the withdrawal of passenger railway services from national park areas is bound to intensify the difficulties which are already being experienced in places with regard to road transport. Nevertheless, there is as yet no sign that the Government is aware of the implications of the present policy, if indeed it is sufficiently interested in the national parks to be concerned one way or another with their future. There, in fact, the deepest note of concern of the whole report is struck. The Commission records its profound disappointment that there is still no sign from the Government that an early place in the legislation programme may be expected for amendment to the 1949 Act. Lord Jellicoe's remarks as Parliamentary Secretary to the Ministry of Housing and Local Government, in addressing the Conference of Park Planning Authorities at Moretonhampstead last May, indicated that prospects of early legislation are not brighter than a year ago and it must now be remembered that the present Parliament reaches the end of its five years in the autumn of 1964. If legislation is not introduced during the next two sessions, prospects of early introduction in a new Parliament are unlikely to be good, particularly if a new Government assumes office.

While it is agreed that more could be done within the framework of the Act as it now stands, the Commission is firmly of the opinion that legislation giving effect to the relatively modest amendments it has recommended would provide much greater scope for the Park Planning Authorities to undertake more positive work because of the increased rate and range of Exchequer grants. In particular, grant for administration would encourage the appointment of staff to deal solely with work concerning the national parks. The Commission considers this to be vital to the successful operation of the national park system and that it cannot press too strongly the real need for the changes suggested. Meanwhile, it is discouraging, both to the Commission and to Park Planning Authorities, that the Government does not care sufficiently about national parks to devote a small part of Parliamentary time to a relatively simple, and politically uncontroversial, piece of legislation.

Lord Strang, the chairman of the Commission, in addressing the Ramblers' Association Conference last September, noted that Parliament can be refreshingly conscious of the interests of national parks, and of this a debate in the House of Commons when a motion was adopted calling for the introduction of amending legislation to the National Parks and Access to the Countryside Act, 1949, is encouraging evidence. From the Opposition Front Bench, Mr. C. Hughes, in a sound but constructive as well as critical speech, supported the motion. However, in accepting the motion on behalf of the Government, Mr. F. V. Corfield, Parliamentary Secretary to the Ministry of Housing and Local Government, declined to give any undertaking about time for amending legislation, although he admitted that the Government had recognized for some time that the Act required amendment. In view, however, of the Parliamentary situation, might not this latest report of the National Parks Commission prompt some determined effort to secure agreement between Government and Opposition to provide Parliamentary time for the introduction of the relatively simple and uncontroversial amending legislation that is now so urgently required?

FIFTY YEARS OF *DROSOPHILA*

Genetics and Evolution

Selected papers of A. H. Sturtevant. Selected and edited by E. B. Lewis. Pp. x + 334. (San Francisco and London: W. H. Freeman and Company, 1961.) 54*s*.

IT is more than fifty years since the results of experiments in breeding the fruit fly began to issue from the small laboratory (it was only 30 ft. by 27 ft.) of T. H. Morgan in Columbia University. The work began in 1910 with Morgan's conversion to the chromosome theory, the theory of Weismann, Boveri and his colleague Wilson. It reached its climax in December 1921 when he in turn tried to convert the reluctant Bateson to the new doctrine. In the intervening period a revolution had been accomplished and the foundations of a new genetics had been laid by Morgan and his pupils.

Now we have a part of the record of this revolution in the selected papers of the youngest of the three chief collaborators, Alfred Sturtevant. When Sturtevant published his first paper (on heredity in horses) he was eighteen years old. Three years later, in 1913, he wrote his most notable work, the account of linkage between "six sex-linked factors" in *Drosophila ampelophila*. The result was a chromosome map which within a few years became the focus and the symbol of the new science. Its discovery constituted the first unmistakable step from the biological side towards the union of the physical and the biological sciences.

After this paper, the first in the present selection, there followed the series of investigations described, or perhaps we should say reported, in this book. Four main lines should be noted.

(1) The re-arrangement of genes, discovered as 'crossing-over-suppressors' in 1917 led to a new view of the different kinds of change in chromosomes in 1921, and later to the conception of different kinds of hybridity and to the theory of interchanges in hybrid species (as in *Œnothera*).

(2) The recognition of the bar-eye mutation as due to a duplication of a bit of chromosome widened this view still further in 1925. It also introduced the idea of the position effect as yet another mode of genetic change in the chromosome materials.

(3) Side by side with these analytical studies, evolutionary and synthetic hypotheses were continually being applied. The discovery of *Drosophila simulans* was the first part of the story of parallel variation combined with divergent changes in related species.

(4) Sex reversal, sex ratio control, sexual selection, intersexes and the origin of gynandromorphs: all these were used to solve ancient problems and to raise important new issues. Thus gynandromorphs, considered develop-

mentally, led on to the study of mosaics, to the principles of gene action and of the diffusion of gene products. Whence, as he points out in an introductory note, Beadle and his colleagues derived a new beginning in biochemical genetics.

These seem to be Sturtevant's main contributions, and they are well represented in the selected papers. Represented, but not, alas, expounded. These papers were written for a circle of *illuminati*. A small circle, it was, but quite sufficient it seemed to its members. Each paper began with the briefest introduction or, more often, with references to one or two earlier papers on *Drosophila*. Here is the first catch. These earlier papers are not usually in the present selection.

But there are still other catches. The whole theory of linkage and crossing-over relies on observations of chiasmata between chromosomes. But these observations were not made on *Drosophila*. There is no reference to them. Again, the importance of the bar mutation is that it confirms, in a limited sense, Bateson's theory of 'Presence and Absence'. Sturtevant indeed explains the mutation as due to 'Presence and Absence'. But he contradicts Bateson's theory: and he does so without mentioning Bateson. This is an extreme example.

In exposition parallel difficulties arise. It often happened that everything turned in a complex linkage experiment on which end of the chromosome was supposed to be left or right and where the 'spindle attachment' was supposed to be. Many more students in remote places must have struggled with these esoteric problems: and some, like myself, may have struggled in vain.

Thus, these papers will be useless without the explanatory volumes published jointly with Morgan and the other collaborators and now unfortunately inaccessible. For the historian of genetics equipped with these volumes, however, they will reveal several matters of interest.

First, these papers show that the driving force in Sturtevant's work has been observation and experiment and not generalization. Not only the driving force but also the continuity. That first sentence with the reference which joins each paper to its predecessors genuinely and without pretence represents the intellectual link: and no summary is usually needed, for the whole is the briefest conceivable abstract. Secondly, these papers show the parts played by the several collaborators. Wilson used to say that Morgan's three greatest discoveries were Bridges, Sturtevant, and Muller. But we can now see that the discoveries were reciprocal. Morgan gave literary coherence as well as scientific perspective to this powerful combination. He could pause to look back and look around while they looked almost entirely forward. Thirdly, we now see the different way they looked forward. The chromosome theory had answered so many questions. The chromosome map had asked so many more. On one hand there was Muller, bent on relentless analysis, pursuing the determinant to its smallest atomic element which he reached by the induction of mutation in the gene. On the other hand there was Sturtevant, turning aside to those awkward problems, biological problems, intermediate between the gene and the chromosome and between the cell and the organism: and both methods we see having consequences which have been reaped by many others. In this contrast, over-simplified, we also see what will continue for some time to be one of the chief polarities of biological inquiry.

The problems that concerned the early 'Drosophilists' interest to-day a widening public in the most practical sense. To-day, one after another, the situations that revealed themselves in the fly—to be confirmed and elaborated soon afterwards by the chromosomes of plants—are revealing themselves in man. There has been a gap of fifty years: and for the benefit of those who are interested in man it is to be regretted that there is still no worthy account of the great *Drosophila* discoveries. Sturtevant's papers are therefore a timely reminder of a still unrecorded passage in the history of science. C. D. DARLINGTON

RADIATION HAZARDS

Irradiation of Mice and Men

By Dr. John F. Loutit. Pp. xii+154. (Chicago and London: University of Chicago Press, 1962.) 5 dollars; 40*s*.

WHILE the threat of nuclear weapons of gigantic destructive power hangs over mankind, interest in the hazards of radiation will be kept alive. It is now generally accepted that all doses of radiation, however small, have a cumulative effect which may be to the disadvantage of individuals exposed to them. The big question is how to balance the disadvantage with the benefit which may be derived from radiation in medicine and industry. Many articles, reports and books are written to explain the immediate danger and to forecast the possible consequences of radiation in the near or distant future. In view of the many diverse opinions expressed by the various authors, under the influence of national, financial, moral or political considerations, this book, though limited in its scope, will be welcomed by all who want unbiased information about the hazards of radiation. The subject of the book is a series of lectures given to the Section of Nuclear Medicine at the University of Chicago in late 1961 by Dr. Loutit, who is director of the Radiobiological Research Unit at Harwell and a member of the International Commission on Radiological Protection.

The reader can thus expect a critical study of the problem and guidance in areas where so far no general agreement has been reached. Dr. Loutit has made extensive use of reports by the United Nations Scientific Committee, the Medical Research Council, the Committee on Radiological Hazards to Patients, the Agricultural Research Council, the International Committee on Radiological Protection and of various other surveys. He has also drawn on his own experience and that of his colleagues at Harwell to provide the sort of first-hand information that only the experimenter can supply.

After an introduction in which the biological targets of radiation are briefly described, the information given in the book centres around two topics: the effect of radiation on the life-span and the incidence of malignant diseases, particularly leukaemia, which might be affected by radiation. Past experience in medical radiology and industry has shown that persons exposed in their occupation to radiation often die prematurely, due mainly to cancer. The mortality pattern of the uranium miners at Schneeberg exemplifies this point. The question remaining is, whether the cumulative effect of low dose chronic irradiation can shorten the life-span. The author marshals the statistical data and the pertinent experimental findings to comfort his reader that so far no evidence has yet been obtained which could suggest any non-specific reduction in life-expectancy, when the exposure is below the officially accepted 'permissible' dose, that is, five rads per annum. In this section the problem of the nature of premature or accelerated ageing, which can be brought about in mice by radiation in specially designed experiments, is discussed in some detail. The author explains the various difficulties which are involved in the interpretation of the experimental findings and indicates their essential strengths and weaknesses, mostly weaknesses, when they are extrapolated to man.

In the second part of the book, Dr. Loutit deals with the possible effect of radiation on the incidence of leukaemia. He summarizes our recent knowledge concerning spontaneous, as well as radiation-induced, leukaemogenesis in mice then proceeds to examine the findings of various surveys carried out on the leukaemia incidence in man. These surveys, one is retrospective the other prospective, arrived at different conclusions; the former revealed an association between leukaemia and radiation; the latter did not. Dr. Loutit critically examines the facts in which some writers on radiation hazards have based their prediction of the shortening of life-span and of the increase in leukæmia incidence which might follow the increase in fall-out or other source of radiation and his conclusion is not flattering to most of the speculators.

A large part of the book is taken up with the thorny problem of strontium-90, the product of nuclear fission which is liberated into the atmosphere by atom bomb explosions. It represents a serious radiation hazard because it is absorbed and retained in the human bones, has a 30-year half-life and, like radium, it does produce anæmia, bone destruction and not infrequently bone cancer. The Radiological Research Unit at Harwell devoted much effort to the examination of strontium metabolism, and the reader will find in the book a great amount of factual data obtained by the group. Perhaps this part will be heavy going to many non-expert readers; but on the other hand this section of the book illustrates very clearly the fact that extensive and painstaking scientific investigation is needed to obtain reliable data for estimating the hazard of radiation to man.

The aim of the author in his series of lectures was to disseminate unbiased information. This aim was well fulfilled, and by publishing the lectures he has made the valuable information available to a much larger public. Let us hope that those who are seriously concerned with the administration of our future will be interested in the information provided. P. C. KOLLER

ANALYTICAL CHEMISTRY IN THEORY AND PRACTICE

Treatise on Analytical Chemistry

Part 2, Vol. 7. Edited by I. M. Kolthoff and Philip J. Elving, with the assistance of Ernest B. Sandell. Pp. xxiii + 567. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, Inc., 1961.) 139*s*.

IN a previous review of the earlier volumes of this *Treatise*, it was remarked that the various volumes were appearing haphazardly. At that time Volumes 1 and 3 of Part 2 had appeared, but not Volume 2. Since that time, so far as is known, Volume 7 is the only further section which has appeared.

In Volume 7 the systematic analytical chemistry of the elements is continued. It consists of chapters on the following elements: sulphur (B. J. Heinrich, M. D. Grimes and J. E. Puckett), selenium and tellurium (T. E. Green and M. Turley), fluorine (C. A. Horton), the halogens (G. W. Armstrong, H. H. Gill and R. F. Rolf), manganese (M. D. Cooper and P. K. Winter) and rhenium (C. L. Rulfs).

All these chapters are set out according to a standard pattern and are well classified. It is possible by reference to the contents page for each chapter to find readily any special information regarding the particular element. Each section describes the occurrence, manufacture and uses, the toxicology and industrial hazards, and the general properties of the various compounds. There are sections on sampling and methods of decomposition, dissolution and preliminary treatment of samples. Reference is made to almost every method available for the determination of a particular element, whether it be instrumental or purely chemical. Each section concludes with a selection of recommended procedures. The high standard of the previous volumes has been maintained, and the weaknesses which are inevitable in such a massive compilation are remarkably few.

A more extensive treatment of barium sulphate precipitation would have enhanced the value of the section on sulphate determination. It is surprising to find this procedure covered in two pages when it has been the subject of so many extensive investigations. There are no references to methods for the purification of barium sulphate, nor to alternative precipitants. It is also somewhat surprising to find the use of tetrahydroxyquinone and rhodizonic acid as indicators still recommended. When these indicators first came into use, there were no satisfactory titrimetric methods for the determination of sulphate ion. Much better procedures are now available.

The chapter on the analytical chemistry of fluorine is the most comprehensive that I have seen, but one would not altogether agree, however, with the methods recommended for the decomposition of organic fluorine compounds, nor the method for titrating fluoride with thorium nitrate.

The chapter on the other halogens is valuable because of the extent of the treatment; nevertheless, there are a few omissions. The section on rhenium is particularly to be welcomed. This metal was not discovered until 1925, hence its analytical chemistry is not as extensive as, and is less well known than, the other elements considered in this volume.

Part 2, Volume 7, is a worthy successor to the earlier volumes, and the editors of the *Treatise* must again be congratulated on their general approach to the problems involved in this type of compilation.

R. BELCHER

THE MYCOPLASMATACEAE

Pleuropneumonia-Like Organisms (PPLO) Mycoplasmataceae

By E. Kleineberger-Nobel. Pp. ix + 157. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1962.) 40*s*.

THE Mycoplasmataceae are now known to be ubiquitous organisms occurring as commensals and pathogens in many animal species and also as unwelcome fellow travellers in tissue-cultured cells. Ignorance of their existence in these situations may lead to serious misinterpretations. By collecting in one small volume much information previously dispersed in the scientific literature, this work should be a valuable source of reference for medical and veterinary diagnosticians and research workers.

Two short chapters describe the causative organisms of the major epizootics and other members of the group which have received most attention in research. They also provide a historical background to development of knowledge of pleuropneumonia-like organisms (PPLO). Chapters on morphology, isolation and metabolism (the latter by S. Razin) form the major portion of the book and present the data clearly and concisely. The large allocation to these topics is justified since technical problems have been the main limitations to progress in the examination of this group of organisms. The chapter on morphology is well illustrated and should be of particular value to those unacquainted with PPLO. Other chapters deal with the susceptibility of PPLO to inhibitory agents, the relationship of PPLO to chicken coccobacilliform bodies and also to the controversial relationship of PPLO to *L*-forms of bacteria. The chapter on serology, immunology and pathogenicity suffers from an important omission since publication preceded recent applications of fluorescent antibody techniques in the elucidation of the association of a PPLO with human atypical pneumonia and in the detection of PPLO in cell cultures. Investigations of the growth of PPLO in tissue cultured cells and the problem of contamination of cell cultures with PPLO receive a small amount of attention considering their practical importance.

With these reservations the volume is authoritative and fills a gap in microbiological literature.

IAN MACPHERSON

BENZENE EXTRACTS OF THE ORGUEIL METEORITE

By Dr. W. G. MEINSCHEIN
Esso Research and Engineering Co., Linden, New Jersey

LIFE cannot be defined in a quantitative manner[1,2]. Living things vary in size, function and composition, and these variations and the instabilities of organic molecules limit the precision with which the existence of prehistoric organisms can be established. Very few remnants of life are preserved in sediments over geological periods of time, and the compositions of these remnants in most cases do not reflect accurately the compositions of their counterparts or precursors in living plants and animals[3]. Nevertheless, the fossil remains of extinct organisms have been recognized as reliable indicators that strange organisms, unlike any seen by man, have existed on Earth. These indicators have been accepted because, so far as is known, only a living thing could have formed these fossils or the templates that gave the fossils their shapes.

Organisms also use templates to synthesize the organic molecules which make life possible[1,4]. Plants and animals are remarkably selective of the compounds they make and use. The precise structures of organic molecules may be equally as indicative of a biological source as are the features of fossilized skeletal remains[3,4]. Based on the established stabilities and the analyses of carbon compounds in sediments and in organisms[3,5-11] certain hydrocarbons appear to be the best-preserved remnants of former life on Earth. Hydrocarbons in association with some organic non-hydrocarbons can be extracted by benzene from most terrestrial sediments. This article will establish that benzene-extractable constituents of the Orgueil meteorite resemble chromatographically and spectroscopically those of some terrestrial sediments. In addition, it will be shown that the mass spectroscopic type analyses of alkanes from Orgueil fragments, terrestrial sediments and organisms are similar.

Reagents, apparatuses, instruments, techniques and controls used in this investigation have been described[3]. Trace metal and mineralogical determinations[12] have demonstrated the authenticity of the Orgueil fragments used in this investigation. Interpretations of mineralogical data suggest that the Orgueil meteorite originated in an aqueous environment[12,13]. Deuterium analyses[14] and data presented here strongly indicate that the benzene extract of these Orgueil fragments were not significantly contaminated by terrestrial organic matter.

Abiotic[15-17] and specifically Fischer–Tropsch[18] processes have been proposed as sources of carbonaceous substances in meteorites. Fischer–Tropsch products are commonly recognized as the best synthetic substitutes for petroleum. Active catalysts are used in making Fischer–Tropsch oils, and the oils are normally hydrogenated and fractionated to obtain petroleum-like products. Although the Orgueil fragments contain elemental sulphur which poisons most Fischer–Tropsch catalysts, a selected Fischer–Tropsch oil is included among the terrestrial samples to be discussed because this oil resembles natural lipids more so than did a variety of other abiotic products which have been analysed in these laboratories.

Infra-red spectra of a crude oil, a Fischer–Tropsch primary oil, and the benzene extracts of terrestrial sediments and the Orgueil chondrite are shown in Fig. 1. Variations are observed in the infra-red absorptions of different natural samples; but certain absorption bands usually appear in the infra-red spectra of the benzene extracts of former biospheres on Earth. In addition to the carbon to hydrogen (2,775–3,000 and 1,330–1,430 cm^{-1}) bands, sediment extracts and crude oils normally absorb near 3,300 (OH or NH); 1,030, 815, and 745 (aromatics), and 720 (*n*-alkyls) cm^{-1}. Recent sediment extracts also show complex carbonyl absorptions with maxima near 1,730 (ester carbonyl) cm^{-1}, whereas the carbonyl absorptions in extracts of ancient sediments are frequently greatest at slightly above 1,665 (organic acid salts) cm^{-1}.

Comparison of the infra-red spectra in Fig. 1 indicates the Orgueil extract absorbs at all the wave-lengths which are generally common to terrestrial sediment extracts and crude oils. Maxima in the carbonyl absorptions of the Orgueil and recent marine sediment extracts both appear at the same wave-length, near 1,730 cm^{-1}. The infra-red spectrum of the Fischer–Tropsch product suggests that it is a mixture of hydrocarbons and fatty acid esters which contains some terminally unsaturated or olefinic compounds (910 cm^{-1} absorption band).

Chromatographic data in Table 1 provide a measurement of the relative abundances of compounds of different types or polarities in the mixtures of compounds from the Orgueil meteorite and various terrestrial sources. Some of the values in Table 1 are average values. The numbers in parentheses, which appear beside the sample designations in Tables 1 and 2, indicate the number of samples averaged to obtain the values given. Standard deviations (σ) are shown for some of the analyses in Tables 1 and 2.

All the terrestrial sediment samples in Table 1 were fractionated prior to the beginning of the meteoritic investigations[11]. The recent marine and some ancient sediment, but none of the soil extracts, contained elemental sulphur. As shown in Table 1, the sulphur was concentrated in the carbon tetrachloride eluates of the sulphur-containing samples. Mass spectral analyses showed sulphur in only 3 of the ancient sediments, and the concentration of sulphur in the eluates of 4 recent sediment extracts were determined. Benzene extracts of the Orgueil also contained free sulphur. It was removed immediately from these extracts to eliminate the possibility of subsequent reaction between sulphur and the meteoritic carbon compounds[18]. All data in Table 1 may be placed on a sulphur-free basis by averaging the ancient sediments which did not contain sulphur and by correcting the eluates of the recent marine sediments for their determined sulphur contents. The sulphur-free data for the recent marine and ancient sediment samples are (per cent): recent marine sediments; n-heptane (n-C_7)–6·0, CCl_4–8·0, benzene (C_6H_6)–5·0, methanol (CH_3OH)–63·0: ancient sediments; n-C_7–30·5, CCl_4–10·3, C_6H_6–23·7, CH_3OH–30·2.

On the basis of sulphur content and the silica-gel chromatographic analyses, the benzene extracts of the Orgueil fragments resemble those of recent marine sediments more than of the other terrestrial samples reported in Table 1. Interestingly the terrestrial samples, with exception of the Fischer–Tropsch product, show a systematic variation in chromatographic compositions. Soils and recent sediment extracts contain lower concentrations of saturated (n-C_7 + CCl_4 eluates) and aromatic (C_6H_6 eluates) hydrocarbons than do ancient sediment extracts and crude oils. Preferential preservation of hydrocarbons in ancient sediments in general[11] and selective accumulation[19–21] of hydrocarbons in petroleum deposits may explain the gradational changes in biologically derived substances from different terrestrial sources[3,11,21]. But, of direct interest to the meteoritic investigation, these differences indicate how to differentiate between the remnants of living things that are initially deposited and those that are eventually preserved or redistributed in ancient sediments or former biospheres.

The similarity between the chromatographic analyses of the benzene extracts of recent terrestrial sediments and the Orgueil fragments affords evidence that the meteoritic fragments were not contaminated appreciably by either crude oils or other carbonaceous materials from ancient terrestrial sediments; whereas the high concentrations of benzene-extractable materials in the Orgueil

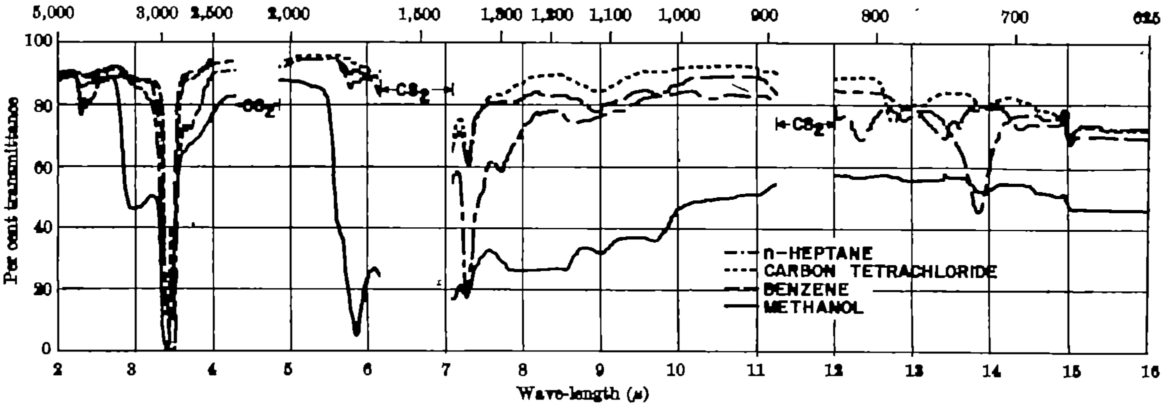

Fig. 2. Infra-red absorption spectra of the silica-gel chromatographic fractions of the benzene extracts of the Orgueil meteorite. Carbon disulphide was used as spectral solvent

chondrite make it unlikely that the meteorite could have acquired these materials from soils which contain on the average less than 1/50 of the concentration of extracts found in this meteorite[3,21].

Infra-red spectra of the silica-gel chromatographic fractions of the Orgueil extracts are presented in Fig. 2. These spectra show only carbon to carbon and carbon to hydrogen bond absorptions for the n-C_7 and CCl_4 eluates. Minor concentrations of aromatic hydrocarbons are suggested by the 795 cm^{-1} absorption band in the CCl_4 eluate spectrum, and the 720 cm^{-1} band in the n-C_7 eluate indicates the presence of n-paraffins in this fraction. These results show that the n-C_7 eluate and a major portion of the CCl_4 eluate are composed of saturated hydrocarbons. Aromatic hydrocarbons are concentrated in the C_6H_6 eluate, and the bands at 1,030, 815 and 745 cm^{-1} in the spectrum of this fraction are typical of the absorptions observed for aromatic mixtures isolated from terrestrial sediments and crude oils[3,23]. These bands have been referred to as 'oil bands' because they appear in the infra-red spectra of all aromatic fractions of petroleum[23]. The spectrum of the CH_3OH eluate in Fig. 2 has the OH or NH absorption at 3,300 cm^{-1} and the carbonyl absorption near 1,730 cm^{-1} which are observed in the infra-red spectra of most recent marine sediment extracts (Fig. 1).

Additional confirmation of the interpretations of the infra-red spectra of the Orgueil eluates is provided by the ultra-violet spectra in Fig. 3. Negligible ultra-violet absorptions by the n-C_7 eluate are indicative of a saturated hydrocarbon fraction, while the small absorptions by the CCl_4 eluate suggest that it consists mainly of saturated hydrocarbons containing minor concentrations of aromatics or conjugated olefines. Aromatic hydrocarbons from the meteoritic extracts are concentrated in the strongly absorbing C_6H_6 eluate, and the maxima in the ultra-violet and mass spectra of this eluate can be attributed to phenanthrenes, pyrenes and chrysenes[3]. Fluorenone has a spectrum resembling the CH_3OH eluate spectrum in Fig. 3.

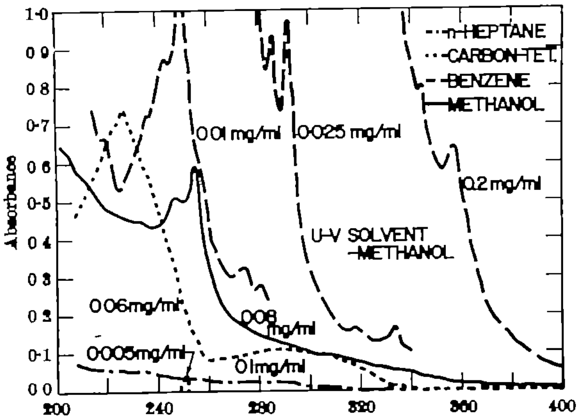

Fig. 3. Ultra-violet absorption spectra of the silica-gel chromatographic fractions of the benzene extracts of the Orgueil meteorite. Iso-octane was used as spectral solvent

Previously reported results show that some recent marine sediments[21] and soils[21,24] contain relatively simple aromatic hydrocarbon fractions. The simplicity of the aromatic mixtures in recent sediments and the structures of aromatic compounds in sediments and petroleum have been cited as evidence that aromatic hydrocarbons are derived from plant and animal steroids, isoprenoids and related compounds[10,11,21]. It has been postulated on the basis of theoretical considerations and the distributions of aromatics in sediments that these compounds are products of the catabolic activity of anaerobes[11].

Mixtures of aromatic hydrocarbons in extracts of ancient terrestrial sediments and in crude oil are much more complex than the aromatic fractions in recent sediments[11,21,25]. The complexity of the aromatic mixtures in ancient sediments has been attributed to the mixing of hydrocarbons from many different sedimental environments that occur during the redistributions of hydrocarbons which take place over geological periods of time and which lead in some instances to the formation of petroleum deposits[11,21,25]. The complexity of the aromatics in ancient sediments also may result partially from chemical alterations that over long periods of time may change the structures of some of the aromatic hydrocarbons in sediments.

As in the case of the chromatographic analyses of the terrestrial samples in Table 1, gradational changes can be observed in the compositions of the aromatic fractions from recent sediments, ancient sediments, and crude oils. These changes may be deduced from the ultra-violet spectra in Fig. 4, and the results in Fig. 4 may be interpreted as supporting the interpretation of the data in Table 1.

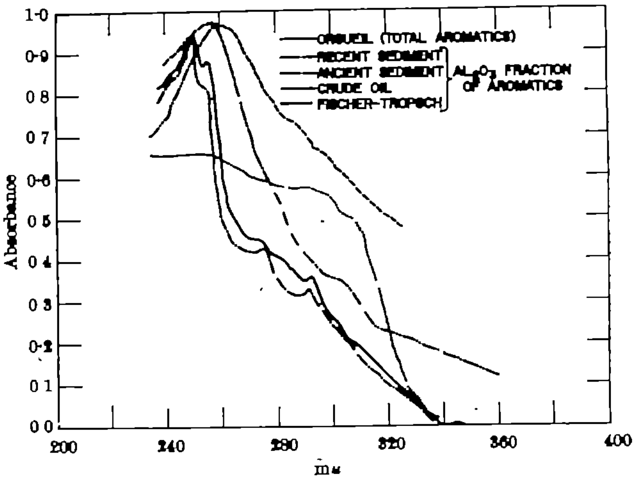

Fig. 4. Ultra-violet absorption spectra of aromatic fractions from the Orgueil meteorite and terrestrial samples. Iso-octane was used as spectral solvent

Relatively simple mixtures of aromatics give sharper absorption bands in the ultra-violet region than do complex aromatic fractions. Although none of the terrestrial samples available for this investigation contained aromatic fractions as simple as those previously reported[21,24], or as simple as the aromatics (C_6H_6 eluate from silica gel) isolated from the Orgueil meteorite, an additional fractionation of the C_6H_6 eluate of the recent marine sediment did yield a fraction as shown in Fig. 4, that had an absorption spectrum similar to the spectrum of the meteoritic aromatics.

Alumina chromatography was used to simplify the mixtures of aromatics from all the terrestrial samples. The ultra-violet spectra presented in Fig. 4 for the terrestrial samples were obtained on equivalent alumina fractions that had the same adsorption properties on alumina as do phenanthrenes, chrysenes, and pyrenes[21]. These alumina fractions were selected because the aromatic fraction of the Orgueil meteorite is composed predominantly of phenanthrenes, chrysenes and pyrenes[3]. These same aromatics are frequently the most abundant aromatics in recent terrestrial sediments[21,24].

It is noteworthy that the sharpness of the absorption bands or detail of the spectra in Fig. 4 decrease from the Orgueil or recent marine sediment fraction spectra to the ancient sediment fraction spectrum to the crude oil fraction spectrum. The ultra-violet spectrum of the Fischer–Tropsch fraction does not resemble the spectra of equivalent alumina fractions from other terrestrial samples. The simplicity of the aromatic hydrocarbons from the Orgueil effectively eliminates the possibility that these compounds were obtained by chance contamination of the meteorite by crude oil or organic matter from ancient terrestrial sediments. Extensive distillations and chromatographic fractionations of a crude oil followed by a careful recombination of selected fractions would be required to obtain a fraction from oil that has ultra-violet and mass spectra[3,26] similar to the aromatics from the Orgueil. Only rarely do recent marine sediments contain so simple a mixture of aromatics as do these Orgueil fragments, and the concentration of aromatics in these fragments are many times the average aromatic concentration in recent terrestrial sediments. Extracts of living things contain negligible concentrations of aromatic hydrocarbons. Neither terrestrial organisms nor organic substances are likely sources of a significant portion of the aromatics in these Orgueil fragments.

Alkane hydrocarbon type analyses[26] are given for the saturated hydrocarbon fractions (n-C_7 eluates) of meteoritic, sedimental, biological and Fischer–Tropsch (abiotic) samples in Table 2. These mass spectrometric analyses indicate the types of alkanes in the various fractions. All the type analyses of the saturated hydrocarbons from the Orgueil meteorite fall within the ranges of values found for biological and sedimental hydrocarbons, whereas the Fischer–Tropsch's saturates contain far higher concentrations of mono*cyclo*alkanes (or perhaps olefines) and much lower concentrations of poly*cyclo*alkanes than do any of the terrestrial samples included in the average analyses reported in Table 2.

Reactants and reaction conditions that existed throughout the evolution, development and destruction of a meteoritic parent body are not accurately known. However, extensive investigations[5–11,21,22] of the composition and origins of carbonaceous materials in terrestrial sediments indicate that living things have exerted a detectable control on the composition of these materials. Although unknown reactants under undefinable conditions may have made the carbon compounds in the Orgueil meteorite, a general dissimilarity between an abiotic (Fischer–Tropsch) product and the benzene extracts of terrestrial sediments has been demonstrated. The analyses in this article show statistically significant agreements between the benzene-extractable fractions of Orgueil fragments and some terrestrial sediments as well as between meteoritic and biological alkanes.

This investigation was suggested by Dr. Bartholomew Nagy of Fordham University, and the extractions of the Orgueil fragments were conducted by Dr. D. J. Hennessy of Fordham University. I thank Drs. Hennessy and Nagy for their helpful discussions of this work, and Drs. Brian Mason, R. F. Folinsbee, Lincoln LaPaz, and E. P. Henderson for providing the meteorite samples. Mr. T. C. Menzel, G. G. Wanless and J. J. Waters assisted in some analyses of meteoritic extracts. A 500-year-old butter sample was contributed by the late Dr. Werner Bergmann of Yale University.

MAGNETIC AND CHEMICAL INVESTIGATIONS OF IRON IN TEKTITES

By A. N. THORPE, F. E. SENFTLE and F. CUTTITTA

U.S. Geological Survey and Howard University,
Washington, D.C.

THE ferric-to-ferrous iron ratio (hereafter designated simply as the ratio) in glasses is dependent on three important factors: (*a*) the thermal history; (*b*) the oxidizing or reducing conditions of the glass melt; (*c*) the time of heating. Abou-El-Azm[1] has shown that the reduction of Fe_2O_3 added to high-silica glass increased rapidly above 1,400° C. Banerjee[2] has discussed the effects of a reducing atmosphere and the time of heating on the ferrous iron in glasses, and Bamford[3] has examined the state of the iron in some reduced glasses.

Friedman, Thorpe and Senftle[4] have compared the chemical composition with the magnetic properties of tektites and some glasses formed by the fusion of terrestrial rocks. They found that the ratios for six rocks fused at 2,500° C in a solar furnace under atmospheric conditions with one exception approached a limiting value of about 0·4. This value is somewhat higher than that of the average ratio (~ 0·13) calculated for tektites from data in the literature[5]. These calculated ratios varied considerably and ranged from 0·03 to 0·31 (ref. 4). The larger ratio (~ 0·4) for the fused rocks was attributed to fusion under normal atmospheric conditions ($P_{O_2} = 1/5$ atm.). The variation of the ratio reported for tektites may be due in part to some scattered questionable analyses in the literature. On the other hand, if these differences were real, it suggests that the partial pressure of oxygen in the melting atmosphere was substantially different for the various tektite falls, and/or that there may have been considerable differences in melting temperatures.

To solve this problem, more, and also more accurate, analyses of the ferric-to-ferrous ratio in tektites from different strewn fields is desirable. To this end, monitored, high-precision chemical analyses have been made on twenty-one bediasites. Analysis of the results shows the ratio to be constant (0·053) within narrow limits for bediasites.

* Cuttitta, F., Carron, M. K., Fletcher, J. D., and Chao, E. C. T., 1962, Chemical composition of bediasites and philippinites: *U.S. Geol. Surv. Astrogeologic Studies Semiann. Prog. Rep. to N.A.S.A.*, Feb. 26, 1961—Aug. 24, 1961. Nickel content is less than 50 p.p.m. (Cuttitta, Carron, Fletcher and Chao, 1962).

Magnetic susceptibility measurements have been made as part of an investigation of the physical properties and chemical composition of tektites. To supplement the chemical analyses, a magnetic susceptibility method was developed for the quantitative determination of total and ferrous iron. The proposed susceptibility method is less tedious and time-consuming than chemical analysis, is non-destructive, can be made on milligramme amounts of sample, and provides results comparable with those obtained by chemical analyses. Both chemical and susceptibility techniques have been used to determine ferrous and total iron in selected tektite specimens from other strewn fields. Similar to bediasites, our results show that the ratio is nearly constant (≈0·05) within narrow limits for these specimens.

Twenty-one bediasites were carefully selected from a collection of about four hundred specimens[6]. The selection was made so as to represent the range of the indices of refraction and specific gravities exhibited by the tektite collection. End members of this suite are *BM*-1, with an index of refraction of 1·4828 ± 0·0004 and specimen *B*-90 with an index of refraction of 1·5076 ± 0·0004. The specimens are listed in Table 1 in increasing order of index of refraction. The bediasites were analysed for manganese, titanium, nickel, ferrous iron and total iron as Fe_2O_3, and with the exception of nickel the results are shown in Table 1. (Nickel analyses are all less than 50 p.p.m. Individual quantitative analyses were made spectrographically by J. D. Fletcher (personal communication).) In addition, the total iron as Fe_2O_3 was determined for 15 other selected tektites (Table 3). These results are averages of duplicate determinations by the various methods, the coefficient of variation of the average being 3 per cent for ferrous iron and total iron, 5 per cent for titanium, and 10 per cent for manganese and nickel. Although spectrophotometric, volumetric, spectrographic, and X-ray fluorescence techniques were used, the average obtained by these methods will be referred to simply as the chemical determination throughout this article. Using these different techniques, the determinations were closely monitored by similar determinations in granite *G*-1, diabase *W*-1, and selected National Bureau of Standards certified samples.

In the spectrophotometric method[7,8] ferrous iron reacts with *o*-phenanthroline in the *p*H range of 2–9 to form a red complex having an absorption maximum at 512 mμ. The complex is stable and conforms to Beer's Law up to a concentration limit of 10 p.p.m. Ferric iron must be reduced to ferrous iron initially with hydroxylamine hydrochloride, hydroquinone, ascorbic acid, or *N,N'*-dimethylformamide. These analyses were made at *p*H 4·5 using acetic acid–sodium acetate as a buffer.

The X-ray fluorescence determination of total iron, titanium, and manganese required 250 mg of sample which was fused with 250 mg of La_2O_3 and 1·000 g of $Li_2B_4O_7$ in a graphite crucible at 1,000° C for 8–10 min[9]. The cooled bead was ground in a mixer-grinder to pass a 325-mesh sieve. The sample was double pelleted with a boric acid backing for additional strength. The analyses were made with a single channel fluorescent vacuum X-ray spectrometer using a lithium fluoride-analysing crystal and a krypton–halogen-filled Geiger counter. X-rays were produced with a tungsten target tube operated at 30 kV and 10 m.amp. The time required to accumulate 10,000 counts for the iron $K\alpha$ line at 57·45° 2θ, titanium $K\alpha$ line at 86·07° 2θ, and manganese $K\alpha$ line at 62·91° 2θ was measured. The X-ray results were obtained by counting each standard and sample twice at random.

The ferrous iron content of the tektites was determined by spectrophotometric and volumetric methods. In the volumetric method, the tektite sample was decomposed with hydrofluoric and sulphuric acids in the absence of air. The ferrous iron in the resulting solution was titrated with $K_2Cr_2O_7$ using sodium diphenylamine sulphonate as an internal indicator.

The spectrophotometric determination of ferrous iron[10] was made on 5–15-mg amounts of sample. Decomposition of the tektite was effected at room temperature by hydrofluoric acid containing pentavalent vanadium to oxidize ferrous iron as it dissolves. The spectrophotometric method utilizes the reversibility of the reaction:

$$V^{5+} + Fe^{2+} \rightleftarrows V^{4+} + Fe^{3+}$$

The direction of this reaction is dependent on *p*H. In strongly acid solution, the reaction proceeds quantitatively from left to right. When the *p*H is increased to greater than 2, ferric iron is quantitatively reduced to the divalent state by quadrivalent vanadium. The re-formed ferrous iron is determined by using *o*-phenanthroline as the chromogenic agent[7,8].

Manganese and titanium were also determined spectrophotometrically. Disodium-1,2-dihydroxy-benzene-3,5-disulphonate (tiron) yields a strong yellow colour with titanium (IV) in the *p*H range 4·3–9·6 (ref. 11). The interference of iron was overcome by reduction with ascorbic acid at *p*H 4·7, and the absorbance of the resulting solution was measured at 410 mμ. The purple permanganate colour was utilized for the determination of manganese. The oxidation was effected with ammonium persulphate (peroxydisulphate) at the boiling point in a phosphoric–nitric acid medium in the presence of silver nitrate. The absorbance of the solution was measured at 525 mμ.

Nickel and manganese were determined by a quantitative spectrographic method similar to that described by Bastron, Barnett and Murata[12].

The total iron plotted against the ferrous iron in Fig. 1 shows a good linear relationship which passes through the origin. Thus:

$$C_{Fe^{t}} = kC_{Fe^{++}} = C_{Fe^{++}} + C_{Fe^{+++}} \qquad (1)$$

where k is the slope of the line, and C is the concentration of the iron. If $C_{Fe^{+++}}/C_{Fe^{++}} = R$, then from equation (1) the ratio $R = k - 1$. From a least-squares analysis of the data, k was determined, and $R = 0{\cdot}053$. As shown in Table 1, the ratio ranges from 0·01 to 0·08 and has a median value of $R = 0{\cdot}051$. This is in good agreement with the value, $R = 0{\cdot}053$, calculated from the data of Fig. 1. It is thus evident that the ferric-to-ferrous ratio in bediasites is constant within relatively narrow limits.

The magnetic susceptibility measurements were made on a quartz helical spring balance developed by Senftle *et al.*[13], and the procedure followed has been described in a previous paper[14]. Care was taken to clean the specimens in hydrochloric acid and to measure the susceptibility at several field strengths to ensure against possible con-

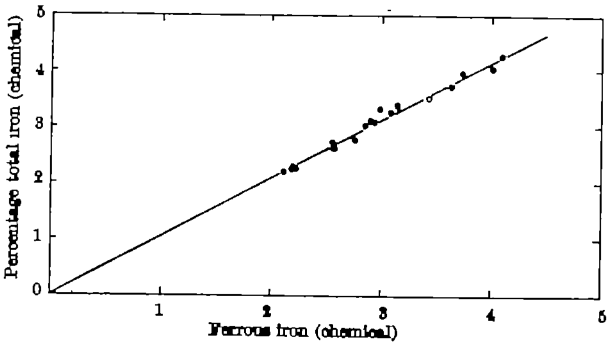

Fig 1 Variation of ferrous iron with total iron in bediasites as determined chemically

tamination with ferromagnetic impurity. All measurements were made at room temperature (29° C).

Tektites exhibit mild paramagnetic but no significant ferromagnetic properties[14]. From the elemental composition of tektites, it is apparent that, to a first approximation, the paramagnetism is a function of the iron content. Nickel, manganese and titanium concentrations are low, and their combined contribution to the paramagnetism is probably less than 2 per cent. Thus, the magnetic susceptibility of a tektite, at a given temperature, can be described as:

$$\chi_T = \chi_{Fe^{++}}C_{Fe^{++}} + \chi_{Fe^{+++}}C_{Fe^{+++}} + [1 - (C_{Fe^{++}} + C_{Fe^{+++}})]\chi_g \quad (2)$$

where $\chi_{Fe^{++}}$ and $\chi_{Fe^{+++}}$ are the specific atomic susceptibilities of ferrous and ferric iron calculated from equation (10) here, $C_{Fe^{++}}$ and $C_{Fe^{+++}}$ are the concentrations of ferrous and ferric iron, and χ_g is the residual magnetic susceptibility of the base glass, including the small amounts of manganese, titanium and nickel. Owing to the almost uniform composition of tektites, χ_g can be considered to be constant for all practical purposes.

The magnetic susceptibilities and a comparison of the magnetically and chemically determined total iron and ferrous iron of the bediasites are shown in Table 2. The susceptibilities are also plotted against the total iron determined chemically in Fig. 2. The relation is remarkably linear, and a least-squares analysis of the data leads to the equation:

$$\chi_T = 193{\cdot}6 \times 10^{-6}\, C_{Fe^{t}} - 0{\cdot}3607 \times 10^{-6} \quad (3)$$

Although the actual points are not shown, to avoid confusion, the curve of susceptibility as a function of the ferrous iron also is a good linear relation and is represented by the broken line slightly above the solid total iron line in Fig. 2. A least-squares treatment of the data yields the following equation:

$$\chi_T = 204{\cdot}5 \times 10^{-6}\, C_{Fe^{++}} - 0{\cdot}414 \times 10^{-6} \quad (4)$$

Actually the susceptibility of the tektite glass without the iron (*y*-intercept) should be identical in both equations, but due to the scatter of the experimental points they are slightly different. However, assuming both are the same, it can be shown algebraically that the ferric-to-ferrous ratio, *R*, is a constant and equal to:

$$R = b - a/a \quad (5)$$

where a is the coefficient of $C_{Fe^{t}}$ ($193{\cdot}6 \times 10^{-6}$) and b is the coefficient of $C_{Fe^{++}}$ ($204{\cdot}5 \times 10^{-6}$) in the foregoing equations. Substituting with numerical values, one obtains an approximate value for the ratio, $R = 0{\cdot}056$. Again, this is in close agreement with the least squares chemically determined ratio (0·053).

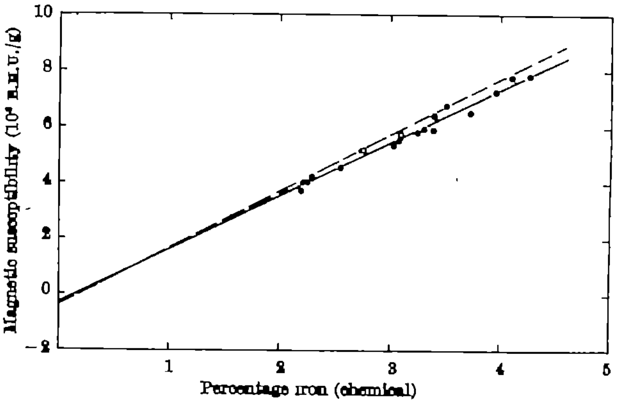

Fig. 2. Variation of the magnetic susceptibility with total iron content in bediasites (solid line). Dashed line is the susceptibility as a function of ferrous iron (to avoid confusion, actual points are not shown) $\chi_T = 193{\cdot}6\, C_{Fe^{t}} - 0{\cdot}3607$

The magnetic susceptibility measurements are good to better than 2 per cent, and hence, assuming no large effects due to other transition elements, the total iron as given by the magnetic measurements and equation (3) should be accurate to slightly more than 1 per cent. The susceptibility measurements are made relatively easy and fast, and thus this technique for total iron analysis proved very convenient for bediasite investigations. As the ratio is nearly constant, it also provided a practical method to obtain the ferrous iron content. Likewise, the ferric iron could be obtained, but due to its relatively low concentration it was not nearly as accurate. (The ferrous and ferric iron contents can be calculated from the expressions:

$$C_{Fe^{++}} = 0{\cdot}489\, \chi_T + 0{\cdot}219 \quad (6)$$

$$C_{Fe^{+++}} = 0{\cdot}0285\, \chi_T - 0{\cdot}031 \quad (7)$$

where C_{Fe} is in percentage and χ_T is the magnetic susceptibility in 10^{-6} E.M.U./g.)

Having established the ferric-to-ferrous iron ratio for bediasites as approximately constant, one now asks whether or not the same ratio holds for tektites from other strewn fields. Ultimately, chemical analyses of total ferrous and ferric iron made on a reasonable sampling from each strewn field would be desirable to answer this question. In place of detailed chemical analyses, however, the magnetic susceptibility technique offers a method of determining this information with only a total iron chemical analysis being required.

If for convenience one expresses equation (1) in terms of the concentration of total iron, $C_{Fe^{t}} = C_{Fe^{++}} + C_{Fe^{+++}}$, then:

$$\chi_T = \left(\frac{\chi_{Fe^{++}} + R\chi_{Fe^{+++}}}{1 + R}\right) C_{Fe^{t}} + (1 - C_{Fe^{t}})\chi_g \quad (8)$$

As $(1 - C_{Fe^{t}})$ is approximately one, and as χ_g is small, one can approximate the last term in the equation by a constant without incurring a large error. Thus:

$$\chi_T = \left(\frac{\chi_{Fe^{++}} + R\chi_{Fe^{+++}}}{1 + R}\right) C_{Fe'} + G \qquad (9)$$

where $G = (1 - C_{Fe'})\chi_g$. This is the analytical expression for the experimentally determined relation, equation (3). In so far as the composition of all tektites is quite uniform, it is reasonable to assume that G will be essentially single valued for all tektites. Thus, if equation (3) can be shown to hold for tektites from other strewn fields one may conclude that the ferric-to-ferrous iron ratio is approximately the same for these tektites.

A comparison is made in Table 3 of the total iron determined from equation (3) with those determined chemically for tektites from several strewn fields. The comparison is very good indicating that within narrow limits the median $C_{Fe^{+++}}/C_{Fe^{++}}$ ratio is nearly the same for all the tektites studied, and essentially the same as that for bediasites, namely, about 0·053. Before a definite conclusion can be made, however, a detailed analysis similar to that made on bediasite should be made on tektites from other strewn fields.

Our results indicate that the ferric-to-ferrous iron ratio for all tektites is relatively constant (approximately 0·05) and low. These results do not concur with ratios calculated from data reported in the literature[4,5,14], which show a considerable variation within a strewn field and also between different tektite families. For example, both the average analyses given for australites by Barnes[4] and the more recent analyses reported by Taylor[14] indicate an average ratio of about 0·12. Taylor mentions that some of his samples were crushed in a steel mortar and mechanically ground in an agate mortar before chemical analysis. It is conceivable that such a preparation in air may have oxidized a significant amount of iron to the ferric state.

As indicated in the introduction, tektites show a relatively uniform composition and history of formation. Unlike other natural glasses (volcanic glasses and fulgarites) and synthetic glasses, the tektites from different strewn fields have one interesting chemical characteristic, namely, a low ferric-to-ferrous iron ratio indicating a relatively uniform thermal history under reducing conditions.

Synthetic glasses of tektite composition prepared under reducing conditions and high temperature should exhibit similar characteristics. It should be possible to calculate their total and ferrous iron content from a magnetic susceptibility measurement and equations (3) and (6). In contrast, synthetic glass melts prepared under normal atmospheric conditions should undergo a slight oxidation of the iron to Fe_3O_4, and hence the calculated total and ferrous iron will be high compared with the chemical values.

Magnetic and chemical analyses on several synthetic glasses of tektite composition prepared in a normal atmosphere of air are shown in Table 4. The total and ferrous iron as calculated from the magnetic susceptibility data is high as compared with the chemical values in almost every case. In two cases, so much Fe_3O_4 was formed that the samples were ferromagnetic and could not be measured.

* Specimens ferromagnetic. Reliable measurements could not be made

These data indirectly support the concept that tektites, unlike other natural glasses, have experienced a thermal history under reducing conditions. Further, the method of calculating total and ferrous iron is valid only for tektites, and not generally applicable to other glasses. The foregoing results lead to some interesting aspects of the magnetic properties of iron in tektites. The paramagnetism of the iron arises from the electrons circulating in orbit around the nucleus. The total magnetic moment of such an electron may be divided into two parts: that due to the spin of the electron, and that due to its orbital motion. While the presence of electrons in neighbouring atoms does not generally affect the spin, the electric fields of nearby electrons can significantly alter the orbit of an electron. In fact, the ligand fields are often strong enough completely to immobilize the orientation of an electron orbit against the effect of an outside magnetic field. The orbital magnetic moment is then said to be quenched, and the resulting orbital magnetic moment is small or zero. For the case of a free ion removed from all external fields, the magnetic susceptibility in electromagnetic units per gramme due to both spin and orbital moments is given by:

$$\chi = \frac{N\beta^2\mu^2}{3kTM} = \frac{N\beta^2}{3kTM}\,[4S(S+1) + L(L+1)] \quad (10)$$

where N is Avagadro's number, β is the unit Bohr magneton, k is Boltzmann's constant, T is the absolute temperature, and M is the atomic weight. μ is the total magnetic moment for the transition elements and is equal to $\sqrt{4S(S+1) + L(L+1)}$, where S and L are the spin and orbital quantum numbers, respectively. In the case of a ligand field which is sufficiently strong to quench the orbital moment, $L = 0$, and the 'spin only' magnetic moment is responsible for the magnetic susceptibility.

Theoretically, $\chi_{Fe^{++}}$ and $\chi_{Fe^{+++}}$, the specific susceptibilities of ferrous and ferric iron, can be determined from equation (10) by inserting the proper spin and orbital quantum number. These can be obtained from consideration of the atomic energy-levels. For ferric iron $S = 5/2$ and $L = 0$, and $\chi_{Fe^{+++}}$ is simply $259{\cdot}4 \times 10^{-6}$ E.M.U./g at 29° C. For ferrous iron, however, the calculation is not so simple. The quantum numbers are $S = 2$ and $L = 2$, and hence $\chi_{Fe^{++}}$ should equal $222{\cdot}4 \times 10^{-6}$ E.M.U./g at 29° C for the free ion. From the rather extensive work on the magnetic properties of synthetic glasses, ferrous iron in glass had indeed been shown[6,7] to have a susceptibility of about 218×10^{-6} E.M.U./g at 29° C, corresponding to an orbital magnetic moment which is only very slightly quenched. However, the normal ferrous iron imparts a blue coloration to the glass. A blue coloration is not evident in tektites which range from a light sea-green to a brownish black in colour. Moreover, previous work[14] on the magnetic properties of tektites has shown that the orbital moment of ferrous iron is almost completely quenched. Thus, one cannot accept this value (218×10^{-6} E.M.U./g at 29° C) for the specific magnetic susceptibility of ferrous iron in tektites.

The fact that the $C_{Fe^{+++}}/C_{Fe^{++}}$ ratio is relatively constant for tektites will allow one to make an approximate calculation of the specific susceptibility of the ferrous iron. By equating the bracketed coefficient in equation (9) with the experimental slope (equation 3) and using the chemical values of the ratio, $R = 0{\cdot}053$, and $\chi_{Fe^{+++}} = 259{\cdot}4 \times 10^{-6}$ E.M.U./g, $\chi_{Fe^{++}}$ is calculated to be $190{\cdot}2 \times 10^{-6}$ E.M.U./g. This corresponds to an almost completely quenched orbital magnetic moment. While this is only an approximation consistent with this value of R, it is sufficiently accurate to show that the moment is almost completely quenched. The significance of this relative to the structure of the tektite glass will be discussed in another paper.

A magnetic susceptibility technique has been devised to give a non-destructive, micro-analysis of the total and ferrous iron content of tektites. The measurements are much easier and faster to make providing an accuracy comparable with monitored, high-precision chemical methods.

The ferric-to-ferrous ratio has been found to be constant within relatively narrow limits for bediasites. The results also suggest that the median ratio is approximately the same for all tektite families, indicating a reasonably uniform thermal history of formation and melting atmosphere. The low ratio (≈ 0·05) implies an atmosphere with a very low partial pressure of oxygen. The constancy of the ratio in comparison with the wider range of ratios reported in the literature indicates that some of the reported ferric and ferrous analyses may be in error by a small but significant amount. The specific magnetic susceptibility of ferrous iron in tektites as calculated from the foregoing ratio shows that the orbital magnetic moment is almost completely quenched.

We thank Dr. E. Chao of the U.S. Geological Survey and E. Henderson of the U.S. National Museum for many of the tektite specimens. We also thank Sherman White. H. Rose and M. K. Carron of the U.S. Geological Survey for their assistance with the measurements and chemical analyses, Dr. Dean Chapman, National Aeronautics and Space Administration, and Dr. T. P. Kohman, Carnegie Institution of Technology, for generously providing specimens for our work, and Dr. H. R. Branson of Howard University and Dr. S. S. Goldich of the U.S. Geological Survey for their interest in this work.

MODEL EXPERIMENTS FOR VORTEX COLUMNS IN THE ATMOSPHERE

By DR. B. R. MORTON

Mathematics Department, University of Manchester

ORGANIZED columns of vorticity are observed in many parts of the Earth's atmosphere, in such forms as dust whirls and dust devils, tornadoes, waterspouts, fire storms and hurricanes. These columnar flows cover a very wide range of horizontal length and velocity scales, say, 10 m–2000 km in length and 10–50 m.p.s. or more in velocity, and they exhibit a wide range of behaviour. However, each may be regarded as a rotating column within which the mean angular velocity (or vorticity) of the fluid is several orders of magnitude greater than ambient. In each case thermal convection plays a fundamental part in the flow development.

It seems to be accepted generally that convergence into convection columns or thermals may produce amplification of existing ambient rotation about the vertical, and that this provides a mechanism for the generation of dust devils in a locally unstable environment. But in spite of the obvious interest and meteorological importance of the growth of rotating columns in the atmosphere, there have been relatively few attempts to investigate the amplification of ambient vorticity through the action of turbulent thermal convection. Recently, Dessens[1] has reported the formation of 'tornadoes' near the base of a large experimental convection column in the atmosphere; and Byram and Martin[2] have reported 'fire whirl' experiments in which a pan of alcohol is burned at the bottom of a vertical cylinder into which air is drawn tangentially. These are both interesting experiments, but they involve a variety of effects and have neither the degree of simplicity nor of experimental control which is needed for a basic study of the convective amplification of vorticity. As a stage in such an investigation, I have been carrying out model experiments on the behaviour of turbulent buoyant jets of alcohol and salt solution in a uniformly rotating tank of water. (The plume from a simple source of buoyancy represents a limiting case of this wider range of source conditions.)

The experiments are carried out in a 'Perspex' tank 75 cm in diameter and 150 cm deep, which can be part filled with water and set rotating about a vertical axis at steady speeds between 0·3 and 4·5 radians per sec. After the water has reached a state of sensibly uniform rotation, a stream of dyed liquid is injected as a vertical jet along the axis, either from a nozzle at the centre of the base or from one just below the centre of the free surface. An upward jet of alcohol/water or a downward jet of salt solution may be termed positively buoyant, a water jet neutral, and an upward jet of salt or downward jet of alcohol negatively buoyant. The inflow is maintained for long enough to generate a jet rather than a 'cloud' of buoyant fluid, and then turned off to avoid significant effects due to the walls and free surface. The development of the rotating plume can be recorded photographically by still or ciné cameras directed: (1) horizontally, from a fixed station, or (2) vertically downward, from a station rotating with the tank. The horizontal records illustrate the development of the rotating column, while vertical streak-photographs of the aluminium-powdered free surface may be used for obtaining angular velocities in the columns.

In terms of jet diameter and mean vertical velocity at the nozzle, the operating range of Reynolds numbers for the issuing jet in the first set of experiments was about 5×10^3–5×10^4; while the range of Rossby numbers based on

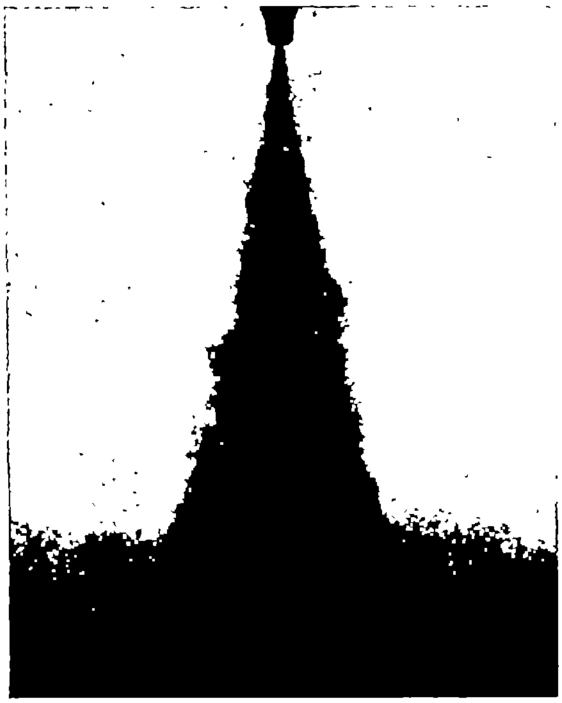

Fig. 1 A positively buoyant downward jet of salt solution in a stationary tank

diameter and mean inflow velocity at the nozzle was $2 \times 10^2 - 2 \times 10^3$, or if based on averaged values over the height of the jet was about two orders of magnitude smaller.

A feature of the experimental arrangement is the fact that small disturbances to the velocity of a rotating fluid propagate in a two-dimensional fashion. This has only a moderate effect on the vigorous initial motion of the jet, but constrains the subsequent pattern of flow quite strongly into a column: hence the flow observed at the free surface relatively quickly adopts a profile appropriate to an average over the greater part of the water depth. This effect may be observed in Fig. 2.

The experimental observations fall into three groups according to whether the jets are positively buoyant, neutral or negatively buoyant. There are only minor differences between the upward and downward jets of specified buoyancy, and these arise from the character of the bounding surface near the nozzle.

When a positively buoyant downward jet of dyed salt solution is released in a rotating tank the outer layers of the jet are swept into vigorous rotation at an angular velocity greater than that of the tank and ambient water. This vorticity diffuses rapidly through the jet to produce a rotating column with typical angular velocity about 2–10 times that of the tank (the precise level depending on the source conditions of the buoyant jet). The rotating column usually remains centred on the nozzle so long as the inflow continues, though it often shows signs of sub-division; but when the jet is stopped the column wanders slowly about the tank and usually subdivides into two or three columns of comparable strength, and occasionally more. These vortex columns persist for a long time.

Fig. 1 shows a downward jet of salt solution in a stationary tank, and is included for purposes of comparison. The development of a rotating plume is illustrated in Fig. 2*a*, *b* and *c*. In this case the angular velocity of the tank was 1·23 radians/sec; the density of the salt solution was 1·18 g/ml.; the jet ran for 15·2 sec; and the photograph reproduced in Fig. 2*a* was taken at 5·2 sec relative to the time of starting the jet, Fig. 2*b* at 20·8 sec, and Fig. 2*c* at 40·2 sec. The vertical scale marks which can be seen are 10 cm apart. The developing jet is much less clearly straight-sided and at first shows a large intermittent variation in width; but shortly after the nozzle flow has ceased (Fig. 2*b*) the decaying jet is roughly straight-sided and occupies a much larger volume than it would in a stationary environment (Fig. 1); the weaker outside disturbances are already taking up a two-dimensional form (Fig. 2*b*). Later (Fig. 2*c*) the jet has separated into two rotating columns with almost vertical edges. Fig. 3 shows a streak photograph of the free surface dusted with aluminium powder taken with a camera fixed relative to the rotating tank. This is a composite shot showing two major vortex columns and one additional weak one which have been generated from an earlier jet emission, together with a vigorous starting column about a second jet emission from the nozzle.

A neutral jet in a rotating tank produces no change in the state of uniform rotation of the ambient fluid (apart from some initial disturbance which soon decays).

A negatively buoyant downward jet of alcohol in a rotating tank of water generates a number of rotating columns (which are now, of course, clustered towards the free surface) in which the angular velocity is smaller than that of the surrounding water.

These effects can be explained quite simply in terms of the distortion of mean vortex tubes by the buoyant jet. When a vortex tube is stretched the associated angular

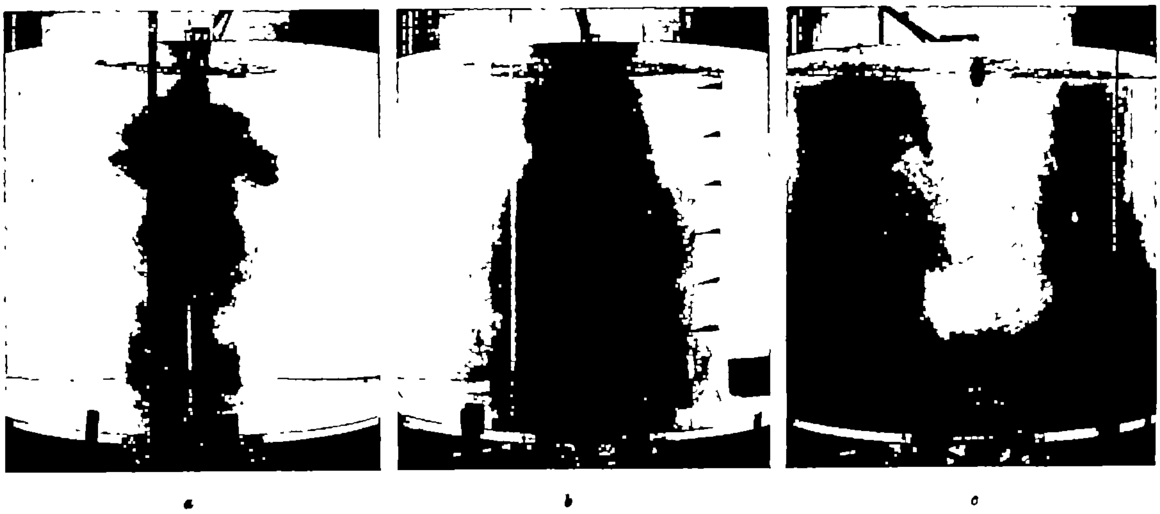

Fig. 2 Development of a positively buoyant downward jet of salt solution in a rotating tank

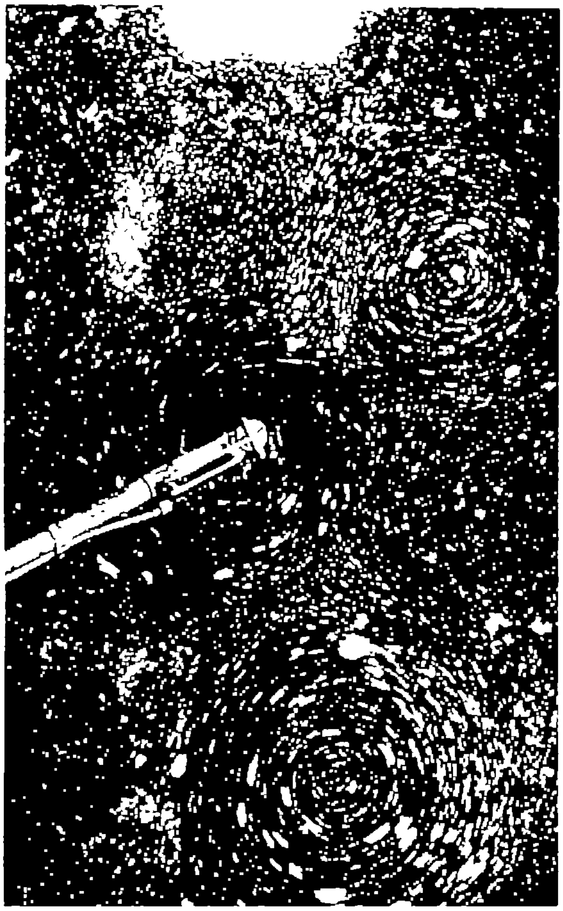

Fig. 3. A surface streak photograph showing the flow relative to the rotating tank. In this case there are two free vortex columns from an earlier discharge of the jet, and a third column anchored around a continuing inflow from the nozzle

velocity increases in proportion to the relative extension; when it is shortened there is a corresponding reduction in angular velocity. All jets entrain ambient fluid and share with it their linear momentum, so that the mean axial velocity in a buoyant jet always decreases with increasing distance from the source (except in short, buoyancy-dominated regions of very buoyant jets). It follows that in the interior of a jet (buoyant or otherwise) there will always be a continuous shortening of mean vortex tubes parallel to the axis. On the other hand, the entrained fluid enters the jet in a slow radially inward stream that will convect ambient vortex tubes into the jet; sections of vortex tube crossing the inclined outer parts of the jet are at first stretched as they are drawn into the faster parts of the flow. Thus, if we were to ignore turbulent diffusion, there would be a net stretching of mean vortex tubes in the outer parts of the buoyant jet, and a net shortening in the interior. Turbulent diffusion rapidly averages these regions of increased and decreased angular velocity, and in a neutral jet the two cancel and there is no modification of the ambient vorticity. But in a positively buoyant jet there is a slower decrease of mean axial velocity with increasing distance from the source, and consequently a net stretching of mean vortex tubes over the jet as a whole, so that the angular velocity in the jet is increased above ambient, while in a negatively buoyant jet there is an overall shortening of mean vortex tubes with a corresponding decrease in angular velocity across the jet as a whole.

This phenomenon is in fact a familiar one and can be demonstrated easily. If a cup of hot black coffee (or tea) is stirred with a rotary motion so as to leave the coffee (or tea) swirling smoothly, and a stream of cold milk is poured into the centre of the cup a small vortex will be formed, and this vortex will often be strong enough to dimple the surface noticeably. Hot milk will not produce such a vortex. In fairness to the experimenter it should be noted that it is relatively easy to mask the effect, and some practice may be needed.

The material of this article was reported at the Boulder Conference on Fluid Mechanics in Geophysics (September 1962) sponsored by the American Physical Society and the American Meteorological Society, and a theoretical analysis and detailed quantitative results will be published elsewhere in due course. I thank the Meteorological Research Council for a grant towards the cost of this work.

RUTHERFORD AND NUCLEAR POWER

By DAVID A. KEYS

Scientific Adviser to the President, Atomic Energy of Canada, Ltd., Chalk River, Ontario

THE completion of the first six-week trial run of the first Canadian Nuclear Power Generating Station at Rolphton, Ontario, brings to mind the predictions made by the late Lord Rutherford and his colleague Frederick Soddy in the early days of this century. During Rutherford's Macdonald professorship in McGill University, Montreal (1898–1907), many of the fundamental researches were performed on which the ultimate release of energy from the atom was attained. In his *Radioactivity*, written in 1902, he realized the atom as a source of large amounts of energy as the following quotations indicate[1]: (The significant predictions made by Rutherford are indicated by italics in this article.)

"*There is thus reason to believe that there is an enormous store of latent energy resident in the atoms of the radio-elements.* This store of energy could not have been recognized if the atoms had not been undergoing a slow process of disintegration. *The energy emitted in radio-active changes is derived from the internal energy of the atoms.*

"The existence of this store of latent energy does not ordinarily manifest itself, since the atoms cannot be broken up into simpler forms by the physical or chemical agencies at our disposal. Its existence at once explains the failure of chemistry to transform the atoms and also accounts for the rate of change of the radioactive processes being independent of all external agencies. . . . *If it should ever be found possible to control at will the rate of disintegration of the radio-elements, an enormous amount of energy could be obtained from a small quantity of matter.*"

The means of controlling at will the rate of disintegration has been found, and so the Nuclear Power Generating Station was able to deliver on its first trial an average power of 14,000 kW of electricity to the Ontario Hydro-Electric Power Commission's system.

It is of further interest to note the following account which appeared in the London *Daily Mail*[2], which may have been the result of some interview the reporter had with Rutherford at the Cavendish Laboratory. The account was headed in bold print:

"THE MIGHTY ATOM"

"Scientific struggle to harness it"

"Leading men of science in Britain, the United States and even Russia are to-day all corresponding over the question of minute advances in their several laboratories on the structure and behaviour of the atom. They believe that they are on the edge of discoveries that may largely, in the sequel, end the struggle for life—at least so far as light and power are concerned.

"The finest instrument in the world is probably that in a Cambridge laboratory and it is opening up new secrets, and Professor Sir Ernest Rutherford, who has some remarkable fellow-workers, such as Mr. Aston, is accepted as one of the world's high priests of the new alchemy. He and others have as good as proved *that each atom, though it is quite incommensurable, has in it the power of a thousand horses. If we can harness this power almost all our material difficulties are at an end.*

"This is still a dream, still a sort of laboratory theory; but little side discoveries—such as that supposed elements (chlorine, for example) are not really elements—are being made continually; and in the course of this co-operation of the world's best brains, all intensely eager in the same hunt, we may expect discoveries greater than the discovery of radium and of more general application.

"*Infinite material power is at our finger-tips, waiting release by finer and finer instruments. Nothing is more likely to benefit humanity than help to the making of such machines.* The best are costly, and this form of science is ill-endowed."

The morning this appeared, the late Dr. G. F. C. Searle directed my attention to the article, making a few characteristic caustic remarks about "the thousand horses".

Soddy in his book[3] spoke of explosive power which the sudden release of energy from radium would produce in the following words:

"In only two days radium gives out more energy, weight for weight, than the most powerful explosive known liberates during its explosion. If the energy liberated in a thousand years could be released instantaneously, a single milligramme of radium would equal in its effect a ton of any known explosive."

Soddy also realized the energy available in the atom as the following statement shows:

"These considerations force us to the conclusion that there is associated with the internal structure of the atom an enormous store of energy which, in the majority of cases, remains latent and unknowable."

Rutherford was responsible for the idea of the possibility of energy being derived from the atom due perhaps to statements made in such popular addresses as that delivered when he was at McGill University. In his address to the Royal Institution[4] in 1904, he stated:

"A few pounds (of radium emanation) would suffice to provide enough power to drive a liner across the Atlantic."

I remember, more than half a century ago, the late Prof. (later Sir John) MacLennan holding up a glass of water and stating that there was enough energy in the atoms of this water to run the *Lusitania* across the Atlantic.

The fulfilment of these early predictions by the new nuclear power reactor in Canada, the country where some of them were first recorded, is of interest to those who knew Rutherford when he performed his experiments which inspired the search for nuclear energy "to benefit humanity".

ASSIMILATION OF MINERALS BY HIGHER PLANTS*

By Dr. GEORGE J. FRITZ

Department of Botany, University of Florida, Gainesville

At the present time there are sixteen elements which are known to be required for the growth and development of higher green plants: carbon, hydrogen, oxygen, potassium, calcium, magnesium, nitrogen, phosphorus, sulphur, boron, chlorine, copper, iron, manganese, molybdenum and zinc. The first nine are required in relatively large amounts and are called macroelements; the last seven are required in much smaller amounts and are known as microelements. The elements cobalt, sodium and vanadium are essential to certain micro-organisms, but their essentiality for higher green plants has not been definitely established yet; but if these three elements are shown in the future to be essential to higher plants, then it can be predicted that their requirements will be only in ultramicro amounts.

The essential elements are supplied as inorganic plant nutrients by the three media of the external environment: atmosphere, water and soil. Thus, the bulk of the carbon and oxygen in the tissues of higher green plants is derived from the carbon dioxide of the atmosphere, and probably all the hydrogen comes from water: in the photosynthetic process, carbon dioxide of the atmosphere is reduced in the leaves by the hydrogen from water to the level of carbohydrates; in this process, the oxygen of water escapes from the plant as oxygen gas, which is a by-product of photosynthesis. Water also is probably utilized in some metabolic processes other than photosynthesis, and these activities might account for the incorporation of small amounts of hydrogen and oxygen into organic matter. Another possible source of small amounts of carbon, oxygen and hydrogen in plant tissue is bicarbonate ion in the soil, which is known to be absorbed and incorporated into cellular constituents such as malic and aspartic acids by plant roots[14]; whether this process contributes a significant part of the total carbon, oxygen and hydrogen in plant organic matter, and if so under what conditions, is still not completely clarified. In summary, these three elements, carbon, hydrogen and oxygen, supplied primarily by the atmosphere and water, are the principal constituents of organic matter; in fact they contribute 90 per cent or more of the total dry weight of the average plant. Since all the other essential elements are supplied to higher plants primarily by the soil (except in those cases in which nitrogen is supplied as a gas), they may properly be called mineral elements.

If the oxygen in organic matter is derived from carbon dioxide, then what part does gaseous oxygen play? Higher green plants carry on aerobic respiration; in this process, gaseous oxygen acts as an electron and hydrogen acceptor and is thereby reduced to water, which mixes with the water already present in plant tissues. Therefore the oxygen gas consumed in respiration does not become organic matter directly, but may become organic matter indirectly if it is incorporated via some metabolic step which utilizes water. Another process is now known which consumes small amounts of gaseous oxygen; plant tissues perform a process[7,11] which may be called 'oxygen fixation', in which a small portion of the oxygen gas which is applied to tissues is added directly to organic substrates. The products of 'oxygen fixation' have not been studied intensively, but probably include organic peroxides.

---

* Substance of a lecture given before the Soil and Crop Science Society of Florida during the twenty-second annual meeting, at Winter Park, Florida, on November 13, 1962.

In a consideration of the transformation of inorganic nutrients of the external environment to cellular constituents of plants, it is difficult completely to divorce the subject from the functions which elements perform, and it is useful to review the general roles in which elements may participate in cellular metabolic processes. Metabolism is a general term which refers to the chemical reactions which occur in a living cell. Except for the metabolism of nitrogen and phosphorus, relatively little is known about the chemical transformations which mineral elements undergo after they are incorporated into the living material of the cell. Assimilation is a term which refers to the chemical events associated with the transformations accompanying the incorporation of inorganic nutrients into organic matter; it is this part of metabolism, especially with respect to mineral nutrients, which is considered here.

The sequence of events by which inorganic mineral nutrients may be assimilated differs from element to element, and in fact some mineral nutrients which have been absorbed by a plant may not be converted to organic matter at all. For example, nitrate ion might be stored in the vacuole as such without undergoing chemical change, or nitrate might be converted first to ammonia and then incorporated into amino-acids or proteins. An element like potassium may be bound by weak electrostatic forces to organic anions produced by cellular metabolism, and thus potassium may serve to maintain cellular electroneutrality. In other cases a nutrient such as iron might exist in an organic form in the external environment even before it is presented to the plant, and might even be absorbed in an organic form by the roots. But in spite of these variations in behaviour of mineral nutrients, the major roles which elements have within a plant may be summarized in a few categories.

An element may be essential to plant growth and development for one or more of the following reasons: (1) it may be a component of a vital protoplasmic constituent; (2) it may participate in a vital biochemical or biophysical event; (3) it may exert a significant effect on an enzyme reaction; (4) it may contribute to the maintenance of protoplasmic organization and integrity; (5) it may function as a free ion. In view of the complexity of higher green plants, it is not surprising to find that some elements function in more than one of these categories; thus magnesium, for example, probably plays a part in all five categories: (1) magnesium is a component of chlorophyll, a vital protoplasmic constituent; (2) magnesium participates in a vital biophysical event, that is, the absorption of light quanta by the chlorophyll molecule; (3) magnesium is well known as an activator of many enzymes which are completely inactive *in vitro* in the absence of magnesium ion; (4) magnesium is known to stabilize water-in-oil emulsions as do other divalent ions and thus probably contributes to the maintenance of protoplasmic organization; (5) magnesium may act as a free ion, for example, by balancing anions, and may serve to maintain cellular electroneutrality.

Assimilation of Nitrogen, Phosphorus and Sulphur

Nitrogen, phosphorus and sulphur are considered together because they are usually supplied as anions. Nitrogen is quantitatively the most important of these: 99 per cent of the living parts of living organisms are made of the four elements carbon, hydrogen, oxygen and nitrogen. Nitrogen is usually supplied to the plant as nitrate ion, although plants can also utilize other sources of nitrogen, such as ammonia; gaseous nitrogen may also be assimilated in some cases in which the higher green plant lives in symbiotic relation with specific micro-organisms. Whether nitrate or nitrogen is utilized, each of these is probably first reduced by the plant to ammonium ion before being incorporated into organic matter. The sequence of events in the reduction of nitrogen from the +5 oxidation state in nitrate ion to the −3 oxidation state in ammonia has been the subject of considerable research in recent years, and has been reviewed periodically[8,14]. While some of the details of the reduction process have not been completely elucidated, nevertheless the outlines are reasonably well known. The following scheme[14] presents probable steps in the reduction, nitrate being reduced successively to nitrite, nitric oxide, hyponitrite, hydroxylamine and ammonium ion:

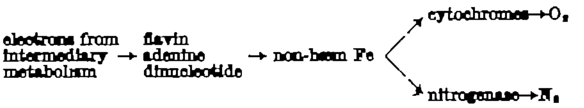
$$\mathrm{NO_3^-} \xrightarrow{(\mathrm{Mo})} \mathrm{NO_2^-} \xrightarrow{(\mathrm{Fe,\ Cu})} \mathrm{NO} \xrightarrow{(?)} \mathrm{N_2O_2^{=}} \xrightarrow{(\mathrm{Fe,\ Cu})} \mathrm{NH_2OH} \xrightarrow{(\mathrm{Mn})} \mathrm{NH_4^+}$$

Some of the indicated molecular species may have only a transient existence during the reduction process. Each step in the sequence requires the participation of a different enzyme system; for example, the reduction of nitrate to nitrite requires a molybdo-flavoprotein enzyme; the reducing power which is required for the reduction is supplied by coenzymes derived from other metabolic processes. The subsequent steps in the sequence also require other enzymes and associated metals as well as reduced coenzymes, and the known micronutrient requirements for each enzyme system are also indicated in the scheme. The indispensability of these particular micronutrients for nitrate reduction is apparent.

Our understanding of the incorporation of nitrogen gas into organic matter by higher green plants which exist in symbiotic relation with certain micro-organisms, as well as the nitrogen fixation by other free-living micro-organisms, has advanced considerably in recent years. It now appears that in nitrogen fixation, nitrogen acts as an electron and hydrogen acceptor and is reduced to ammonia[15,17]. The intermediates may never be isolated in sufficient quantities to be identified with certainty; the reduction probably occurs in a stepwise fashion as follows:

$$\underset{\text{nitrogen}}{\mathrm{N{=}N}} \xrightarrow{+2\mathrm{H}} \underset{\text{diimide}}{\mathrm{NH{-}NH}} \xrightarrow{+2\mathrm{H}} \underset{\text{diamine}}{\mathrm{NH_2{-}NH_2}} \xrightarrow{+2\mathrm{H}} \underset{\text{ammonia}}{\mathrm{2NH_3}}$$

Nicholas[15,17] has recently shown for the micro-organism *Azotobacter vinelandii*, a free-living aerobic organism capable of nitrogen fixation, that gaseous nitrogen and gaseous oxygen used in respiration compete with one another for electrons supplied by other metabolic activities of the cell. The competing pathways, and the probable electron carriers, based on evidence presented by Nicholas[15], may be shown schematically as follows (the enzyme system which activates gaseous nitrogen is called nitrogenase):



electrons from intermediary metabolism
flavin adenine dinucleotide
non-hæm Fe
cytochromes→O_2
nitrogenase→N_2

The microelement requirements for nitrogen fixation by *A. vinelandii* include at least iron, molybdenum and cobalt; the iron is needed in the complex which contains iron in a non-hæm form; molybdenum and probably also cobalt may be a part of the nitrogenase system[16]. Cobalt is required for nitrogen fixation by *A. vinelandii*[16], and it is also required when certain leguminous species grown under symbiotic conditions are actively fixing nitrogen gas[1]; however, this latter requirement may reflect a need for cobalt by the infecting bacteria rather than by the root cells themselves.

Whether nitrogen is absorbed as ammonia, or is reduced to ammonia from nitrogen or nitrate ion, the ammonia is rapidly incorporated into organic matter. The assimilation of ammonia has been reviewed recently by Webster[19]; to summarize briefly a process which may have further complications, it appears that initial ammonia assimilation probably proceeds to a large extent in the formation of glutamic acid by a process called reductive amination, catalysed by the enzyme called glutamic acid dehydrogenase:

$$\alpha\text{-ketoglutaric acid} + NH_3 + NADH_2 \longrightarrow \text{glutamic acid} + NAD + H_2O$$

Aspartic acid and alanine are also found when labelled ammonia is applied to plant tissues, but in lesser amounts than glutamic acid; they are probably formed by transamination from glutamic acid as follows:

$$\text{glutamic acid} + \underset{\text{(or pyruvic acid)}}{\text{oxalacetic acid}} \rightarrow \alpha\text{-ketoglutaric acid} + \underset{\text{(or alanine)}}{\text{aspartic acid}}$$

These three amino-acids, glutamic acid, aspartic acid and alanine, serve as a pool from which most of the other amino-acids can be formed, as well as amides and proteins and other products of nitrogen metabolism. (Over-simplification of this subject might possibly lead to misunderstanding, and Webster[19] should be consulted for details.)

The assimilation of phosphorus probably occurs mostly if not entirely by esterification of phosphate ions. Inorganic phosphate is absorbed by the plant from the external environment as $H_2PO_4^-$ or HPO_4^{--} ions, depending on the *p*H, and is then esterified into one or more of several classes of organic phosphate compounds which are found in plants[9]. These groups may be listed as: (1) carbohydrate phosphate esters and carbonyl-phosphate esters; (2) nucleic acids, that is, ribose and deoxyribose phosphate diesters which unite nitrogen bases; (3) phosphoproteins, including hydroxyamino-acid phosphate esters and guanidino phosphates; (4) polyphosphates in biologically important coenzymes such as flavin adenine dinucleotide, adenosine triphosphate, nicotinamide adenine dinucleotide, etc.; (5) phospholipids such as glycerol phosphate esters and diesters of nitrogenous bases; (6) inositol phosphate esters such as phytic acid and phytin.

Assimilation of sulphur in higher green plants has been studied to a much lesser extent than the assimilation of nitrogen and phosphorus. The form in which sulphur is usually supplied to the plant is the sulphate ion; the reduction of sulphur from an oxidation state of +6 in sulphate ion to −2 in sulphydryl (—SH) has been studied in some micro-organisms, and the subject has been recently reviewed by Thomas[18] and by Wilson[21]. Tracer experiments with higher green plants have also demonstrated that inorganic sulphate is found especially in the amino-acid cysteine ($HS—CH_2—CH(NH_2)—COOH$). By assuming that the reduction pathway in higher green plants is similar to that in micro-organisms and goes through sulphite and thiosulphate to sulphydryl, and also by assuming in analogy with pathways demonstrated for micro-organisms that sulphydryl groups react with the amino-acid serine to produce cysteine, then a pathway of sulphate assimilation in higher plants which is consistent with our present-day knowledge may be outlined as follows:

$$SO_4^{=} \rightarrow SO_3^{=} \rightarrow S_2O_3^{=} \rightarrow \text{—SH} \xrightarrow{\text{serine}} \text{cysteine}$$

Sulphur is a component of many molecules of great biological interest, including thiamine, biotin, glutathione, coenzyme *A*, methionine, cystine and others; various thioethers, sulphoxides and thioesters of greater or lesser complexity also occur in plant tissues. The investigation of the synthesis, function and degradation of these compounds has only begun.

Assimilation of Potassium, Calcium and Magnesium

Even though it is probable that some anions absorbed by a plant may not be metabolized at all, and may perhaps serve only to neutralize cations, yet it is evident from the discussion so far that assimilation of the bulk of nitrogen, phosphorus and sulphur is accompanied by an active and intense metabolism; the chemical transformations which these nutrients undergo in their conversion from inorganic to organic forms is drastic. In comparison with this behaviour, potassium, calcium and magnesium may be considered to be metabolized to a lesser extent. Substances like organic acids and proteins probably exist in the cellular milieu as anions; neutral substances like carbon dioxide are also converted by photosynthesis into organic anions; these anions are neutralized either by hydrogen ions produced metabolically or by the ions K^+, Ca^{++} and Mg^{++}. Thus, one of the important functions of cations is their action as free ions in the maintenance of electroneutrality; relatively weak electrostatic forces bind the inorganic ions to the organic anions. Cations like potassium, calcium and magnesium probably support the maintenance of protoplasmic organization and integrity in the cell. Protoplasm is a complex colloidal system of an emulsion-like nature, and requires stabilization *in vivo*. Our present knowledge of this phase of cell biology is very scanty, but it is widely recognized[9] from studies of colloidal systems *in vitro*, that monovalent-metal soaps, being soluble in water, act as stabilizers of oil-in-water emulsions, whereas divalent-metal soaps, being water-insoluble and oil-soluble, serve as efficient stabilizers for water-in-oil emulsions. Probably both these kinds of emulsions are present in protoplasm, and monovalent and divalent cations may thus play important parts.

Not only can potassium, calcium and magnesium function as simple charged particles, but these substances may also have physiological importance as insoluble salts. The middle lamella of the cell wall consists largely of insoluble pectic compounds which are mixtures of calcium and magnesium pectates; phytin, the calcium–magnesium salt of inositol, is found in large amounts in seeds and seedlings. Whether physiologically important potassium salts of low solubility occur in plant tissues is still an open question, but their existence may be suspected because of the wide range of known potassium salts which have low solubilities[16].

Other more complicated forms of potassium, calcium and magnesium also exist in plant tissue. Metal ions form complex or co-ordination compounds with organic groups which donate electrons to the metal. The complexes which result when electron-donor atoms are attached to each other as well as to the metal are called chelate or sequestered compounds. Donor atoms which undergo combination with the metal in the formation of these complexes are usually nitrogen, oxygen and sulphur. Complexes and chelates are formed by nearly all metals, including alkali and alkaline earth metals[4,12]. Among potassium, calcium and magnesium, the best-known naturally occurring chelate is chlorophyll: the magnesium atom is present in the centre of the porphin ring, and is bound to the four pyrrole nitrogen atoms much as the iron atom in iron porphyrin. Organic anions such as citrate, tartrate, malate and various amino-acids also form stable chelates with metal ions, including calcium and magnesium. Less well known is the fact that alkali metals like sodium and potassium can also form chelate compounds[4,12]. Many cases of non-specific activation of enzyme systems by univalent and divalent cations may possibly find their explanations in part in this phenomenon. Without doubt the common observation that sodium can replace potassium as a nutrient stems from the action of potassium as a free ion in the plant, bound ionogenically by neutral polar valences to organic anions and functioning as a charge neutralizer or as a stabilizer of protoplasmic emulsions. But the fact that sodium cannot replace potassium completely—potassium is an essential element to higher green plants whereas sodium is not—leads to the conclusion that potassium performs a function which sodium cannot perform; but this special function of potassium has not yet been discovered. It is suggested here that organic complexing agents exist in plant tissue which have higher affinities for potassium than for sodium; the resulting co-ordination of chelate compounds of potassium, functioning perhaps as an unknown essential cellular constituent, may account for the essentiality of potassium.

In summary, the cations potassium, calcium and magnesium may exist in plant tissues in one or more of the following forms: (1) simple charged particles, bound ionogenically to particles of opposite charge by normal polar valences; (2) co-ordinated compounds (complexes, chelates) bound by non-ionogenic auxiliary valences; (3) substances of low solubility (for example, phytin, calcium-oxalate, calcium-pectate, etc.).

Assimilation of Micro-elements

Our knowledge of the roles of some of the micro-elements has increased considerably during the past decade or so. Elements like copper, iron, manganese, molybdenum and zinc have been shown to act as nuclei of metalloprotein enzymes or as enzyme activators, and their roles have been reviewed[13,14]. Chloride ion has been shown to be required in the photo-oxidation of water by isolated chloroplasts[3]. Boron probably forms sugar borate complexes which are associated with the translocation of sugars[8]. So far, major research emphasis has been placed on the roles of micro-elements in enzyme systems; other roles not now investigated, such as possible effects on membrane structure, cell organization, etc., should also be considered[14]. But in spite of increasing awareness of the functions of micro-elements, remarkably little detailed information is available concerning the processes of assimilation of the micronutrients.

With the possible exception of Cl$^-$, probably very low concentrations of free micro-element ions are present in soils and in plant tissues. The elements copper, iron, manganese and zinc occur in the soil as cations which form insoluble salts with systems such as sulphate, chloride, carbonate, phosphate and many others; boron and molybdenum usually occur as oxy-anions which form insoluble salts of other metals. These metals in soils are locked in the mineral portion of the soil in the form of insoluble inorganic salts; the metals are converted to soluble form by weathering processes, perhaps first involving conversion to bicarbonates of low or intermediate solubility by the action of carbon dioxide dissolved in rain-water, or by attack by natural organic chelating agents produced by micro-organisms or by plant roots, which secrete small amounts of organic anions which tend to solubilize the micro-elements[6]. Inside the plant, micronutrient cations like copper, iron, manganese and zinc may be incorporated into chelate compounds by reaction with cellular metabolites; molybdenum also may form co-ordinated or chelate compounds of biological interest, perhaps involving the binding of the molybdyl ion (MoO$_2$) (ref. 20). It is becoming increasingly clear that organic substances of various kinds bind metals with greater or lesser tightness. The story of the assimilation of the micro-elements involves numerous interactions of metals with metabolites of various kinds, ranging from those which bind metals so tightly that the metal must be considered not in equilibrium with other substances present which might otherwise interact with the metal, to other binding agents which have low affinities for the metal and in which the metal bonds are labile. The porphyrins bind iron and vitamin B_{12} binds cobalt with extreme tightness; other substances like organic acids, amino-acids, peptides and proteins bind metals less tightly so that the metals remain exchangeable. Purines, pteridines, nucleotides and nucleic acids also have been shown to bind metals, but little work has been done to measure the affinities of these substances for individual metals[2]. Thus, a metal may be carried within the plant as a chelate or co-ordination compound, and may undergo exchanges with other metabolites which form complexes of greater stability. The process of absorption of micronutrients from the external environment by plant roots may involve in part simple replacement at the root surface of one complexing agent for another. Considerable efforts by biochemists and physiologists will be needed to attain detailed knowledge of assimilation of micronutrients.

The preparation of this article was supported in part with funds provided by the U.S. Atomic Energy Commission (contract *AT*-(40-1)-2834).

OBITUARIES

Prof. A. G. Ginetzinsky

PROF. A. G. GINETZINSKY, head of the Laboratory of the Institute of Evolutionary Physiology in Leningrad and corresponding member of the Academy of Medical Sciences of the U.S.S.R., died on October 20, 1962, at the age of sixty-seven. To many of his colleagues abroad, Ginetzinsky's contributions to physiology became known only comparatively recently, despite the fact that he was the author of a series of important discoveries over the past forty years. He was born at Vologda in 1895. After graduating at the Medical Institute in Leningrad, he joined the laboratory of the late Academician L. A. Orbeli, whose influence as a teacher continued to guide him in the pursuit of problems in nerve and muscle physiology. After holding for many years the chair of physiology in the Medical Pediatric Institute, Leningrad, Ginetzinsky moved to the Sechenov Institute of Evolutionary Physiology.

Of his many scientific studies, I shall refer to four which have gained international interest and recognition (though some very belatedly and not until his findings had been rediscovered in other places).

In December 1922, Ginetzinsky gave an important communication at the thirty-seventh Physiological Congress in Petrograd, describing the effect of sympathetic nerve fibres on fatigued muscle. He showed that stimulation of sympathetic nerves can influence and, under certain conditions, restore the force of muscle contraction evoked by motor nerve impulses. The work was done, I believe, at the suggestion of Ginetzinsky's teacher; but there is no doubt from Orbeli's writings that his pupil had played a very prominent part in this discovery, which for some reason is commonly referred to in the non-Russian literature as the 'Orbeli phenomenon'.

In 1935, Ginetzinsky and N. I. Michelson reported that in muscles which had been completely paralysed by curare, a nerve impulse still evokes a small electric response in the region of the nerve-muscle junction. This was the first description of a phenomenon which became known, and intensively studied, several years later under the name of the 'end-plate potential'.

In 1942, Ginetzinsky and N. M. Shamarina published a most interesting paper the main findings of which were rediscovered seventeen years later in Sweden and in Great Britain. It confirmed the well-known fact that 'adult' skeletal muscle fibres are not very sensitive to acetylcholine except in a narrow region around their nerve-muscle junctions. The authors proceeded to show that, a few days after birth, the whole length of the muscle fibre reacts to low concentrations of acetylcholine, and that the final state, of a locally restricted sensitivity, is not attained until later. Furthermore, when adult muscles are deprived of their nerve supply, their acetylcholine sensitivity again begins to spread, from the nerve-muscle junction along the whole length of the muscle fibres.

During the last years of his life, Ginetzinsky's principal interests had turned to problems of kidney physiology, especially the control of water excretion and the mechanism of action of the anti-diuretic hormone. In 1958, he published a note in *Nature* (**182**, 1218; 1958) in which he put forward a new theory, namely that the re-absorption of water in the renal tubules is controlled by a local release of hyaluronidase which causes a temporary breakdown of the intercellular 'cement substance' in the wall of the distal and collecting tubules and so opens up channels for osmotic water flow. His evidence indicated that a hyaluronidase is released from the kidney cells under the influence of anti-diuretic hormone, and that the action of the free enzyme raises the water permeability of the tubular wall. This novel hypothesis has aroused much interest and some controversy; but its main features have been greatly strengthened by subsequent work done in Britain and by Ginetzinsky himself.

I had the pleasure and privilege of meeting Prof. Ginetzinsky in Moscow in 1961 and, like many of our colleagues, I was greatly looking forward to his intended visit to Britain in 1963, when he was to have given a series of lectures in the University of London. Ginetzinsky's contributions to physiology took a considerable time to cross the language barrier: if recognition outside his own country was belated, it fortunately did not come too late, and I like to think that he derived a good deal of satisfaction from it during the last years of his life.

BERNARD KATZ

Academician A. V. Topchiev

ACADEMICIAN A. V. TOPCHIEV, a noted organic chemist, a skilful administrator and a clever '*cultur*' diplomat, died in Moscow on December 27.

Born in 1907, Alexander Vasilievich Topchiev graduated at the Moscow Institute of Chemical Technology in 1930. After his graduation he made rapid progress and soon achieved eminence as a scientist and as a specialist in the field of petroleum chemistry. His numerous papers, a number of them dealing with petroleum hydrocarbons, earned him world-wide recognition. He also played an important part in the creation and development of the Soviet petroleum, chemical and polymer industry. Among his publications one may single out a few of the more outstanding ones, such as one on the nitration of hydrocarbons, another on boric fluoride as a catalyst and one on radioactive isotopes, the last paper being presented at the Congress on the Peaceful Uses of Atomic Energy held in Geneva in 1958.

In 1947–49 he acted as deputy Minister of Higher Education. In 1949 he was elected a member of the Soviet Academy of Sciences, and eventually he was entrusted with the key post of scientific secretary of the Academy. He was also director of the Institute of Petroleum–Chemical Synthesis. He received the Stalin Prize and the Order of Lenin for his work. As a very active member of the Communist Party, he was a deputy in the Supreme Soviet of the Russian Federation. His abilities as an administrator and a diplomat ensured his election to a number of committees and he was often sent abroad.

Topchiev was a frequent visitor to England, since his first visit in 1955 when he came to London as the leader of a group of Russian scientists attending a conference on nuclear energy. At this meeting he spoke with much feeling of the desire of the Russian scientists to restrict nuclear energy to peaceful uses. In 1956 he again led a party of Russian scientists attending the opening of Calder Hall. He was known as a most active fighter for peace and international scientific co-operation, and he was one of the founder members of the Pugwash peace movement at its first conference in 1957. At a scientific gathering in the United States in 1961, Topchiev again spoke eloquently about problems of peace and international co-operation. He was also a frequent and eloquent expositor of the Russian space programme, a circumstance which suggests that he had an important part to play in this.

To sum up, one may say that Topchiev was an outstanding scientist, an outstanding administrator, an organizer of international scientific and cultural co-operation and a most popular ambassador of his country, greatly admired by his fellow delegates and by his hosts for his frankness of speech, sincerity of purpose and good humour.

S. I. TOMKEIEFF

Dr. J. Howard Dellinger

DR. J. HOWARD DELLINGER, formerly chief of the Central Radio Propagation Laboratory at the National Bureau of Standards, U.S. Department of Commerce, died on December 28.

Dr. Dellinger, who initiated radio research at the Bureau in 1911, was also known for his work at national and international conferences on radio problems. He is credited with the discovery of the simultaneous occurrence of solar eruptions and radio effects (the Dellinger effect). He also investigated the ionosphere and high-frequency radio propagation and supervised the development of many basic radio aids to air navigation, and the initiation of the U.S. standard frequency broadcast service (*WWV*).

After retiring from the Bureau in 1948, Dr. Dellinger continued his work as a radio consultant and adviser.

Dr. Dellinger joined the staff of the National Bureau of Standards in 1907. He began working on the determination of the conductivity of copper for a few years. He was appointed chief of the Radio Section in 1919.

During the Second World War, Dr. Dellinger was selected by the Armed Services Joint Communications Board to direct the work of the Interservice Radio Propagation Laboratory. It was the task of this group to draw together accumulated research knowledge and data from which to make radio propagation predictions for the Armed Services. In 1946 this organization became the Central Radio Propagation Laboratory, and the prediction service was made available for civilian as well as military use. Dr. Dellinger continued as chief until his retirement from the Bureau in 1948.

Dr. Dellinger was born in Cleveland, Ohio, in 1886. He attended Western Reserve University during 1903–7 and received his bachelor of arts degree from George Washington University in 1908. He was a fellow at Princeton during 1912–13, receiving his Ph.D. there in 1913. He was elected to Phi Beta Kappa at Western Reserve and was presented with a D.Sc. degree by George Washington University in 1932.

He was author of more than 200 papers in his fields, and was radio editor for *Webster's Dictionary*. He was a Fellow of the Institute of Radio Engineers (vice-president in 1924, president in 1925, Medal of Honor in 1938), a member of the U.S. Academy of Sciences (vice-president in 1935, 1939 and 1941), and a member of the International Scientific Radio Union (honorary member for life of the U.S. National Committee, honorary president for life).

NEWS and VIEWS

The National Research Council of Canada :

Dr. B. G. Ballard, O.B.E.

Dr. B. G. Ballard, vice-president (scientific) of the National Research Council of Canada since 1954, and acting president since the death last August of Dr. E. W. R. Steacie (*Nature* Obituary, 196, 110; 1962), has been appointed president of the Council. Dr. Ballard was born in 1902 at Fort Stewart, Ontario, and graduated from Queen's University, Kingston. Following a Westinghouse graduate course in electrical engineering in 1924–25 he joined the staff of the Westinghouse Electric and Manufacturing Co., East Pittsburg, Pennsylvania. In 1930 he was appointed to the National Research Council's Division of Physics, and throughout the following ten years built up the electrical engineering section of that Division. In 1946 he was appointed assistant director of the Division of Physics and Electrical Engineering, and two years later, when a full Division of Radio and Electrical Engineering was established, he became director. He was awarded an O.B.E. for his war-time work on the development of mine-sweepers, and the Ross Medal of the Engineering Institute of Canada in 1949 for his publication entitled *Recent Canadian Radar*; in 1953 he received the Coronation Medal. Dr. Ballard is president of the Canadian Standards Association. He is an honorary member and former president of the Engineering Institute of Canada, a Fellow of the Institute of Radio Engineers, and of the American Institute of Electrical Engineers, of which he was a former vice-president.

Dr. L. Marion, F.R.S.

Dr. Léo Marion, senior director of the National Research Council of Canada, and director of the Division of Pure Chemistry, has been appointed vice-president (scientific) of the Council in succession to Dr. B. G. Ballard. Dr. Marion was born in Ottawa in 1899. He graduated with honours from Queen's University in 1926 and gained his Ph.D. degree from McGill University in 1929. The same year he began his career with the National Research Council of Canada, continuing in the field of organic chemistry, principally alkaloids, on which he did postdoctoral work at the University of Vienna in 1934–35. Since 1947, Dr. Marion has served as editor-in-chief of the Canadian journals of research and since 1952 as editor of the *Canadian Journal of Chemistry*. He also serves on the editorial board of three other scientific journals. He became head of the organic chemistry section of the Division of Chemistry in 1943, director of the Division of Pure Chemistry in 1952, and senior director of the National Research Council in 1960. Dr. Marion was elected a Fellow of the Royal Society of London in 1961. He is also a Fellow of the Royal Society of Canada and a past-president of Section III; a Fellow of the Chemical Institute of Canada and immediate past-president of the Institute; past-president of l'Association Canadienne-Française pour l'Avancement des Sciences; a member of the American Chemical Society, and a Fellow of the Chemical Society of Great Britain. He has received many awards for his contributions to the field of alkaloid chemistry, including the Médaille Léo Pariseau of l'Association Canadienne-Française pour l'Avancement des Sciences, the Palladium Medal of the Chemical Institute of Canada, and the Gold Medal of the Professional Institute of the Public Service of Canada.

The Commonwealth Scholarships (Amendment) Bill

The debate in the House of Lords on February 5 on the second reading of the Commonwealth Scholarships (Amendment) Bill added little to the points stressed in the House of Commons (see *Nature*, 197, 731, 749; 1963). The Earl of Lucan referred to the need of the overseas universities for large numbers of expatriated teaching staff and said that the African universities alone were estimated to need something like 5,000 teachers in the next twenty years. He urged that the Government and leaders of the professions could not be too emphatic in their assurances that those who took posts overseas for limited periods to help in higher education would not prejudice their careers but rather improve their prospects. Lord Peddie stressed the importance of non-academic students expanding educational facilities, but Lord Ogmore strongly urged that postgraduate study was most advantageously pursued in one of the more mature countries, and suggested some of the British graduates should hold their Commonwealth fellowships in African and Asian universities. In replying on the debate for the Government, the Duke of Devonshire pointed out that the 500 places provided for under the scheme should be considered against the 35,000 students from Commonwealth countries who were already studying in Great Britain. He gave no indication that the £6 million provided over the period 1960–65 would be increased, but added that he understood that under the scheme £200 a year maintenance was allowed for a scholar's wife.

The Diploma in Technology

In a written answer in the House of Commons on February 8, the Minister of Education, Sir Edward Boyle, stated that of 2,697 first-year students for the Diploma in Technology, 2,097 qualified by the General Certificate of Education and 538 by Ordinary National Certificate. Of these first-year students, 1,234 were college-based and 1,463 works-based; for second-, third- and fourth-year students the corresponding figures were given as 666 and 1,367; 375 and 1,019; 310 and 856. Of first-year students at January 31, 1963, 1,718 were in engineering (including 122 in chemical engineering, 596 in electrical, and 517 in mechanical engineering); 445 in applied chemistry and 225 in applied physics. For the second-, third- and fourth-year students the corresponding figures are: 1,328 (85, 515 and 443), 299 and 179; 954 (40, 377 and 308), 187 and 136; and 847 (45, 300 and 282), 132 and 87.

The Expanding Universities

In a written answer in the House of Commons on February 12, the Financial Secretary to the Treasury, Mr. A. Barber, stated that Exchequer grants to the universities for recurrent and non-recurrent expenditure would rise from £84·1 million in 1961–62 to an estimated minimum of about £130 million in 1966–67. Student numbers would increase from 111,385 to 150,000 in the same period. The universities had estimated that the entry in 1966 should be more than 10,000 higher and would represent about the same percentage of the much larger age-group.

British Medical Aid to the Developing Countries

In opening an adjournment debate on medical aid to the developing countries in the House of Commons on February 11, Mr. J. Boyden concentrated on the report of Sir Arthur Porritt and his Working Party, endorsing an earlier tribute of the Secretary for Technical Co-operation to the work of Sir Arthur and his colleagues. Mr. Boyden emphasized the urgency of the problem, pointing out that the Working Party itself had noted a further decline in British influence in the medical field overseas during the four months it was at work. Replying for the Government in the absence of Mr. D. Vosper through illness, the Joint Parliamentary Secretary to the Ministry of Health, Mr. B. Braine, said that the Government's policy in providing technical assistance was to meet the requests of developing countries in whatever form they appeared. The delay in publishing the report was due to the new financial provision involved which could be considered only in the context of the estimates of the Department of Technical Co-operation for 1963–64. Mr. Vosper would not have been able to make a statement had he been present, but would do so at the earliest opportunity, and meanwhile, Mr. Braine said that the Government accepted the greater part of the recommendations in the report.

To-day, 900 undergraduate students from overseas are studying in Britain's medical schools and there are 9,000 student nurses from overseas in Britain's hospitals. Almost half the doctors at registrar level in the hospitals are from overseas, and in the past two years the Department for Technical Co-operation has arranged and paid for postgraduate training for 265 doctors and 170 nursing sisters from overseas, in addition to 170 doctors from the dependent territories for postgraduate training at the expense of their own Governments. Under the Overseas Assistance Scheme, 1,385 medical staff have been designated for the coming year at a cost of £1·6 million. The Department also recruited 131 doctors during the past two years for service overseas, and many medical appointments were made under the Colombo Plan and the Special Commonwealth African Assistance Plan, while medical equipment to the value of £68,000 was provided under these plans in 1961–62, and £262,000 is at present being expended on medical research for the benefit of developing countries.

Mr. Braine admitted to some disappointment in the response to serve overseas. The Government proposed to create 25 bursaries for postgraduates from the developing countries, and these would be administered on lines similar to those provided under the Colombo Plan. The supervision of postgraduate education in non-teaching hospitals, he said, was now in hand with the aid of £250,000 provided by the Nuffield Provincial Hospitals Trust. The Government was aiming at establishing 12 senior and 6 junior lectureships in 1963–64 at the two schools of tropical medicine as a contribution to preventive medicine overseas. If all the 235 vacancies at present existing were to be filled, a climate of opinion must be created in the medical profession and the hospital boards as favourable to service overseas as that already created in the teaching profession, and to that end Mr. Braine welcomed the publicity afforded by the debate.

Reactor at Full Power at Buchanan, New York

Full power operation has been achieved at Con Edison's Indian Point atomic–electric generating station in Buchanan, New York, thirty-five miles from the centre of New York City. At full power, Indian Point generates 275,000 kW for Con Edison's six million kW system serving the area of New York City. The steam which drives the turbine at Indian Point receives approximately two-thirds of its heat from the atomic reactor and one-third from oil-fired superheaters. The reactor, according to its designer and builder, the Babcock and Wilcox Co., has operated smoothly since it achieved criticality. The core of the reactor, the first power reactor to use thorium as fuel, will last approximately two years without re-fuelling.

The Imperial College of Science and Technology

A brochure, *A Decade of Expansion: 1953–1963, Imperial College*, describes, with diagrams and illustrations, the progress made since January 1953 with the expansion of the Imperial College of Science and Technology from about 1,650 full-time students to 3,000 (Pp. 36. London: Imperial College, 1963). This target has almost been achieved. Academic work has at no stage been interrupted, while standards have been maintained and even improved, and many pioneering academic ventures have been started. In South Kensington the area has grown from 9 to 25 acres and the floor space from 800,000 to almost 1·8 million sq. ft. gross, and many semi-obsolete buildings have been replaced. While these developments have been achieved basically through national funds made available through the University Grants Committee, substantial help has come from charitable foundations, industry, and private individuals. Capital expenditure on buildings of more than £17 million was involved. The academic staff of 491 includes 51 professors and 75 readers, and there are some 1,100 postgraduate students, and the total of 2,900 students includes 659 from overseas, while the annual income for supported research exceeds £500,000, half of which comes from the Department of Scientific and Industrial Research. Despite this encouraging picture when the brochure looks to the future, it points out that the grants announced for the new quinquennium 1962–67 are so low that the College will be unable to man completely the large, and sometimes unique, new buildings which have been or are being completed. This will have a serious effect on the admission of students and the quality of the specialist postgraduate education provided; the Departments of Mathematics and of Chemistry would be special sufferers. Remedial action is urgently needed if the full benefits of the expansion are to be realized, and, in its absence, it is anticipated that the number of students will not exceed 3,100, whereas on the recurrent grant applied for a total of 3,700 was visualized. Reference is also made to the social needs of students. By the end of 1962–63 residence should be provided for 22 per cent of the students, perhaps about one-third of the demand, but unless finance permits the expansion of the College to be resumed these figures will have deteriorated by the end of the quinquennium.

Hazards to Health due to Radiation

The first edition of the *Code of Practice against Radiation Hazards* for the guidance of members of the Imperial College of Science and Technology, University of London, was issued in June 1957. The latest edition, the fourth (October 1962), supersedes former editions and gives the regulations applicable to the use of equipment producing ionizing radiation, to accelerators, and to the use of sealed and unsealed radioactive isotopes. The first eight pages of the booklet contain the *Code*, which is mandatory. The purpose of the *Code* is to control the hazards to health arising from radiation, to ensure the safe disposal of waste material and effluent, and to avoid contamination of laboratories and their surroundings, and it deals mainly with administrative procedure and instructions. The remainder of the booklet consists of eleven appendixes, in which detailed information, interesting physical data, and extremely valuable advice on practice are given. Maximum permissible levels of radiation; protection against ionizing radiation particularly from X-ray apparatus; classification of radioisotopes; requirements for radiochemical laboratories; monitoring; storage and disposal of active materials and waste; emergency procedures and fire precautions are some of the topics discussed. An extensive bibliography is also provided. For other university departments which have yet to establish their own radiation safety committee and produce their own regulations, the *Code* should prove an excellent model to copy.

U.K. Library Telex Directory

The second edition of the *Library Telex Directory*, compiled from 700 questionnaires issued to organizations known to have access to telex and reported to possess library or information services, contains entries for 400 libraries compared with 131 in the first edition in 1960 (Pp. 24. London: The Library Association, 1962. 8*s*.; L.A. members 6*s*.). Some entries are qualified by restrictions. Some notes on the use of telex in libraries which preface the *Directory* stress the importance of stating the urgency of a request, of not economizing in words at the expense of clarity, of sending brief acknowledgments of action taken or to be taken, and of spacing loan requests on the paper roll and including name and address with each separate item.

The Quarter-Inch Map of Great Britain

February 1 saw the completion of the Ordnance Survey's Fifth Series of the *Quarter-Inch Map of Great Britain* when the last two sheets were published. Hence the whole of Britain is now covered by this post-war series begun in 1957. The quarter-inch 'travellers' map, as it could be called—for here lies its greatest utility—owes its beginning to the War Office and the Ordnance Survey. It was begun in 1859, but its publication was delayed for almost twenty-five years owing to the all-out effort of the engravers of the day to complete the one-inch map then on hand; moreover, its sale to the public was not until 1887. In order to conform with continental practice and the requirements of air navigation the scale of the *Quarter-Inch Map of Great Britain* is, in fact, now 1 : 250,000 and not 1 : 253,440. As with previous editions, the Fifth Series has been derived from the one-inch map, in this case the post-war Seventh Series. Compared with the *Quarter-Inch Fourth Edition*, the amount of detail on the Fifth Series has been reduced in the knowledge that there exists an up-to-date one-inch map for more detailed reference. Relief is shown by hypsometrical or layer tints and contour lines, with the addition of hill shading to give a more readable picture of the ground. Special effort has been made to make the map useful to the motorist by clearly defining Motorways, Class I and II roads and dual carriageways.

The Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme

Awards under the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme have been made as follows: Dr. Madge G. Adam, university demonstrator in astronomy, Oxford, to assist her to visit Mount Stromlo Observatory for a year from August in order to use the 74-in. telescope there for a study of magnetic stars in the southern sky; Dr. U. Aswathanarayana, reader in geology, Andhra University, to enable him to familiarize himself with recent advances in methodology and experimental techniques of radioactivity methods of dating, at Oxford, from April until September; Dr. N. Collis-George, associate professor of soil science, University of Sydney, to enable him to become acquainted at first-hand with the theoretical and experimental methods of describing the movement of water through soils, at Cambridge, from July until December; Dr. P. J. Grubb, university demonstrator in botany, Cambridge, to enable him to investigate the sodium/potassium relations of the *Atriplex* spp. growing in the arid areas near Adelaide, from April until October; Dr. J. R. Richards, Fellow in the Department of Geophysics, Australian National University, to assist him to gain further experience in the measurement of lead isotope ratios and to extend his experience in the arts of isotope geology and geochronology at the University of British Columbia and the University of Toronto, for about eight months from March; Dr. C. G. Winder, associate professor of geology, University of Western Ontario, to enable him to gain experience of studying conodonts at the University College of Swansea and to study the type exposures of the Ordovician, Silurian and Devonian systems of rocks which occur in Wales and Devon, from April until September 1963.

Announcements

Mr. J. West has been awarded the recently instituted City and Guilds of London Institute's Prince Philip Medal. This award, which is made annually, is restricted to persons under 40 years of age who have "travelled the City and Guilds path" and passed one of the Institute's examinations. Mr. West, when assistant manager of P. and O. Orient Management, Ltd., was the designer of the 45,000-ton passenger liner *Canberra*.

A members' day incorporating the annual general meeting, arranged by the National Vegetable Research Station Association, will be held on March 12. Further information can be obtained from the Secretary, National Vegetable Research Station, Wellesbourne, Warwick.

The fourteenth annual meeting of the Tissue Culture Association will be held at the Somerset Hotel, Boston, during May 27–30. Three of the six sessions will be devoted to a symposium on "Metabolic Control Mechanisms in Animal Cells". Further information can be obtained from Prof. P. Goldhaber, Harvard School of Dental Medicine, 188 Longwood Avenue, Boston, Mass.

A conference on "Semiconductor Power Controls", arranged by Texas Instruments, Ltd., will be held in Bedford on March 18. Subjects under discussion will include: basic SCR circuit considerations; gate-controlled switches; proportional power controls; motor-control circuits; d.c. motor-control circuits; a.c. motor-control circuits; power supplies. Further information can be obtained from Mr. W. A. Yates, Texas Instruments, Ltd., Manton Lane, Bedford, England.

An international symposium on "Aqueous Reprocessing Chemistry of Nuclear Fuels", organized by the European Company for Chemical Processing of Irradiated Fuels and the Organization for Economic Co-operation and Development, European Nuclear Energy Agency, is to be held in Brussels during April 23–26. Further information can be obtained from the Organization for Economic Co-operation and Development, European Nuclear Energy Agency, 38 Boulevard Suchet, Paris 16 ème.

The jubilee meeting of the British Ecological Society will be held at Queen Elizabeth College, London, during March 28–31. The programme has been divided into six sessions: ecology and conservation; Quaternary ecology; the history of ecology in Britain; experimental and autecological studies; production ecology; the community concept. Prof. W. H. Pearsall will give the Jubilee Address, entitled "The Development of Ecology in Britain", on March 29. Further information can be obtained from A. Macfadyen, Department of Zoology, University College, Swansea, or from Dr. P. J. Newbould, Department of Botany, University College, Gower Street, London, W.C.1.

EXPENDITURE ON RESEARCH AND DEVELOPMENT IN BRITAIN

IN the final section of its annual report for 1961–62*, the Advisory Council on Scientific Policy again reviews the expenditure on scientific and technical research and development, which in 1961–62 is estimated at £634 million or about 2·7 per cent of the gross national product, of which about £67 million was capital expenditure. Private industry carried out about 58 per cent of total research and development, universities and technical colleges being responsible for 5·1 per cent, research associations for 1·3 per cent, Research Councils for 3·6 per cent, and public corporations for 3·4 per cent. On the other hand, the Government provided 60·7 per cent (£385 million) of the finance, of which 38·7 per cent was from defence departments and 4·6 per cent from the research councils, while private industry provided 33·6 per cent (£213 million), only 0·2 per cent coming from the universities and technical colleges. Of current expenditure by the Government, £86·4 million was by defence departments, £45·7 million on civil research and development, and £19·4 million on the research councils. Technical colleges spent £1·8 million, universities £24·8 million, research associations £6·5 million, public corporations £15·4 million, and private industry £340·8 million.

The proportion of the gross national product expended on research and development continues to rise, from 1·7 per cent in 1955–56 and 2·3 per cent in 1958–59. Expenditure by universities and technical colleges has risen from £14·4 million in 1955–56 to £32·4 million, by research associations from £4·9 million to £8·1 million, by public corporations from £5·8 million to £21·4 million, by research councils from £10 million to £23 million, and by private industry from £185 million to £367·7 million, while that by defence departments has only risen from £65·7 million to £93·2 million. Government expenditure in work carried out in private industry was nearly £177 million, and most of this was in the electronics, electrical engineering, and especially the aircraft industry. Total expenditure in the United States in 1961–62 is estimated at about £5,360 million, or 2·89 per cent of the gross national product, excluding capital expenditure.

A note on the scope and methods used in this inquiry into research and development expenditure appended to the report gives the qualified manpower employed on research and development in private industry as about 31,000 and the number of science mathematics graduate teachers in grant-aided schools in England and Wales as 20,055 and in Scotland 5,109, increases of 968 and 85 respectively, on the previous year. The additional scientific manpower is computed from 6,844 first degrees and diplomas awarded in pure science in 1960–61, 3,982 in technology, 620 diplomas in technology, 158 associateships of educational institutions, and 5,885 new members of scientific and technological professional institutions. Government expenditure on civil research in 1960–61 was £18·19 million and is estimated at £21·5 million in 1961–62 and £27·2 million in 1962–63. For agriculture, forestry, fisheries and food the figures are £10·66 million, £12·7 million and £12·9 million, respectively; for industry and communications, £20 million, £19·2 million and £23 million; medical and health, £5,255 million, £6·3 million and £6·66 million; overseas research, £1·52 million, £1·5 million and £1·6 million; universities and learned societies, £19·37 million, £21·4 million and £23·9 million; and for nuclear science, £54·1 million in 1961–62 and £56·7 million in 1962–63. Of the expenditure on Research Councils, estimated at £36·4 million in 1962–63 compared with £31·6 million in 1961–62 and £27·7 million in 1960–61, £17 million was for current and £5·1 million for capital expenditure on the Department of Scientific and Industrial Research with a scientific staff of 3,650. For the Agricultural Research Council the corresponding figures are £6·8 million, £954,000 and 2,672; for the Medical Research Council, £5·4 million, £441,000 and 1,883; and for the Nature Conservancy, £534,000, £56,000 and 121.

TRAINING OF GRADUATE SCIENCE TEACHERS IN BRITAIN

A REPORT on the training of graduate science teachers in England, Wales and Scotland, issued as the first section of Part 2 of the Science and Education Report of the Science Masters' Association and the Association of Women Science Teachers*, is based largely on information supplied by the twenty-three university departments of education in England and Wales in answer to a questionnaire. Some seventy senior science teachers were also consulted and twenty-seven others with less than five years' experience, and a joint meeting was held with the Standing Conference of Heads of University Departments of Education in December 1960.

The report points out that the present shortage of science teachers and consequent rapid promotion to senior posts may quickly cause the young graduate to be faced with the general supervision and maintenance of a laboratory as well as to be asked to produce new teaching syllabuses and to devise new courses. It is hoped that he will wish to keep himself informed of developments within and on the fringe of his own subject as well as in the field of education. This clearly requires a comprehensive course of study, not merely coaching in practical techniques, and the sub-committee responsible for the report submits that a successful teacher is one who can convey clearly and accurately both the established knowledge of science and the spirit of scientific inquiry and can indicate the part which science plays in the wide field of human achievement, practical and intellectual. The Associations believe that all intending science teachers should undergo an effective training course, but they also believe that the potential value of present courses is often not realized.

Their inquiries revealed that eight out of twenty-three departments of education had no practical facilities, four had a small room or laboratory, seven had one laboratory, and four had two or more laboratories. Many of the small rooms were for one subject only, and some departments used facilities elsewhere in the university. Only eleven departments held laboratory courses, ranging from five to sixty hours per year, and the money spent on apparatus averaged £2 8s. per student per year; in fitting out new laboratories the capital expenditure in 1959–60 was £9 per student. The sub-committee concluded that the facilities provided for practical work were quite inadequate both in time and in accommodation. If practical work is to be given adequate time, science students must be prepared either to devote more hours weekly to their training, or to have their training extended beyond the present university terms.

---

* *The Training of Graduate Science Teachers in England, Wales and Scotland.* (A section of Part II of the Science and Education report issued by the Science Masters' Association and the Association of Women Science Teachers.) Pp. 32. (London: John Murray. Published for the S.M.A. and A.W.S.T., 1962.) 2s. net.

To overcome the inadequacy of laboratory accommodation, the report recommends the establishment of Science Teaching Centres in all universities, in the departments or institutes of education or elsewhere. These centres should have adequate laboratory accommodation, be organized by a director and have a panel of visiting school teachers. It is suggested that the establishment of such centres would help to meet the present need for refresher courses for established teachers and for part-time courses leading to a higher professional qualification, such as university diploma in the teaching of science. It is also recommended that the training course to be taken by all intending science teachers should pay adequate attention to general principles of education and to studies in the philosophy, method and social consequences of science. School practice should comprise a complete school term and only in schools where adequate supervision and help are provided. There should be more liaison between school supervisor and departmental tutor both at the personal and professional level. Departments of Education should be asked to consider the merits of continuous assessment and the time spent on method and practical work, and Department of Education staffs and local branches of the Science Masters' Association and the Association of Women Science Teachers should ensure that effective and continuous contact exists between each Department and the science teachers in its area. Conditions in Scotland are regarded as in many ways in advance of those in England and Wales; but there is considerable dissatisfaction with the student/staff ratio and the inadequate provision of rooms and equipment in the colleges.

CHALLENGES OF SCIENCE IN SOUTH AFRICA

IN his presidential address to the Diamond Jubilee Congress of the South African Association for the Advancement of Science at Cape Town, July 1962, Prof. J. P. Duminy, under the title "The Challenges of Science To-day", discussed more particularly the universal shortage of manpower which, he suggested, arises out of the unplanned and unexpected advances in technology in the past decade—out of what can be described as an explosion in the field of scientific knowledge. But for this, South Africa might have been able to cope with its internal post-war demands for trained personnel. However, extreme difficulty is now being experienced in attracting men from abroad to institutions there and in training South Africans in their own universities to meet the manpower needs.

South Africa has never enjoyed the means of providing facilities at its universities necessary for training men to the levels of teaching and research in science and technology which are essential. Many of those who go overseas in order to obtain qualifications never return. Some mobility and interchange are desirable, but for several years the movement has been consistently one way. Investigations into the sources of trained manpower have shown that the universities will be powerless to play their full part unless the interest of youth is aroused and larger numbers are stimulated to take up careers in science and technology. The Manpower Development Foundation, created under the auspices of the Association and in collaboration with the Federation of Science Teachers' Associations, seeks to improve the teaching of science in the schools. Publication of a periodical dealing with methods and material for teaching physics, chemistry, mathematics and biology is planned. A significant contribution is also being made by the Permanent Exhibition of Modern Science.

In conclusion, Prof. Dunning, observing that science is not independent of philosophy and that philosophical thinking is not incompatible with scientific concepts, urged that the schism between the humanities and the sciences must be healed and science enabled to make its full contribution in our thinking about the realities of human existence and the relations between human beings.

PROGRESS AND INNOVATION IN SCIENTIFIC RESEARCH

IN his Peter Le Neve Lecture to the Royal Society of Arts on January 9, on "Progress and Innovation", Mr. J. C. Duckworth, managing director of the National Research Development Corporation, said that in these days of the large development and design team it is often difficult to decide what is truly invention and what is purely the logical outcome of applied research or development work. The actual invention of a new device or process can occur very soon after the requisite knowledge is available, and indeed almost as part of the process of acquiring it, or the invention may come long after the necessary knowledge is available. On the other hand, the inventor may be too far ahead of the 'frontiers of knowledge' for his ideas to be practicable.

Mr. Duckworth suggested that over the past two centuries the nature of invention has changed. The principle of designing new equipment to meet a need is now well established and such design should not be considered invention unless it incorporates some novel feature or concept beyond that which the ordinary design engineer can be expected to provide. The fact that ideas such as the hovercraft can be conceived by an individual should encourage those who believe that inventions may be possible by those outside the large research and development teams. Moreover, it is probable that individual inventors will have most success where a combination of different disciplines is required to produce the new idea.

After emphasizing that an invention only makes its impact if the economic and social climate is ready for its acceptance, in addition to the need for technical development to reach a sufficiently advanced stage, Mr. Duckworth observed that within the team the creative genius of invention is still required to make more than humdrum progress. The National Research Development Corporation was set up partly due to the belief that inventions of obvious merit were being suppressed because their development jeopardized the position of established products; however, the Corporation found no reliable evidence of this. Development contracts involve an appreciable proportion of the effort and expenditure of the Corporation which operates its development activities in an area in which it is particularly difficult for the individual inventor to succeed. In many other industrialized nations industry is more receptive to new ideas and will generally take up innovations more quickly and enthusiastically than in Britain, or is prepared to take greater risks where final commercial viability is less easy to assess. The Corporation generally becomes directly involved where the technical possibility is more in doubt, the commercial prospects are difficult to assess, or where it appears that there may be a benefit to the community as a whole, and where the benefit to one branch of industry may be marginal.

There is no doubt that the individual inventor now has a difficult task and that in the scientific field the inventor is increasingly a highly qualified man working with adequate resources. True inventiveness should always be encouraged and in spite of the fact that the lone inventor now has a smaller chance of making significant scientific advances, if he does succeed in doing so he has a better chance than ever before of getting his ideas adopted, followed by fair treatment and financial reward.

THE EUROPEAN ORGANIZATION FOR NUCLEAR RESEARCH

THE seventh annual report of the European Organization for Nuclear Research (CERN) * covers the period to the end of 1961 and gives a detailed account of the activities of the Organization during a year which Prof. V. F. Weisskopf, the director-general of the Organization, describes in his introduction to the report as "an experimental year". It was the first year in which the research programme got into something approaching its full stride and in which tentative solutions were tried out to the problems of internal organization, of the shaping and management of the programme itself, and of relationships with other research organizations and research physicists.

The staff on December 31, 1961, numbered 1,091, of whom 187 were scientists and engineers, 573 technicians, 149 administrative and 182 ancillary members. They were organized in twelve divisions under a directorate of three and the director-general. The total expenditure during 1961 amounted to 70·2 million Swiss francs, of which 36·2 million was devoted to capital expenditure, mainly on buildings and on the accelerators and experimental equipment; 8·4 million on general expenditure; and 25·6 million on staff salaries and expenses.

The mean intensity of the proton synchrotron remained at about $2{\cdot}5 \times 10^{11}$ protons/pulse with a trapping efficiency of 50 per cent. The machine time allocated to nuclear physics experiments increased by about 50 per cent, from 62 h per week during January to 93 h per week during October. About 15 per cent of the total machine time was lost through various breakdowns. The commissioning during August of a new experimental hall (North Hall) made room for two extra beams to be set up, making a total of five beams in use round the machine at the end of 1961.

Two CERN-designed electrostatic separators came into operation during the year. A voltage of 750 kV could be held over a gap of 14 cm in a 3–4 GeV/c. antiproton beam and of 500 kV over a gap of 8·5 cm in a 1·5 GeV/c.K⁻ beam. Other new separators, including a radio-frequency separator, are under construction.

The research performed by members of the Nuclear Physics Division with the proton synchrotron was very fruitful. In the section of the report dealing with the activities of this Division, 16 experiments with the proton synchrotron and 11 with the synchro-cyclotron are described in some detail. For the proton synchrotron these include elastic and near-elastic scattering of protons on protons; total cross-section measurements of high-energy pions on hydrogen; strange particle physics; the measurement of resonances in the two-pion system using a spark chamber; the determination of the lifetime of the neutral pion, about 2×10^{-16} sec; muon electron scattering; and the search for magnetic monopoles. Long experiments were performed with the help of two large French bubble chambers. 300,000 photographs were taken with the 81-cm Saclay hydrogen bubble chamber in a beam of slow antiprotons and 80,000 pictures by the same chamber in a fast (3·0–4·0 GeV) antiproton beam. (It was in the latter series of pictures that for the first time, early in 1962, a charged anti-*Xi* particle was found.) Interesting results were also obtained in the study of photographs taken with the 30-cm hydrogen bubble chamber.

The experiments with the synchro-cyclotron included the outstanding experiment to measure the magnetic moment of the muon to an accuracy of 1 in 200,000, thus establishing that the muon is accurately described as a Dirac particle with no interaction other than the electromagnetic and the weak kinds—that is, that it behaves exactly as a heavy electron. During 1961 an experiment on the scattering of negative μ-mesons on *C* was started, and the reaction $\mu^- + p \rightarrow n + \nu$ was investigated directly without nuclear complications in the Italian 20-cm hydrogen bubble chamber. The energies of μ-mesic X-ray transitions (2*p*–1*s* and 3*d*–2*p*) were measured for many nuclei throughout the Periodic Table, and the search for the neutrino-less conversion of a muon into an electron using an improved μ^- beam intensity and a spark chamber has continued.

Using a modular system of construction, the Electronics Workshop has produced a comprehensive range of transistorized nucleonic instruments for use in the nuclear physics experiments. The range includes a fast triple coincidence circuit, fast discriminator, 5-way splits, delays and triggers, 100-Mc/s pre-scaler, fast-pulse amplifier with a gain of 10 and rise of 2 nsec, and pulse burst generators. Some work has been initiated in the field of image intensifiers and scintillation chambers.

During the year under review it became clear that more attention would have to be given to data handling and analysis, and that more and more machine time would be required from computers with faster operation and larger memories. The introduction of a 709 computer has greatly increased the computing facilities; but the absence of a link between the 709 and the *Mercury* computer has been the main bottleneck. A number of general-purpose programmes have been added and an improved compiler has been introduced to simplify the testing of *Autocode* programmes.

The staff of the Theoretical Study Division at the end of 1961 comprised ten scientists, one computer-programmer and two secretaries. In addition, about thirty theoreticians under the CERN and Ford Foundation fellowship programmes were working at any one time in the Division. Various problems characteristic of the very-high-energy region opened up by the CERN proton synchrotron were given special attention. Near-elastic scattering of nucleons on nuclei, inelastic nucleon–nucleon scattering with very small energy loss, and the interactions of high-energy neutrinos with complex nuclei, were the main subjects of study. A variety of problems relating to the physics of pions and nucleons and of strange particles have also been investigated. The Theoretical

---

* CERN, European Organization for Nuclear Research. Annual Report for 1961. Pp. 153. (Geneva: CERN, 1962.)

Study Division organized an international conference at CERN on the theoretical aspects of very-high-energy phenomena during June 5–9, 1961. The proceedings were published as *CERN Publication 61–22.*

The Film-badge Service of the Health Physics Group monitored 1,069 people for γ-radiation, and in addition about 140 people were also under neutron film-badge control. Only 78 people received a dose exceeding 1 rem for the year. In seven cases the maximum permissible annual exposure of 5 rems was approached. Arrangements for making blood tests of people exposed to radiation were improved and extended. A monitoring system for all waste leaving the CERN site has been set up. Routine weekly surveys of the radiation-level from the proton synchrotron and from the synchro-cyclotron were made.

Careful consideration was given during the year to the question of the rate of growth of the Organization in the future. The Council agreed on a budget for 1962 which would permit a moderate rate of growth and decided that during 1962 a more profound study should be undertaken by a special working party of the basic questions on which any policy for the future should be founded. Provision was made in the budget for 1962 for an intra-European study-group to produce design studies of two possible future projects, a storage ring device to be fed from the present proton synchrotron and a 300-GeV high-intensity proton synchrotron. The device is likely to consist of two storage rings of the same size as the proton synchrotron, but with d.c. magnets with split focusing and bending. The r.f. system would also be smaller and more delicate. The cost is estimated to be less than twice the cost of the proton synchrotron and the construction time about five to six years.

Because of a serious shortage of staff in the Public Information Office the production of the *CERN Courier* had to be practically suspended and many other activities were greatly handicapped. Four television programmes and ten radio programmes were arranged. English, French and Italian versions now exist of the CERN film ***Matter in Question***, which was awarded the Grand Prix in its class at the International Festival of technical and scientific films in Budapest. A German version is to follow during 1962. A total of 5,867 people in 206 conducted parties were shown around the establishment, and a new scheme of visits is being worked out to allow visitors still to see as much as possible although the accelerators are now practically inaccessible. The separate report of each Division concludes with a list of publications by members of the Division, and in two appendixes to the annual report are listed the 1961 CERN publications; reprints of publications during 1961 in other periodicals by members of the staff of CERN; and details of the lectures, seminars and colloquia held at CERN.

S. WEINTROUB

RECENT DEVELOPMENTS IN ASTRONOMIC AND SPECTRONOMIC INSTRUMENTS

WORK undertaken during 1962 by Sir Howard Grubb Parsons and Co., Ltd., has included a number of interesting and unusual projects. A 48-in. reflecting telescope has been erected at the Victoria Observatory, British Columbia, and a rather uncommon type of telescope, a twin 16-in. reflector, has been manufactured for the Royal Observatory at Edinburgh. Each tube of the twin reflector contains a 16-in. primary mirror and a Cassegrain mirror giving an overall focal ratio of $f/15$. One of the tubes can be off-set from the other in any direction up to 5° and simultaneous photometry can be carried out on two stars. The operation of the telescope can be made fully automatic.

Because of difficulty in obtaining acceptable glass blanks for the components of the complex optical system for the 40-in. reflector for the Cape Observatory, the completion of the telescope has been held up. The optical system uses a parabolic mirror and a lens system affording a wide field of good definition at the prime focus. A large correcting plate is located at about the prime focus and a correcting lens is inserted in the beam just before it comes to a focus. When the optical system is assembled it will be necessary to mount it in the telescope tube and test it in the tube. The test will be carried out in the test tower at the works. All the heavy items and fabrications for the 98-in. Isaac Newton reflecting telescope have been received and many of the machining operations have been completed.

Newly developed instruments include the 'Spectromaster', an infra-red spectrometer, covering a wavelength range of 0·6–25μ, and an interferometric spectrometer based on the work of Dr. H. A. Gebbie at the National Physical Laboratory. New techniques have been developed to produce very narrow band interference filters for the visible and selective filters for the infra-red. For the U.K. Atomic Energy Authority establishment at Harwell, two remotely controlled gas analysers to monitor carbon monoxide and carbon dioxide in a helium test loop for *Pluto* have been made, and four glass windows have been polished for use in a liquid hydrogen bubble chamber. Four oval windows for a similar purpose are to be ground and polished for use by the European Organization for Nuclear Research (CERN). Measuring 70 × 25 × 6 in. and weighing approximately 1,300 lb. each, they will constitute the largest pieces of optical glass ever to be manufactured anywhere in the world.

PALÆONTOLOGY IN THE U.S.S.R.

CONSIDERABLE advance has been made in palæontological research in the U.S.S.R. during the past half-century, following on the great development in this field of scientific activity in Russia during the nineteenth century. Characteristic of the present-day approach is the re-orientation of palæontology so that it is no longer treated as a mere annex of stratigraphy but is linked more closely with biology (theory of evolution, ecology, geological facies and conditions of fossilization). The Palæontological Society, founded in 1916, has actively sponsored this research and much has been done by the numerous geological institutes and the universities. Publication has been covered by various scientific periodicals, more particularly the four series—*Palæontology of the U.S.S.R.*, *Problems of Palæontology*, *Palæontological Journal* and *Transactions of the Palæontological Institute.*

The old-type description of fossils, collected by overworked geologists, is replaced by planned systematic work, specially organized to combine field and laboratory investigations. Examples of such work can be seen in recent expeditions to investigate a large accumulation of fossil bones of reptiles of Permian age, discovered in 1949 near the village of Eschovo, south of the town of Ochera on the River Kama. The systematic excavation of this fossil field was begun by members of the Palæontological Institute in 1957 and is still in progress. The results so far obtained are summarized by P. K. Chudinov (*Priroda*, 4, 78; 1962). The majority of fossils belong to the group of *Deinocephalia*, genera *Estemmenosuchus* and *Eotitanosuchus*. The name *Ocheria* is given to the remains of a new genus. There are also a few remains of *Amphibia*, such as *Melanosaurus*. The fauna, as a whole, is considered to be intermediate between those of North American and South Africa. Another important ossuary, discovered by members of the East Siberian Geological Institute in a locality 15 km south-west of Ulan-Ude Transbaikal region, and reported by L. N. Ivaniev (*Priroda*, 6, 78; 1962), consists of fossil bones of Tertiary and Quaternary mammals. They include well-preserved remains of Hipparion and other genera belonging to the same faunistic group.

The following is a very brief guide to some of the work covered during the past decade:

Protozoa, especially Foraminifera—by a number of research workers, especially micropalæontologists.

Archaeocyathidae, a group of rather problematic fossils intermediate between corals and sponges, found in the deposits of the Lower and Middle Cambrian, especially in the Asiatic part of the U.S.S.R. A. G. Vologdin (*Priroda*, 10, 185; 1962) describes a large amount of work on the investigation of this group since the expert summary by A. P. Borisyak (*Priroda*, 7–9, 315; 1919). More than one thousand species have been described. Cœlenterata, B. S. Sokolov; Bryozoa, M. I. Shulga-Nesterenko and A. I. Nikiforov; Brachyopoda, Chernyshev *et al.*; Trilobita, V. V. Weber and E. V. Lermontova; Quadrupeda, P. P. Shushkin; fossil plants, I. M. Pokrovskaya and S. M. Naumova.

The only way of dealing with the abundant palæontological literature published during the past three years is to give the titles of the recent volumes of the *Transactions of Palæontological Institute*:

80, The Spiriferidae of the Kazan stage of the Russian platform and the conditions of their co-existence, by A. D. Slyusareva (1960); 81, The Devonian bivalve Phyllopoda, by N. Novozhilov (1961); 82, The late Devonian sea of the Kuznetsk depression, history of its development, population and deposits, by T. N. Bel'skaya (1960); 83, The principles of systematics, system and phylogeny of Palæozoic Ammonoidea, by V. E. Ruzhentzev (1960); 85, Palæozoic insects of Kuznetsk basin, by E. E. Beckerr-Migdasova, O. M. Martynova and A. G. Sharov (1961); 86, Devonian Bryozoa of the Minusinsk and Kuznetsk basins, by I. P. Morozova (1961); 87, Artinskian Ammonoidea of the Middle Urals, by M. F. Bogoslovskaya (1962); 88, Ecology and the development of Silurian and Devonian brachiopoda of the Kuznetsk, Minusinsk and Tuva basins, by E. A. Ivanova; 89, Cambrian Algae of the south-eastern part of the Siberian platform, by K. B. Korde (1961); 90, Fundamental problems in the systematics of Nautilidea and related groups, by V. N. D. Shimansky and F. A. Zhuravleva (1961); 91, Saline-water Pliocene Cardiatidae of the U.S.S.R., Part 4, by A. G. Eberzin (1962).

But the most spectacular and certainly the most important publication in the Soviet Union is the projected 15-volume *Principles of Palæontology* written by two hundred specialists and containing not only accounts of recently discovered fossils in the Soviet Union but also a systematic account of the world's fossils, illustrated by numerous photo-reproductions and line drawings, and accompanied by a critical discussion of their systematics, nomenclature and distribution in space and time.

The titles of the fifteen (non-numbered) volumes of the *Principles of Palæontology* (*Osnovy Paleontologii*) are: General part, Protozoa; Porifera, Archaeocyathidea. Cœlenterata; Mollusca: Loricata, Bivalva, Scaphopoda Supplement: Vermes; Mollusca: Gastropoda; Mollusca: Cephalopoda. I, Nautiloidea, etc.; Mollusca: Cephalopoda. II, Ammonoidea, etc.; Bryozoa. Brachiopoda, Supplement: Phonoronidea; Arthropoda: Trilobita, Decapoda; Arthropoda: Trachaean, Chelicerata; Echinoderma, Hemichordata; Astomata, Pisces; Amphibia, Reptilia, Aves; Mammalia; Algae, Fungi, Bryophyta, Pteridophyta; Gymnospermae. Angiospermae.

One can get more information by looking at the particulars of the two most recently published volumes in this series:

Bryozoa. Brachiopoda. Suppl.: *Phonoridea*, edited by T. G. Sarycheva, written by twenty authors. 343 pp. 82 plates, 485 text-figs. 1960. Price 3 r. 82 k.

Mammalia, edit. by V. I. Gromova. Written by thirteen authors. 421 pp. 543 text-figs. 1962. Price 2 r. 61 k.

The *Principles of Palæontology* (*Osnovy Paleontologii*) is produced by the Palæontological Institute, Moscow Academy of Sciences (Lenin Prospect, 33, Moscow B-71) in collaboration with a number of other institutes.

S. I. TOMKEIEFF

BIOLOGICAL SIGNALS AND NOISE

By DR. L. MOLYNEUX

Department of Physics, Kings' College (University of Durham), Newcastle upon Tyne

THE word 'noise' in a scientific context is usually used to describe random fluctuations of potential; however, the definition can be usefully expanded to mean 'extraneous information of the same kind as that which is of interest in a particular situation'. For example, if the biological phenomenon is the movement of some part of the anatomy with respect of its surrounding tissue (say, the pulsation of an artery), then 'noise' will include any movement of the artery with respect to the pick-up device which is not directly due to arterial expansion.

Or again, if the biological signal is the potential difference between two points on the skin (say, the electro-encephalogram) then the 'noise' will include any potential difference appearing across the input electrodes, regardless of whether the source of the disturbance is external (alternating current mains supply) or internal (muscle potentials).

Anyone who has tuned a radio from station to station will have heard between the stations fairly 'white' noise. The expression 'white' here means that the frequency spectrum of the noise is spread over most of the audible band-width, and that it is not concentrated at a particular frequency. It is noticeable that a weak station can be better understood in the presence of 'white' noise than if the interference is coming from another station broadcasting in the same language. This is because, in the case of the interfering station, the 'noise' more closely resembles the signal than do the random background disturbances. The difficulties of separating two signals consisting of the spoken word in the same language may be demonstrated by imagining the definition of the necessary filter. It would certainly be elaborate, depending, for example, on the timbre of the voices or perhaps (with the help of a fast electronic computer) the content of the two messages.

The use of the word 'definition' to mean a functional account in everyday language of the characteristics of a device can form a bridge between the doctor and the engineer, which each can interpret in his own terms. For example, suppose it was necessary to have some reliable indication of each time that the heart pumped blood into the aorta. The phenomenon, the pumping of blood, is not directly detectable in the intact body and the definition of the signal must be based on some aspect of it. Each of these definitions will include 'noise' and the first consideration in the design of a suitable instrument must be the selection by definition of the aspect that gives the best signal-to-noise ratio. Suppose that the problem outlined here was being discussed by interested parties. The blood rushing around the aortic arch causes the whole body to jerk a little, though this aspect of the phenomenon, while directly related to it, is clearly mixed with much 'noise', since the movement of the body due to this cause is very small and is easily confused by incidental movement of the subject. It would, therefore, be rejected as a signal source. Pulsations of an artery would probably also be rejected because of movement of the subject, though this would depend to some extent on the conditions of use and, in some circumstances, anaesthesia, for example, might provide a useful signal.

The heart is a complicated muscle, and each time it beats a small potential difference, the electrocardiogram, may be detected on the surface of the skin. The 'noise' mixed with this wave-form consists of any other potentials of comparable or greater magnitude and, for reliable results, it is not sufficient to rely on detecting this wave-form in its entirety; some aspect of it must be chosen. Discussion would reveal that the R wave is reasonably constant in form and is always present when the heart contracts. The definition of the heart pumping blood into the aorta can therefore be narrowed to only the R wave of the electrocardiogram.

At this point the preliminary discussion is at an end; the doctor knows that the instrument will respond to each R wave, but he also knows that some abortive beats of the heart which pump no blood (extrasystoles) will appear as a beat, since the phenomenon is accompanied by an R wave. He will therefore have to take this aspect of the signal-to-noise ratio into account when interpreting the results. The engineer is left with the problem of re-defining the R wave in electrical terms. This is most difficult, since there is at present very little basic information on the technical nature of the various physiological phenomena. What, for example, is the typical frequency of the R wave? At the moment, it is only possible to make a guess and then test the apparatus embodying the guess on as many subjects as possible. This is a lengthy and tiresome procedure and adds little to the knowledge of the basic phenomenon.

There is at the present time a need for some means of collecting and sorting information of this kind; perhaps an appropriate body might take an interest in the work.

VISCO-ELASTIC PROPERTIES AND THE FRICTION OF SOLIDS

Friction of Polymers: Influence of Speed and Temperature

THE frictional behaviour of polymers as a function of speed has not been systematically studied, and much of the published data are contradictory. In our own laboratory such studies have been limited to very low speeds (10^{-2} cm/sec) where frictional heating is trivial or at very high speeds (10^{4} cm/sec) where frictional heating and its effect on surface layers is dominant. This article describes briefly experiments on the friction of polymers at speeds up to a few 100 cm/sec (20–30 f.p.s.) and at ambient temperatures from − 60° C to 300° C (ref. 1). The polymers range from amorphous and crystalline thermoplastics, where the molecular chains have considerable freedom of motion to highly cross-linked polymers which retain their strength and rigidity up to relatively elevated temperatures.

The friction was measured between a flat rotating disk and a cylindrical pin which was loaded with its axis normal to the plane of the disk. Dead loading was used, and the frictional force was measured with strain gauges attached to suitably mounted spring strips. Heating coils were incorporated so that the ambient temperature could be raised from room temperature to 300° C and the friction chamber could be evacuated to about 10^{-4} mm mercury. The polymer specimens were generally prepared by abrasion under water on silicon carbide papers. Except where otherwise stated, the friction was measured at a pressure of 10^{-4} mm mercury.

Friction of Polytetrafluoroethylene: effect of speed and temperature. Because frictional heating at speeds of a few 100 cm/sec might cause chemical degradation, the first polymer chosen was P.T.F.E., which has high melting and decomposition temperatures and is chemically very stable.

The first marked observation is that the friction rises with increasing speed (Fig. 1). With specimens containing a higher degree of crystallinity the increase is more gradual.

If the rise in friction is due to thermal softening produced by frictional heating, the rise should be observed at lower sliding speeds if the specimen starts off at a higher temperature. Experiments on these lines (see Fig. 1) show that the exact opposite occurs.

Friction and deformation properties. Earlier work[2,3] suggested that the friction of polymers could be expressed mainly in terms of the shear-strength of the material and the area of contact during sliding. Experiments were, therefore, carried out on the shear-strength s and the indentation hardness p as a function of rate of deformation. The ratio s/p did not, however, correlate particularly well with the observed dependence of friction on speed and further investigations on these lines are desirable[4]. It was also considered that energy might be dissipated by the impact of surface asperities, especially during high-speed sliding; but again there was poor correlation, between the observed friction and the impact strength of

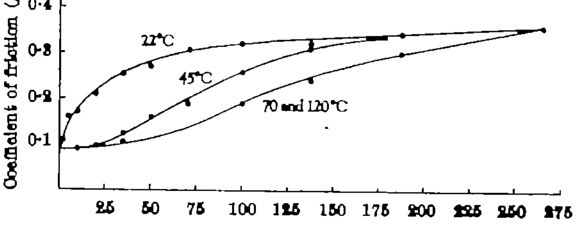

Fig. 1. Variation of friction with speed for P.T.F.E. sliding on P.T.F.E. (40 per cent crystalline). Environment 10^{-4} mm mercury. Load 100 gm. At room temperature the friction rises from about $\mu = 0.07$ to $\mu = 0.3$ when the sliding speed increases to about 100 cm/sec. As the ambient temperature is increased the rise in friction is shifted into the higher speed-range

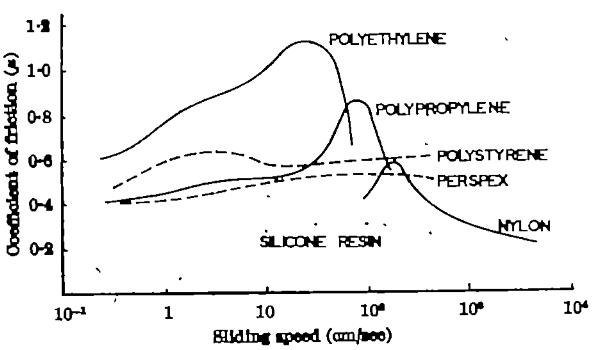

Fig. 2. Variation of friction with speed at room temperature for thermoplastic crystalline polymers (polyethylene, polypropylene, 6,6-nylon), for thermoplastic amorphous polymers (polystyrene, 'Perspex') and for a typical thermo-setting polymer (silicone-resin). With the first group there is a marked rise in friction and a drop when the speed exceeds about 100 cm/sec. The resin shows the least effect of speed on friction

the polymer as a function of temperature and speed of deformation. Finally, experiments were carried out in which a hard steel ball was rolled over the polymers at various speeds. This reproduces approximately the bulk deformation losses occurring during sliding[4]. It was found that under the conditions of our experiments this deformation component constituted a small fraction of the observed sliding friction, a result in close agreement with the work of Flom[5].

Frictional behaviour of other polymers. Similar experiments were carried out on thermoplastic crystalline polymers (polyethylene, polypropylene, 6,6-nylon) on thermoplastic amorphous polymers (polystyrene, polymethyl-methacrylate) and on thermo-setting polymers such as silicone-, polyester- and formaldehyde-resins. Some typical results are shown in Fig. 2. It is seen that with the crystalline polymers there is a marked increase in friction with speed and a drop above about 100 cm/sec. At higher ambient temperatures, not shown in Fig. 2, the curves are again displaced towards higher speeds. With the amorphous polymers the variation of friction with speed (and temperature) is less marked, while with the cross-linked polymers there is practically no change of friction with speed. It is evident that the friction becomes less dependent on speed and temperature as the polymer structure becomes more rigid. This may be seen from Table 1, in which the physical properties of the polymers are compared with their friction–velocity dependence. In general, a high impact-strength and a large elongation-to-fracture are associated with marked flexibility of the polymer chain. It is apparent that polymers with these properties have a large friction–velocity dependence.

Table 1. PHYSICAL PROPERTIES OF SOME POLYMERS AT ROOM TEMPERATURE

Polymer	Character	Impact strength notched Izod (ft. lb.)	Tensile strength lb./in.^{2}	Elongation at tensile break (per cent)	Friction–velocity dependence
I. *Thermoplastic crystalline*	Flexible chains				
P.T.F.E.		4	2,500	50–400	Marked
Polythylene		3	2,500	450	Marked
6,6 Nylon		2·5	11,500	90	Marked
Polypropylene		1	5,000	220	Marked
II *Thermoplastic amorphous*	Some flexibility: 'glassy' at room temperature				
Polymethylmethacylate		0·4	8,000	5	Moderate
Polystyrene		0·2	4,500	1	Moderate
III. *Thermosetting cross-linked*	Rigid structures				
Epoxy resin		0·2	10,000	1·7	Very little
Polyester		0·2	5,000	2	Very little
Melamine		0·3	10,000	0·7	Very little

Mechanism of polymer friction. These results show that under the conditions of our experiments the major part of the friction does not arise from bulk deformation losses, in contrast to results obtained with well-lubricated surfaces[7]. Nor does it appear to arise from impact with surface asperities. The greater part must arise from some type of adhesion mechanism.

Experimentally the most striking observation is that the friction increases with speed, and that if the temperature is raised the increase in friction occurs at a higher sliding speed. The speed effect cannot, therefore, be due primarily to frictional heating. It is useful to plot the friction as a function of speed, using a linear scale for the friction and a logarithmic scale for the speed. Results for P.T.F.E. are given in Fig. 3, the results for speeds greater than 1,000 cm/sec being taken from the work of Bowden and Persson[8]. The friction rises to a maximum and then falls. At higher temperatures the curve is displaced into the region of higher speeds.

These curves closely resemble the dynamic loss characteristics of a polymer as a function of frequency of deformation. A schematic description is inserted in the top left-hand corner of Fig. 3. The damping loss rises to a maximum at a characteristic frequency and then falls as the frequency increases. Raising the temperature shifts the curve into the region of higher frequency.

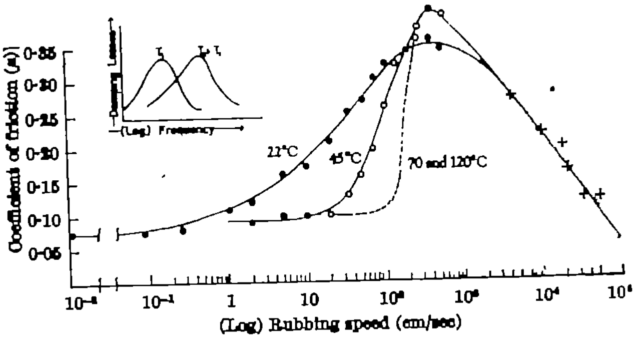

Fig. 3. Friction of P.T.F.E. on P.T.F.E. (40 per cent crystalline) as a function of sliding speed. Speeds greater than 1,000 cm/sec are from Bowden and Persson (ref. 8). The insert shows damping losses as a function of frequency. If the temperature is raised the peak is shifted to a higher frequency

This suggests that the frictional behaviour involves time- and temperature-dependent properties which are closely connected with the visco-elastic properties of the polymer. McCrum[9] has found a marked damping peak for P.T.F.E. at 176° K at a frequency of 1 c/s. By using these data and assuming an activation energy of 18 kcal/gm mol (ref. 9) we may apply an Arrhenius shift to calculate the position of the peak at, say, 22° C. It occurs at a frequency of about 10^9 c/s. In the frictional experiments at this temperature the maximum friction occurs at a speed of about 500 cm/sec. Without specifying a detailed mechanism we may regard the sliding at the interface as resembling the shear process in a visco-elastic medium. Then to obtain a frequency of 10^9 this implies a displacement of about 50×10^{-8} cm, that is, 50 Å. This is of molecular dimensions. Similar results are observed with the other polymers studied, displacements of the order of 10–100 Å being deduced. This therefore indicates an adhesion process on a molecular scale rather than a process involving asperity encounters or sub-surface deformation. This is supported by the observation that the deformation component of friction constitutes only a small part of the observed friction.

There is, of course, considerable uncertainty involved in applying the damping-loss characteristics to explain the frictional behaviour. This arises primarily from the effect of frictional heating. The damping-loss characteristics describe the properties of the material at well-defined temperatures. In the friction experiments the frictional process itself produces surface heating so that the exact temperature of the material at the sliding interface is not known with any precision. (The same uncertainty applies to the results of Bulgin, Hubbard and Walters[10] in their work on the friction of rubber.) For speeds less than, say, 100 cm/sec the temperature rise is probably of the order of tens of degrees C. At higher speeds it can be very much greater. For example, the very low friction shown on the right-hand portion of Fig. 3 obtained at speeds of 10⁴ cm/sec is almost certainly due to surface melting[8]; sliding occurs on a thin molten surface layer of relatively low viscosity. However, many of the polymers show a rise and fall in friction within a speed range of 100 cm/sec (Fig. 2). Under these conditions surface melting cannot be an important factor.

The most striking confirmation for this connexion between the frictional behaviour and the visco-elastic properties of the sliding materials is provided by the experiments of Grosch on rubber (following communication). He carried out friction measurements over a wide range of temperatures and sliding speeds, but the sliding speeds never exceeded 3 cm/sec, so that frictional heating was always trivial. His results show that the whole of the frictional behaviour can be described by a single 'master-curve' if the data are subjected to the Williams, Landel, Ferry[11] transform. This transform applies to the damping properties of polymers above their glass transition temperature. The new point brought out in the present work is that a similar correlation is probably valid for polymers below the glass-transition temperature. Here, of course, the transform involves an Arrhenius shift rather than the Williams, Landel, Ferry transform.

In a qualitative way this broad correlation is supported by the comparative behaviour of polymers of different types, the main factor being the flexibility of the polymer chains. Linear crystalline polymers which have the greatest impact strength and the largest elongation-to-fracture in tension are polymers with the greatest chain-flexibility. They show the most marked dependence of friction on speed. Linear amorphous polymers are less flexible and exhibit a smaller variation of friction with speed. (However, they show a marked increase in friction when they reach the glass–rubber transition temperature.) Finally, cross-linked thermo-setting polymers which have the most rigid structures and are relatively brittle show the smallest dependence of friction on speed.

Earlier work showed that with polymeric materials the deformation component of friction is a function of the visco-elastic or hysteresial properties of the polymer. The results described here show (in agreement with the work of Grosch (following communication) and of Bulgin, Hubbard and Waters[10]) that the adhesion component involves speed and temperature-dependent properties which also reflect the visco-elastic properties of the sliding materials.

We thank Dr. F. P. Bowden for his continued encouragement, Messrs. Small and Parkes for a grant to the Laboratory, and especially to Dr. A. Schallamach and Mr. K. A. Grosch for the free discussion of their frictional work on rubber prior to publication.

Relation between the Friction and Visco-elastic Properties of Rubber

IT has recently become increasingly apparent that friction of rubber on hard surfaces is due to two causes: (1) the adhesion of rubber to the surface; (2) to deformation occurring in the rubber when it slides on rough surfaces. Schallamach[1] and Bartenev[2] showed that the adhesional friction could be considered as an activated rate process with activation energies similar in magnitude to those associated with the visco-elastic behaviour of the rubber, and Tabor and others explained lubricated and rolling friction of rubber in terms of deformation losses[3-5].

Experiments have now been carried out, sliding several rubbers of widely differing visco-elastic properties on smooth and rough surfaces over a wide range of temperatures and sliding velocities. The highest value of the sliding velocity was kept below 3 cm/sec so that rises in temperature in the interface were small and could be neglected.

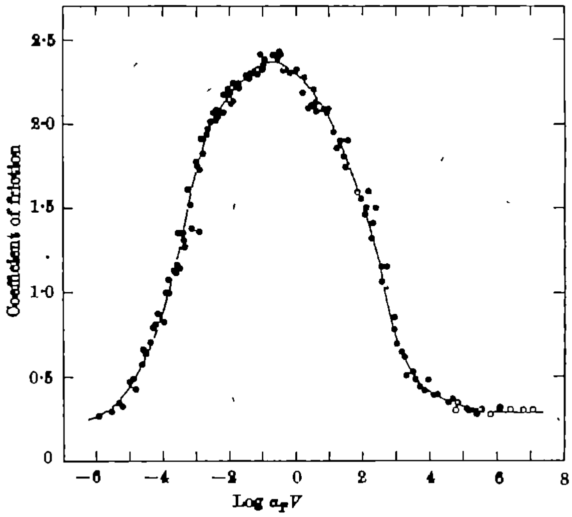

Fig. 1. Composite master curve for the coefficient of friction of an acrylonitrile–butadiene gum vulcanizate sliding on glass; reference temperature: 20° C

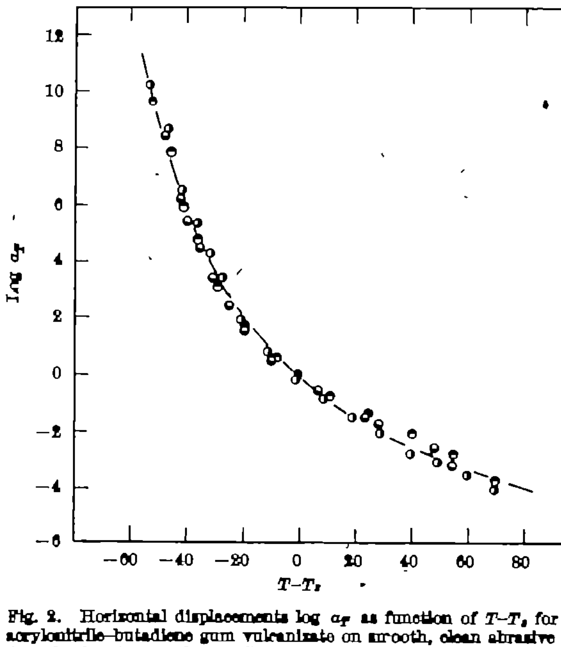

Fig. 2. Horizontal displacements log a_T as function of $T-T_s$ for the acrylonitrile–butadiene gum vulcanizate on smooth, clean abrasive and dusted abrasive surfaces. Solid line represents W.L.F. equation, $T_s = +32°$ C

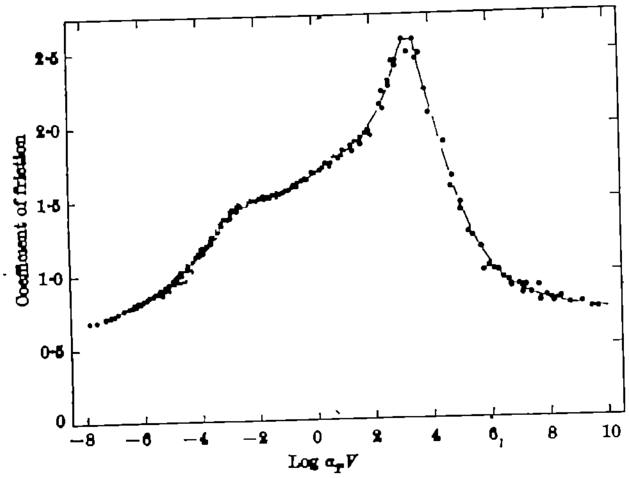

Fig. 3. Composite master curve for the coefficient of friction of an acrylonitrile–butadiene gum vulcanizate sliding on clean silicon carbide paper; reference temperature: 20° C

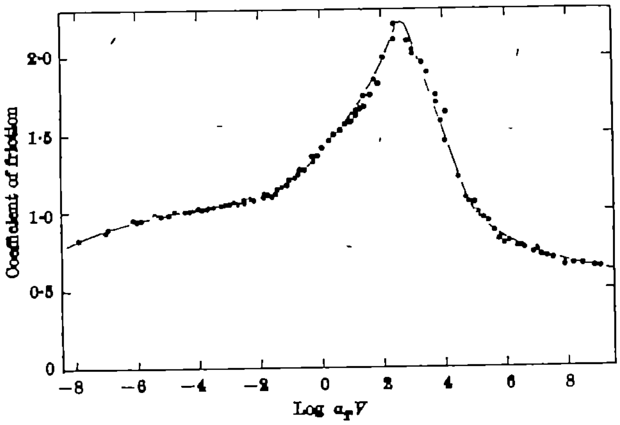

Fig. 4. Composite master curve for the coefficient of friction of an acrylonitrile–butadiene gum vulcanizate sliding on a silicon carbide abrasive, dusted with magnesium oxide powder; reference temperature: 20° C

It is found that curves giving the coefficient of friction as a function of the sliding velocity at different temperatures are segments of a single 'master curve' which describes the coefficient of friction over an extended range of sliding velocities at a selected reference temperature T_0. The master curve can be constructed from the individual segments by displacements parallel to the logarithmic velocity axis until they superpose with the curve at the selected reference temperature. An example of such a master curve is shown in Fig. 1 for an acrylonitrile-butadiene rubber vulcanizate sliding on glass. Similar curves have been obtained with other non-crystallizing rubbers on smooth and rough surfaces. This close connexion between rate and temperature dependence is common to the visco-elastic properties of a large number of polymers[6–8]. Williams, Landel and Ferry (W.L.F.)[9] have shown that the horizontal displacements necessary to construct the master curve can be expressed by a single relation, the W.L.F. equation, independent of the material and the type of visco-elastic property in question if a standard reference temperature T_s is chosen instead of the arbitrary reference temperature T_0. As Fig. 2 shows, friction conforms very closely to this general visco-elastic behaviour, the displacement functions being in excellent agreement with the W.L.F. equation. The standard reference temperatures are material constants simply related to their glass transition temperatures T_g, that is, $T_s \simeq T_g + 50$, and here, too, there is close agreement between T_s values derived from friction experiments and this requirement. The friction of a rubber on a particular surface is therefore described completely by its master curve and the glass transition temperature of the rubber.

Master curves obtained on a smooth surface are similar for all rubbers in that they are almost symmetrical around a single maximum. If direct contact between rubber and glass is prevented by dusting the surface with a fine powder (magnesium oxide was used in the present case), the friction remains almost constant over the whole range of velocities and temperatures, demonstrating that friction on a smooth track is due only to interfacial adhesion between rubber and surface. The velocity of maximum friction, V_s, increases as the glass transition temperature of the rubber decreases. This can be related quantitatively to the frequency $f_{E''}$ at which the loss modulus is a maximum if compared at the same temperature, thus:

$$\frac{V_s}{f_{E''}} = \lambda = 6 \times 10^{-7} \text{ cm}$$

irrespective of the rubber. As the loss modulus reflects the relaxation spectrum of the rubber[10] maximum adhesional friction of rubber appears to be linked to the relaxation time τ_m for which the spectrum is a maximum:

$$V_s \tau_m = \lambda$$

Friction curves on a clean rough surface, such as an abrasive paper, are always asymmetrical and the maximum usually occurs at a higher velocity than on the smooth surface, with a distinct hump appearing on the curve near the velocity for which the friction on the smooth surface is a maximum (Fig. 3). As the rubbers investigated had only a single relaxation peak, the maximum and the hump on the friction curve must be associated with the two friction mechanisms. When magnesium oxide powder is applied to the rough surface, the hump disappears while the maximum remains almost unaltered in magnitude and position as shown in Fig. 4. The maximum on the dusted rough surface appears therefore to be due to deformation losses and a correlation of the frictional behaviour with the visco-elastic properties of the rubber shows that the velocity of maximum friction on the rough track V_R bears a constant relation to the frequency f_T for which the loss factor has its maximum, both being compared at the same temperature, that is:

$$\frac{V_R}{f_T} = \alpha = 1{\cdot}5 \times 10^{-2} \text{ cm}$$

The distance α agrees closely with the spacings of the abrasive particles on the track surface used.

These experiments thus demonstrate clearly the existence of the two friction mechanisms, that is, adhesion occurring along the slopes of the asperities and cyclic deformation occurring in the rubber as it passes over them, both being visco-elastic in nature.

I thank Drs. D. Tabor and A. Schallamach for their interest.

NATURE OF ORIENTATIONAL DEFECTS IN ICE

By Prof. J. D. DUNITZ

Organic Chemistry Laboratory, Swiss Federal Institute of Technology, Zurich

Each oxygen atom in ice is surrounded tetrahedrally by four others at a distance of 2·76 Å (ref. 1). Bernal and Fowler[2] proposed that water molecules are preserved in the crystal and that there is one hydrogen atom between every pair of oxygen atoms, which are thus linked by hydrogen bonds. According to Pauling[3], all configurations compatible with these conditions occur with equal probability, giving a disordered structure which does not become ordered on cooling. This description of the hydrogen atom arrangement can be regarded as confirmed by the more recent results obtained by neutron diffraction[4].

In order to account for the electrical properties of ice[5], the existence of two kinds of defects, ionic and orientational, has been postulated by Bjerrum[6]. In ionic defects, protons are supposed to have migrated from one oxygen atom to another, thus giving rise to an equal number of H_3O^+ cations and HO^- anions. In orientational or valence defects (Fig. 1), water molecules are supposed to have rotated through 120° about an O—H . . . O axis. Such a rotation generates a vacant O . . . O separation (L-defect) and a doubly occupied O—H . . . H—O one (D-defect). A subsequent or coupled rotation of the adjacent water molecule into the vacant site has the effect of separating the D- and L-defects, which are then supposed to migrate through the crystal, thus providing a mechanism for the rotation of water molecules.

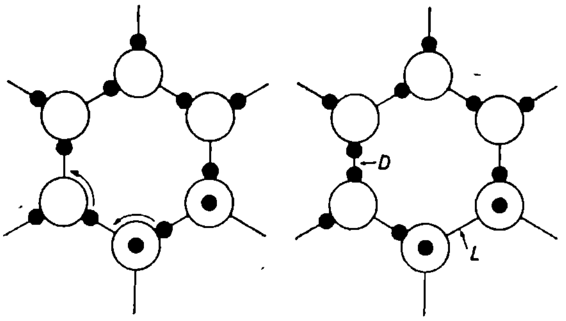

Fig. 1. Formation of a DL-pair of orientational defects in ice according to Bjerrum

The main objective of this article is to direct attention to the unlikelihood that D-defects, as already defined, can exist. Another type of defect, also complementary to the L-defect, will be proposed as an alternative to the D-defect. Finally, it will be shown that rotation of water molecules is more likely to occur by diffusion of L-defects than of the complementary type of defects. The discussion will be based on the assumption that the structures of the defects can be related to their energies; but, to anticipate certain quite legitimate criticisms, it must be emphasized that the present state of theory permits this to be done only in a rather crude fashion. We shall frequently have to be content with rough order of magnitude estimates, little better than guesses, of the energy quantities involved.

The formation of a pair of D- and L-defects corresponds to the reaction 2 $N \rightarrow$ D + L, where N represents a hydrogen bond. If E_N is the energy associated with the formation of a hydrogen bond from separated water molecules and E_D and E_L the energies associated with the formation of D- and L-defects respectively, also from separated water molecules, then the energy of the reaction is:

$$E_{DL} = E_D + E_L - 2E_N$$

The experimental value[7] of E_{DL} is 15·7 kcal mole^{-1} (0·68 ± 0·04 eV), that of $-E_N$ is between 3 and 7 kcal mole^{-1} (ref. 8). Experimental values of E_D and E_L separately are not available.

Bjerrum estimated the energy of a fault site on the basis of an electrostatic point charge model in which water molecules are represented as regular tetrahedra of radius 0·99 Å with charges of ± 0·171 e (e being the electronic charge) at the corners. According to this model, $E_D = E_L$, since both types of defect are regarded as identical apart from reversal of all charges. Bjerrum obtained values of 6–7 kcal mole^{-1} for E_D, E_L and $-E_N$, corresponding to about 24 kcal mole^{-1} for E_{DL}. The agreement with the experimental values of E_N and E_{DL} is satisfactory but, nevertheless, the values for E_D and E_L are easily shown to be unreasonable.

The energy of a L-defect is almost certainly much lower than that of a D-defect. The L-defect consists of two water molecules separated by about 2·76 Å and not linked by a hydrogen bond. Hence $E_L - E_N \sim 3–7$ kca lmole^{-1}, the energy required to break a hydrogen bond, and $E_L \sim 0$. It may be remembered that the van der Waals radius of oxygen and the crystal radius of O^{-2} are both given[9] as 1·40 Å and that many crystal structures are known in which oxide ions are separated by distances of 2·5–2·8 Å.

On the other hand, Bjerrum's estimate for the energy of a D-defect seems much too low. Since the oxygen–oxygen distance in ice is 2·76 Å and the O—H distance is 0·96 Å in water[10] and probably close to this value in ice[11], Bjerrum's model of "two protons placed between two adjacent oxygen atoms" implies that the two hydrogen atoms in the doubly occupied bond would only be about 0·8 Å apart. At this distance they would certainly exert a very strong repulsion on one another. No structure in which two hydrogen atoms are separated by such a short distance is known. The shortest reported distances between hydrogen atoms not bonded to a common atom occur in derivatives of *cyclo*nonane[12] and *cyclo*decane[13] and lie in the range 1·8–2·0 Å. It is probable that the strain energies of these *cyclo*alkanes, amounting to some 12 kcal mole^{-1} (ref. 14), are derived largely from the occurrence of such short hydrogen–hydrogen distances which can be regarded as already corresponding to repulsion energies of the order of a kcal mole^{-1} or so. The hydrogen–hydrogen distance in the supposed D-defect would thus be less than the smallest reported distances by a factor of about 2·25, corresponding to a tremendous increase in the mutual repulsion energy for any reasonable assumption for the form of the potential energy curve in this region.

Abandoning the point-charge model, we can most simply regard a D-defect as a pair of water molecules oriented so that two of the O—H bonds point directly at one another. This arrangement is not conducive to the formation of a hydrogen bond, and the energy of the system, E_D, is predominantly the interaction energy of two non-bonded hydrogen atoms separated by about 0·8 Å.

A number of different potential energy functions for the interaction of two non-bonded hydrogen atoms have been proposed by several authors and used to estimate hydrogen–hydrogen interaction energies in organic molecules. Three such functions are:

$$E(r) = 10{,}000\exp(-4{\cdot}6\,r) - 49{\cdot}2/r^6 \text{ (ref. 15)} \qquad (1)$$

$$E(r) = 6{,}600\exp(-4{\cdot}08\,r) - 49{\cdot}2/r^6 \text{ (ref. 16)} \qquad (2)$$

$$E(r) = (166/r + 366 + 23{\cdot}1\,r + 580\,r^2 + 1{,}828\,r^3)\exp(-4{\cdot}35\,r) \text{ (ref. 17)} \qquad (3)$$

where E is expressed in kcal mole^{-1} and r in Å. The first two functions are derived semi-empiricially from data pertaining to large values of r and are evidently quite incorrect for small r values when the negative attraction term in the formulæ dominates over the positive repulsion one. This can be corrected for by inclusion of an additional repulsive term, say, $1{\cdot}0 \times r^{-12}$. The third function is based on a theoretical approximation[18] to the triplet state energy of the hydrogen molecule; it is probably the most reliable for r values of less than about 1 Å. For r = 0·8 Å all three functions lead to an interaction energy of about 60 kcal mole^{-1}, a value that is much higher than Bjerrum's estimate for E_D and quite incompatible with the experimental value for E_{DL}.

Apart from this discrepancy, there is another unsatisfactory feature of the D-defect proposed by Bjerrum. Since repulsion between the two non-bonded hydrogen atoms is the dominating force, any movement of these hydrogen atoms from the oxygen–oxygen line must lower the energy of the system. The situation represented in Fig. 1, whatever its energy may be, must correspond to an energy maximum with respect to rotation of one or both water molecules, and although it might conceivably correspond to a transition state for some reaction it cannot correspond to a stable arrangement of water molecules.

That the collinear O—H . . . H—O situation corresponds to an energy maximum has recently been recognized by Cohan, Cotti, Iribarne and Weissmann[19], who used a more elaborate point charge model based on certain quantum mechanical approximations to estimate the various energy quantities involved. These authors give a value of 50 kcal mole^{-1} (2·12 eV) for E_{DL}, assuming the D-defect to be collinear. As the two water molecules involved in the D-defect are rotated as rigid bodies out of their head-on position, E_{DL} decreases, reaching a minimum of about 25 kcal mole^{-1} (1·06 eV at a rotation angle of 20°–25°), when allowance is made for the concomitant variation in the energies of the six surrounding hydrogen bonds. A 22·5° rotation of both water molecules increases the hydrogen–hydrogen distance to about 1·3 Å, corresponding to an interaction energy of some 15–23 kcal mole^{-1} according to the potential functions (1)–(3). Thus the foregoing estimate of 25 kcal mole^{-1} for E_{DL} seems fairly reasonable. These authors consider the model with both water molecules rotated out of the head-on position to be a satisfactory representation of a D-defect, but they did not, apparently, examine other possibilities. In particular, the variation in the energy for rotation angles of more than 30° was not examined, nor the effect of rotating only one molecule of the pair.

These considerations have shown that the Bjerrum model of the D-defect, at least in its collinear form, corresponds to a too high energy. The question then arises: Are there other, energetically more reasonable models? Examination of the structure of ice shows that there is indeed such a model, which is illustrated in Fig. 2 and described here.

If a water molecule in the normal ice structure is rotated about an O—H . . . O axis by 60° instead of by 120°, its second hydrogen atom is brought into a position midway between an O . . . H—O and an empty O . . . O (L-defect) direction. This situation is clearly unstable, for there will be an uncompensated force tending to restore the original situation in which all O—H bonds pointed along oxygen–oxygen directions. However, a subsequent or coupled rotation of the adjacent water molecule through 120° to bring one of its hydrogen atoms into the empty O . . . O direction is all that is required to make a stable arrangement.

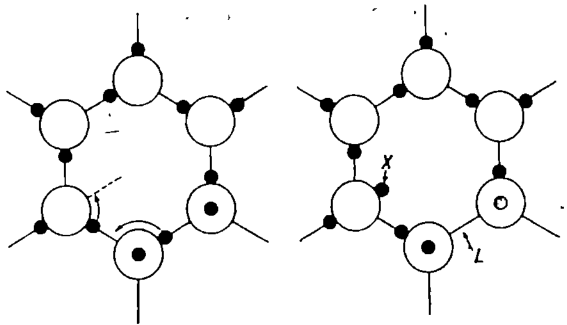

Fig. 2. Formation of an XL-pair of orientational defects in ice

The 'extra' hydrogen atom is now symmetrically situated between two neighbouring O . . . H—O bonds (to prevent confusion with the Bjerrum D-defect we shall refer to this type of situation as an X-defect) and is separated from the L-defect, which cannot spontaneously diffuse back. Once the defect pair has been formed and separated, both kinds of defects can diffuse through the crystal by jumps that involve rotation of water molecules. Each jump of the X-defect involves a coupled rotation of two adjacent water molecules, each through 60°; each jump of the L-defect involves rotation of one water molecule through 120°. In the Bjerrum model, each jump of either kind of defect involves rotation of one molecule through 120°. This appear to be the only formal difference between the two types of mechanism and the only question is: which is the more reasonable from an energetic point of view?

As in the case of the Bjerrum model, an exact calculation of the energy of an X-defect is out of the question, but again a crude estimate can be made by considering the non-bonded interactions. The extra hydrogen atom associated with an X-defect is about 1·5 Å from each of its two closest hydrogen neighbours on other molecules, assuming best possible hydrogen bonds and tetrahedral HOH angles. This distance is much longer than the hydrogen–hydrogen distance in the collinear D-defect (0·8 Å) and appreciably longer than in the D-defect with 22·5° rotation of both water molecules from collinearity (1·3 Å). But it is still too short, compared with the shortest known non-bonded hydrogen–hydrogen distance of 1·8–2·0 Å. It may, however, be easily increased to about 1·7 Å by appropriate 20° deviations of the three O—H bonds involved from their ideal directions. Such deviations can be achieved by rotating the water molecules as rigid bodies, thus weakening the local hydrogen bonding system, or by distortion of the HOH angles from the tetrahedral value. Both modes are relatively cheap in energy for small deformations and the energy increment for these 20° deviations, shared between both modes, is not expected to exceed a few kcal mole^{-1}. The interaction energy of two non-bonded hydrogen atoms separated by 1·7 Å is estimated to be 2·0, 4·4 and 6·9 kcal mole^{-1} from functions (1), (2) and (3) respectively. Equation (3) is probably the least reliable in this region. A value of about 10 kcal mole^{-1} for the energy of two such interactions is thus at least of the correct order of magnitude. We then have $E_X \sim 10$, $E_L \sim 0$ and $-E_N \sim 5$ kcal mole^{-1} and the experimental value of 16 kcal mole^{-1} for E_{XL} seems quite in keeping with these estimates. The X-defect is therefore regarded as more reasonable, on energetic grounds, than the D-defect as proposed by Bjerrum.

It remains now to consider the activation energy for diffusion of such defects. The experimental value has been given[5] as 5·4 kcal mole^{-1} (0·235 eV). Now, each jump of an L-defect involves a rotation of a single water molecule through 120°. The half-way position, with the rotating O—H bond at an angle of 60° to both O . . . O directions, is probably close to the transition state. Since no short non-bonded interactions are present in this position, the activation energy cannot be more than the energy of the hydrogen bond that is broken in the process, and it is unlikely to be much less. Thus a value of about 5 kcal mole^{-1} seems reasonable as the activation energy for diffusion of an L-defect.

Diffusion of an X-defect involves rotation of two molecules, each through 60°. The activation energy for this process is more difficult to estimate but the transition state is probably rather similar to that proposed by Cohan, Cotti, Iribarne and Weissmann[19] for the D-defect, but with both molecules rotated out of the head-on position by about 30°. From their results, this state appears to be stabilized by about 25 kcal mole^{-1} (the potential minimum at 20°–25° is quite shallow) with respect to the collinear situation. If this and our previous energy estimates are roughly correct, then the activation energy is 15–25 kcal mole^{-1}, that is, appreciably larger than for diffusion of an L-defect. It seems reasonable that the activation energy for diffusion of an X-defect should be larger than for an L-defect. The forces holding the X-defect in its equilibrium position depend on hydrogen–hydrogen repulsions, deformations of HOH angles and rotations of water molecules from preferred hydrogen bond directions. At the equilibrium position, these forces balance out but all three components, taken separately, are strained so that any movement of the system from equilibrium must be associated with a fairly steep increase in the potential energy. On the other hand, the force holding the L-defect in equilibrium depends on only one of these factors, namely, the dependence of the hydrogen bond energy on the O—H . . . O angle.

These considerations suggest that the a.c. conductivity of ice arises almost exclusively from molecular rotations associated with diffusion of L-defects. In pure ice, the active L-defects can only be formed together with an equal number of inactive X-defects, but if the latter have only a minor influence on the electrical properties, this should be apparent from measurements on ice doped with small amounts of ammonia and hydrofluoric acid. Addition of HF molecules should increase the number of active sites and decrease the number of inactive ones, whereas addition of NH_3 molecules should have just the opposite effect.

I thank Prof. H. Gränicher for several useful discussions.

Unfortunately, some of the results of this paper are expressed in terms that give rise to possibilities of misunderstanding. It is said that the model leads to $E_X = -0·31$ eV, $E_{DL} = 2·12$ eV and $E_L = 0·14$ eV. No value for E_D is given. Since E_X is certainly negative and E_{DL} positive, the results reported leave the sign of E_L and the magnitude of E_D in question.

SYNTHESIS OF ORGANIC COMPOUNDS BY ELECTRIC DISCHARGES

By Prof. J. ORÓ

Lawrence Radiation Laboratory, University of California, Berkeley, California, and Department of Chemistry, University of Houston, Houston, Texas

THE use of electric discharges for the synthesis of organic compounds under possible primitive Earth conditions was initiated by Miller[1–4]. Miller obtained some amino-acids, hydroxy acids and a few other organic compounds by the prolonged action of spark discharges on mixtures consisting essentially of methane, ammonia and water. These results have been confirmed by other investigators under identical or slightly different conditions[5–10].

Further investigations on this synthesis were carried out in this laboratory with the hope of obtaining additional amino-acids and perhaps also some ultra-violet-absorbing compounds.

In order to increase the probability of formation of new compounds, ethane was also included in the reaction mixtures. The use of ethane in these experiments is justifiable since the C_2 species has been detected spectroscopically in star atmospheres, comets and interstellar space[11,12]. In order to determine the over-all pattern of the compounds formed, ^{14}C-hydrocarbons, mainly ^{14}C-methane, were used as tracers. Furthermore, it was thought that the patterns obtained by autoradiography of two-dimensional chromatograms of the products may help in establishing a correlation between these and other experiments[13–15].

The results obtained show that an appreciable number of organic compounds are formed by the action of electric discharges on the foregoing mixtures. The products obtained include glycine, alanine, aspartic acid, asparagine, isoleucine (or isoasparagine), glycinamide and possibly proline; a yellowish oil, a highly insoluble polymer, and several ultra-violet-absorbing compounds. The formation of other products which give purple, green and brown derivatives with ninhydrin, suggesting the presence of amines, amino-nitriles, amino-amides and peptides, has also been observed. The ^{14}C-patterns produced by autoradiography of two-dimensional chromatograms of the products are reasonably simple. They are not much more complex than the patterns produced by spraying the same chromatograms with ninhydrin.

Conditions of the reaction. Fig. 1 shows the design of the apparatus used, which consists of a 3-l. flask provided with removable tungsten electrodes, and with inlets and outlets for reactants and products. Temperature and pressure of the system were measured by means of a thermometer and a vacuum gauge, respectively. The liquid phase was agitated by means of a magnetic stirrer. The spark gap of the electrodes was usually 1·5 cm; but in later experiments it was increased to 3 cm. The current was supplied by a transformer (Thordarson Electric Manufacturing Co.: V.P. 110, Sec. 25,000, V × A 1,000, cycle 50–60) from an X-ray apparatus connected to a 110-V line through a 'Variac' which was used to regulate the voltage. The discharge voltage was approximately 10,000 V when the spark gap was 1·5 cm and 15,000 V when the electrodes were separated 3 cm.

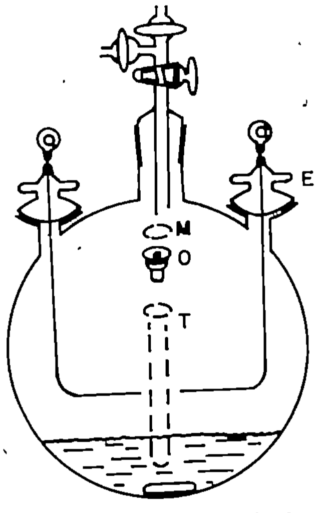

Fig. 1. Diagram of apparatus for the synthesis of organic compounds in an electric discharge. *E*, removable electrodes; *M*, manometer connexion; *O*, gas-sampling orifice; *T*, thermometer well. Dotted lines are used to represent parts on the back of the reaction vessel

After complete evacuation of the apparatus, 300 ml. of boiled distilled water were admitted into it. Then, methane, ethane and concentrated ammonium hydroxide (15 M) were allowed into the system. Pressure readings were obtained after the introduction of each component. Whenever ^{14}C-hydrocarbons (1 mc. or less) were used, they were admitted into the evacuated apparatus before anything else (water, non-radioactive hydrocarbons and ammonium hydroxide). All the reactants used were C.P. reagents. Care was exercised to prevent any infiltration of air into the system. Apart from this, no special treatment was followed to eliminate traces of air possibly present in the reagents. Table 1 gives the results for each experiment.

Table 1. COMPOSITION OF GAS MIXTURES AND OTHER DATA OF THE EXPERIMENTS WITH ELECTRIC DISCHARGES

	Exp. No.						
	S–1	*S*–2	*S*–3	*S*–4	*S*–5	*S*–6	*S*–7

Conversion of ^{14}C-methane to volatile water-soluble products (per cent)					28	15	

*Residual gaseous products from *S*–5, containing probably a large amount of hydrogen.

Course of the reaction. The reaction time was only 7 h or less, instead of the usual one week. This was done, in part, to make possible the detection of some of the presumed amino-acid intermediates such as amino-nitriles and amino-amides, and in part, to have reaction times comparable with those of similar experiments carried out with high-energy electrons[13–15].

The course of the reaction in the gas phase was followed by measuring the increase with time of the pressure of the system (Fig. 2). It can be seen that under the conditions used, the increase in pressure levels off after 7 h or less, depending on the concentration of the reactants. The temperature oscillation between the start and end of the experiment was only 2° or 3°, usually from 27° to 30° C, and the pressure values were not corrected for the resulting small variations in pressure.

By comparison of different experiments it can be seen that the curves are quite reproducible, and their shape is mainly determined, as might have been expected, by the initial reactant concentration in the gas phase and by the energy put into the system (spark gap). Analyses of the gas phase were not made, and therefore the nature of the gases responsible for the increased pressure was not determined. However, on the basis of previous results and knowing that dehydrogenation takes place with electric discharges, it is considered that hydrogen was one of the main gases formed. Thus, the levelling off would simply indicate that equilibrium of the dehydrogenation reaction in the gas phase at a given discharge voltage had been reached. By increasing this voltage the equilibrium would be displaced to higher hydrogen pressures. Such a change of equilibrium can be seen in curve *S*–5 of Fig. 2.

The curves of Fig. 2 should not only give an indication of the formation of hydrogen but also of the resulting dehydrogenation products, that is, alkenes, alkynes, aldehydes, hydrogen cyanide, nitriles, hydrazine, etc., which are supposed to be precursors of organic and biochemical compounds. These curves, however, do not give any information on the processes which go on in the liquid phase. It is obvious that condensations, and mainly hydrolytic and ammonolytic reactions, will continue in the liquid phase even after the gas phase appears to have reached equilibrium.

Analysis of products. In general, the analysis was undertaken as soon as the electric discharge was discontinued. The gas phase was not analysed. The total volume of the liquid phase (about 350 ml.) was filtered and then concentrated in a vacuum rotating evaporator at 40°–45° C. When the volume had been reduced to less than 20 ml. it was transferred to a tared 50-ml. flask and the evaporation was continued to dryness. The distillate was collected in a very large trap immersed in liquid nitrogen. The distillates were set aside. The flasks with the dry residues were first weighed (Table 1) and the residues were then dissolved in 5 ml. 0·1 N hydrochloric

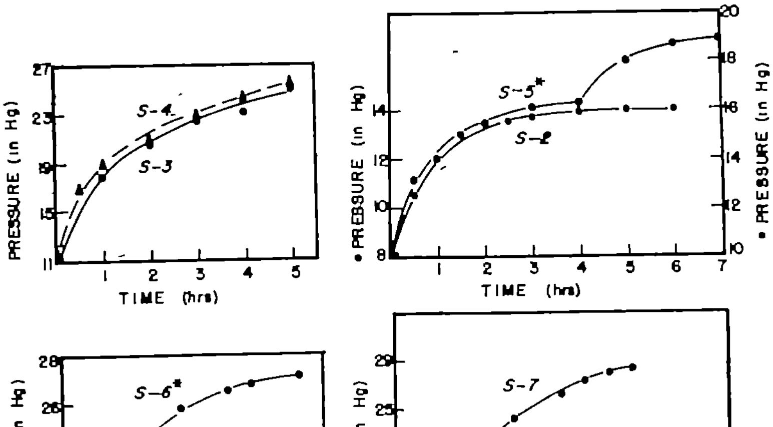

Fig. 2. Course of the reaction in the gas phase of the experiments with electric discharges The increase in pressure is supposed to be due mainly to the hydrogen formed by dehydrogenation reactions. The experiments marked with an asterisk were carried out with ^{14}C-reactants. At the fourth hour of experiment *S*–5, the spark gap was increased from 1·5 to 3 cm.

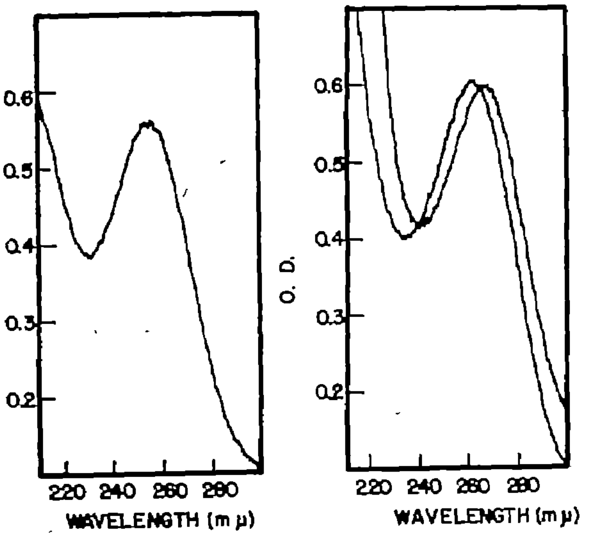

Fig. 3. Ultra-violet spectra of two compounds eluted from two-dimensional paper chromatograms of experiment *S*–3. The spectrum of *A* (left) was obtained in 1 *N* hydrochloric acid and the spectra of *B* (right) in 0·1 *N* hydrochloric acid and in 0·12 *N* sodium hydroxide

acid. The solutions thus obtained were used in the subsequent analyses which were carried out by two-dimensional paper chromatography, ion exchange chromatography, autoradiography and spectrophotometry.

Ultra-violet-absorbing compounds. The solutions from the first three experiments, after appropriate dilution with 0·1 N hydrochloric acid, were directly examined for ultra-violet-absorbing compounds. They gave somewhat similar spectra. An aliquot of *S*-1 diluted 25 times showed a sharp absorption band at about 236 mμ (O.D. ≃ 0·85). An aliquot of *S*-2 diluted 100 times and also an aliquot of *S*-3 diluted 200 times, showed a shoulder at about 236 mμ (O.D. ≃ 0·6) and a broad absorption band between 250 and 300 mμ.

Aliquots of the same solutions were then analysed by two-dimensional chromatography by the ascending technique, using Whatman No. 1 paper and *n*-propanol/1 N ammonium hydroxide, 3 : 1 (PA) and *n*-butanol/acetic acid/water, 4 : 1 : 1 (BAW) as solvents. The dry chromatograms were scanned with a short wave-length (2537 Å) ultra-violet-light lamp. Two major ultra-violet-absorbing compounds were detected in the three chromatograms. One of these two compounds (*A*) had R_F 0·80 in PA and 0·40 in BAW. The other (*B*) had R_F 0·42 in PA and 0·17 in BAW. By the intensity of the spots the formation of both these compounds followed in this quantitative order in the three experiments: *S*-3 > *S*-2 > *S*-1.

The areas corresponding to *A* and *B* from experiment *S*-3 were cut from the paper and the compounds were eluted with hydrochloric acid. Their ultra-violet spectra are shown in Fig. 3. As can be seen, compound *A* shows a maximum at 257 mμ and a minimum at 232 mμ. For comparison, isocytosine shows a maximum at 257 mμ and a minimum at 235 mμ at *p*H 1. Compound *B* shows a maximum at 262 mμ and minimum at 234 mμ in 0·1 N hydrochloric acid. This maximum shifts to 267 mμ in 0·12 N sodium hydroxide. For comparison, under the same conditions, adenine shifts from 262 to 269 mμ and purine from 261 to 273 mμ.

Although a certain similarity of compounds *A* and *B* with purines and pyrimidines is apparent, no definite statements in this respect can be made until these compounds are isolated and characterized more fully. The formation of ultra-violet-absorbing compounds in experiments with electrical discharges has also been observed recently by Knight[16].

Amino-acids and other ninhydrin-positive compounds. The reaction product was next analysed for amino-acids by paper chromatography and by ion-exchange chromatography. Fig. 4 shows the reproduction of two-dimensional chromatograms (Whatman No. 3 *MM*, ascending) of *S*-1, *S*-2 and *S*-3 after spraying with ninhydrin. There are three chromatograms for each reaction product. The first corresponds to the reaction product before ion-exchange treatment, the second to the water eluate (W) from 'Dowex 2', and the third to the acid eluate (A) from the same resin. Several ninhydrin-positive compounds, which are likely amino-acids, peptides or other derivatives of amino-acids can be observed in the chromatograms of the acid eluates. At least 8 spots were observed in *S*-1-A, 16 in *S*-2-A and 20 in *S*-3-A. The ninhydrin-positive compounds of the water eluates are presumed to be amines, amino-amides and amino-nitriles. Some of the compounds in the acid or water eluates gave a green (G) or a yellow (Y) coloration with ninhydrin. Other compounds gave first a tan or yellow-brown coloration which eventually changed into purple. Some of the amides of amino-acids are known to give the foregoing colours with ninhydrin[17].

The amino-acids present in the acid eluate from experiment *S*-3 were identified by ion exchange chromatography using a Beckman–Spinco automatic analyser. (These analyses were carried out in Dr. F. H. Carpenter's laboratory, University of California, Berkeley.) The results are given in Fig. 5. The amino-acids which were identified by their positions in the eluate from a long column include aspartic acid, asparagine, glycine, alanine and isoleucine (or isoasparagine). Traces of other amino-acids can also be observed. One of these corresponds to proline by its position in the eluate and the colour given with ninhydrin.

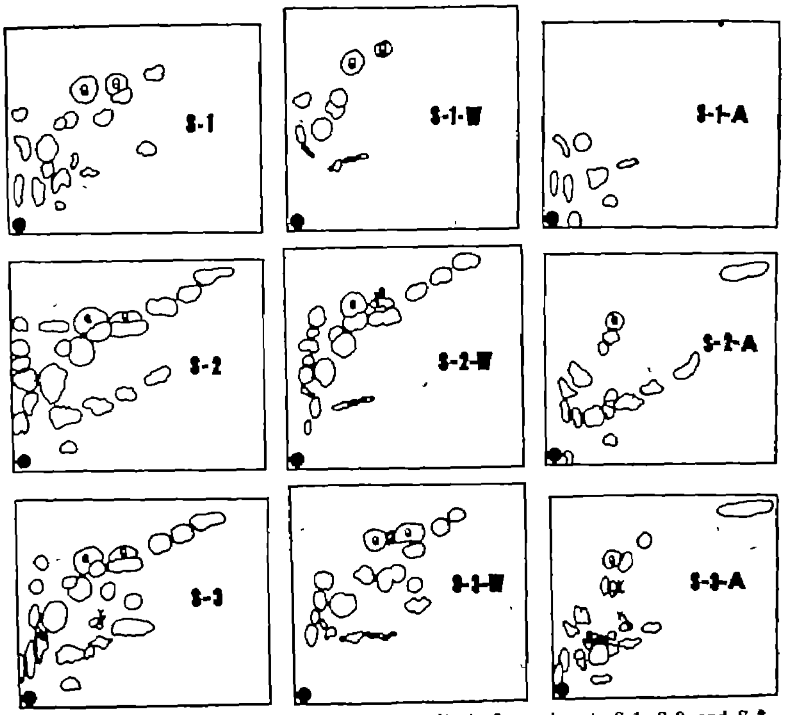

Fig. 4. Two-dimensional chromatograms (ascending) of experiments *S*–1, *S*–2, and *S*–3 sprayed with ninhydrin. The dark spot represents the origin. The development was first in *n*-propanol/1 N ammonium hydroxide, 3.1 (ordinate) and then in *n*-butanol/acetic acid/water, 4 1.1 (abscissa). The unlettered spots were purple or brown-purple in colour. To make chromatograms less complex the ultra-violet-absorbing spots are not shown here

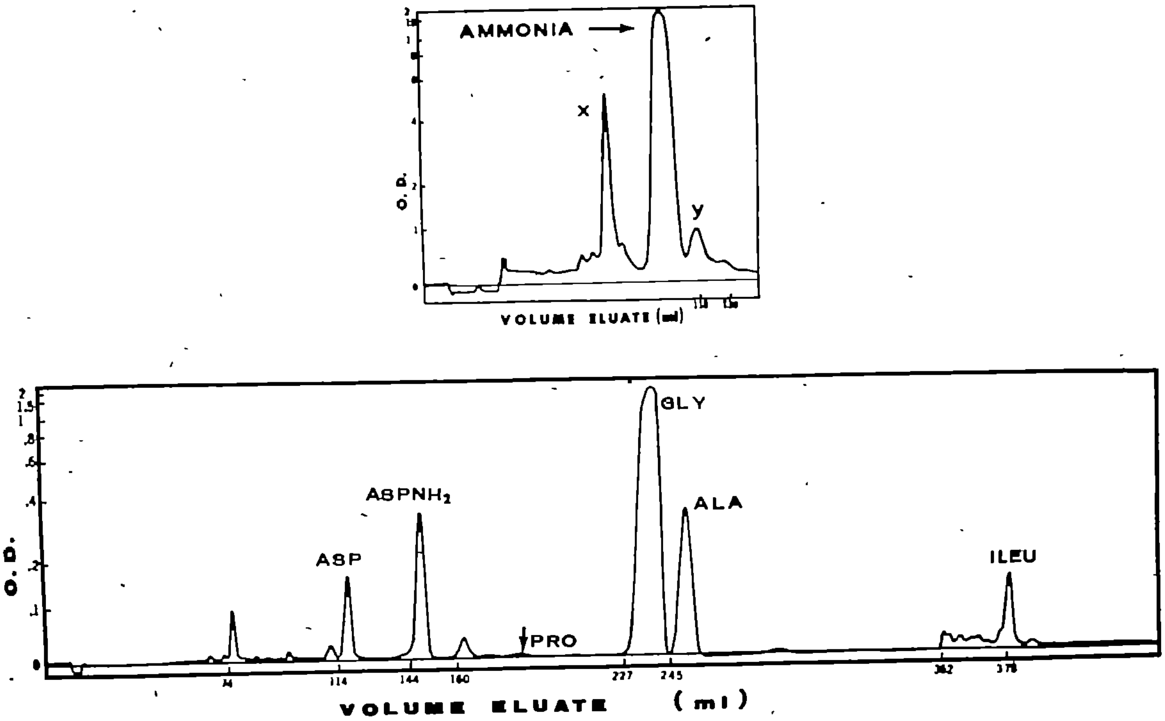

Fig. 5. Elution diagrams of the amino-acids of S-8-A separated by two ion exchange columns. A short column (top) was used for basic amino-acids and long one (bottom) for acidic and neutral amino-acids (Beckman-Spinco model 120 analyser)

Several unidentified peaks (X, Y, etc.) can also be observed in the eluate from the short column which is usually run for basic amino-acids. The large ammonia peak shown here is no doubt the result of hydrolysis of amino-acid amides such as asparagine.

Evidence for the formation of asparagine was also obtained in experiment S-7 by comparing a two-dimensional chromatogram of the reaction product of this experiment (Fig. 6) with that of a standard mixture of amino-acids containing asparagine (Fig. 7). (These chromatograms were obtained by descending development, using oxalic acid-washed Whatman No. 4 paper and n-propanol/15 M ammonium hydroxide/water, 6 : 3 : 1 (PAW) and n-butanol/propionic acid/water, 14 : 9 : 10 (BPW), as the first and second solvents, respectively). A spot with R_F 0·49 in PAW and 0·36 in BPW can be observed in Fig. 6. This spot showed a change in colour from brown to purple (Br → P). Authentic asparagine has R_F 0·53 in PAW and 0·39 in BPW (Fig. 7) and showed an identical change in colour (Br → P). The small differences in R_F were probably caused by the higher ionic strength of S-7 relative to that of the standard mixture of amino-acids.

To the right of asparagine (Fig. 6) a more intense spot which underwent the same colour change (Br → P) can be observed. By its R_F in the two solvents this compound corresponds to glycinamide. The characterization of this amide and other possible amino-amides which are suggested by the spots with similar colour changes (Br → P) in the upper right corner of the chromatogram (Fig. 6) was not carried out further because ion-exchange column chromatographic data have not yet been reported for amino-amides. It may be added that no identification of the green spots (G) of S-7 was attempted at this time. Tentatively these spots are presumed to be amino-amides and amino-nitriles since aspartic acid diamide[17] and β-aminopropionitrile[18] form green derivatives with ninhydrin.

The detection of asparagine and glycinamide is significant in two respects. First, it confirms earlier observations[19] made in our laboratory that the amino-amides are the immediate precursors of the amino-acids formed in these experiments. Secondly, it adds experimental support to the hypothesis that amino-amides may have played a part in the synthesis of polypeptides under possible primitive Earth conditions[20], since it has been shown that polypeptides can be obtained from glycinamide[20] and asparagine[21] in aqueous systems.

The compound labelled as isoleucine (Fig. 5) may very well be isoasparagine, since the latter compound has an almost identical elution time to that of isoleucine in polystyrene sulphonic acid resins[22]. It should be pointed out, however, that valine, leucine and isoleucine have been identified recently in our laboratory[18] in experiments where the action of electric discharges on mixtures con-

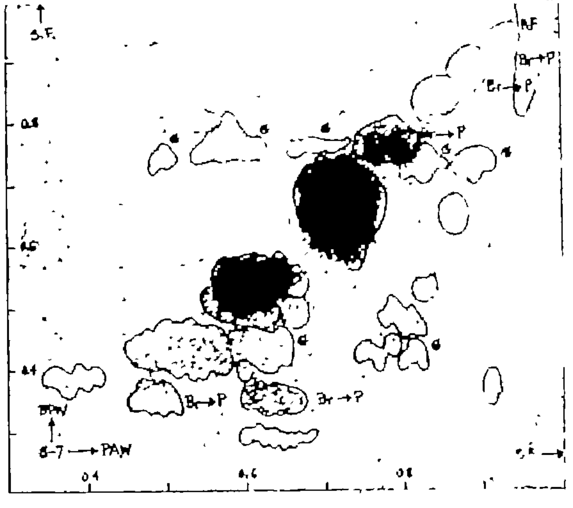

Fig. 6. Photograph of a two-dimensional paper chromatogram of S-7, sprayed with ninhydrin. Descending development in the BPW and PAW solvents (see text). Letters to the right or above the spots indicate colour or colour changes, That is, G, green ; Br→P, colour first brown, then turned into purple. Unlettered spots are purple

taining C$_2$ and C$_3$ hydrocarbons was allowed to proceed for a period of 24 h or longer. It appears that under these conditions the probability of formation of C$_4$ and C$_5$ aldehydes which are presumed to be the precursors of valine and the leucines increases significantly.

With regard to the formation of proline it should be stated that a small peak was obtained at the corresponding elution place for this compound (Fig. 5). As in the case of proline, the ninhydrin derivative of the eluted substance showed an optical density at 440; 100 per cent higher than at 570. If this peak corresponds to proline the small peak in front of proline should probably correspond to glutamic acid.

Carbon-14 *compounds*. Two experiments were carried out with carbon-14 reactants. In the first of these experiments (*S*-5) one millicurie of ^{14}C-methane (8 mg) was used. The unreacted ^{14}C-methane and other gaseous ^{14}C-components from *S*-5 were recovered and used in a subsequent experiment (*S*-6). This was done as follows: At the end of the experiment, the gases of the reaction product were trapped into two cold traps immersed in liquid nitrogen which were connected in series. The trap farther away from the flask contained 50 g of molecular sieve (Linde type 4*A*, 1/16-in. pellets) for the absorption of methane. In less than 1 h the pressure in the reaction flask fell to about 1 in. mercury, which is approximately the vapour pressure of water at 27° C. This indicated that essentially all the gases and volatile compounds had been condensed in the cold traps. After removing the main reaction product (yellowish solution) from the flask, the latter was evacuated and connected again to the traps, which were allowed to warm to room temperature. In this manner the bulk of the gases from the traps diffused back into the reaction flask. These gases, together with additional non-radioactive methane, ammonia and water, were used as reactants for the second experiment (*S*-6).

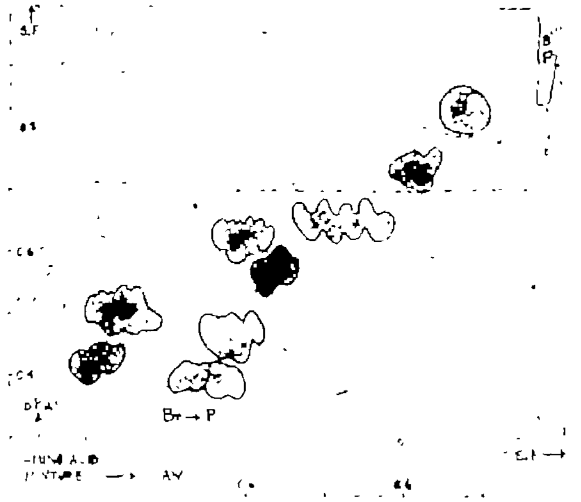

Fig. 7. Photograph of a two-dimensional chromatogram of a standard amino-acid mixture. From top to bottom following approximately the diagonal line the spots correspond to: leucine + isoleucine, valine, α-*n*-butyric acid, β-alanine, alanine, glycine + serine, asparagine (Br→P) and lysine. The two spots on the left correspond to glutamic acid (upper) and aspartic acid

The concentrated reaction products from *S*-5 and *S*-6 were then individually chromatographed in the PAW–BPW solvent system described previously. Autoradiographs of these two chromatograms are shown in Figs. 8 and 9. By comparing the autoradiograms of *S*-5 and *S*-6 with the ninhydrin-sprayed chromatogram of *S*-7, a general resemblance of distribution of spots in the three chromatograms can be observed even though different methods of detection were used and the three chromatograms correspond to three different experiments.

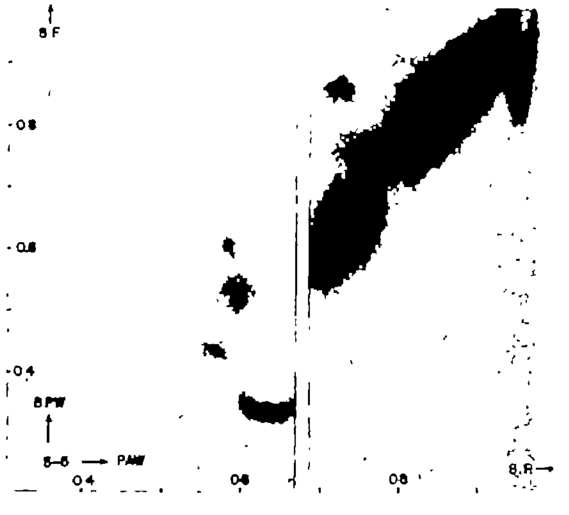

Fig. 8. Autoradiograph of a two-dimensional chromatogram of *S*–5. Because of their size this and other chromatograms had to be folded to expose two film plates which were placed back to back in the same holder. The white band corresponds exactly to the bent portion of the paper chromatogram

The first three spots on the diagonal line of *S*-6 (Fig. 9) correspond, very likely, to asparagine, glycine and alanine, as shown by comparing this chromatogram with that of *S*-7 (Fig. 6) and with the chromatogram of a standard mixture of amino-acids (Fig. 7). Radioactive and ninhydrin-positive spots can also be detected in the areas corresponding to valine and the leucines. However, since no separation of bases from amphoteric substances was carried out before chromatography, some of these spots may correspond to the amides of the foregoing amino-acids, instead of the amino-acids as such. The ^{14}C-spot to the right of asparagine (Fig. 9) corresponds, most likely to glycinamide.

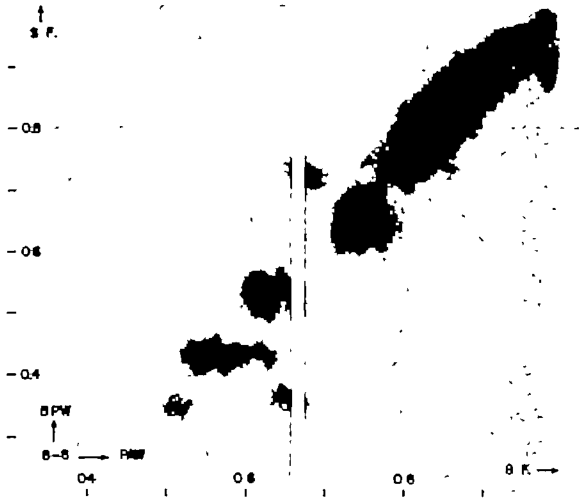

Fig. 9. Autoradiograph of a two-dimensional chromatogram of *S*–6. See Fig. 8 for explanation of white band

The largest and most diffused ninhydrin-positive compound of *S*-7 (Fig. 6) is probably caused by an aliphatic amine. (Aliphatic amines are known to produce diffused spots.) A radioactive spot corresponding to this compound can be observed clearly in *S*-5 (Fig. 8).

Aside from amino-acids, amino-amides and aliphatic amines, it is of interest that other radioactive spots appear in the area of purines and pyrimidines[11]. It should be possible to identify these compounds by eluting them from the chromatogram and co-chromatographing them individually with the suspected authentic compounds. However, a more systematic approach would be to obtain a sample sufficiently large and submit it to analytical ion exchange chromatography. The eluate could be automatically scanned with a short wave-length ultraviolet lamp and with a radioactive scintillation counter. Coincidence of ultra-violet-absorption with radioactivity would exclude any possibility of contamination.

Polymers and other compounds. In a number of experiments a transparent solid material was observed to be formed on the glass surface of the apparatus close to the electrodes. It extended in the form of a thin layer, around each electrode, to about one-fourth of the total area of the flask.

This product was insoluble in ordinary organic solvents and water, and could not be dissolved, degraded, or hydrolysed by boiling in 6 N hydrochloric acid overnight. Only after long standing in acid could it be separated in the form of thin flakes from the glass surface. This material is presumed to be similar to that obtained by Wilson[24] in analogous experiments with electric discharges. Because of its nature, which is supposed to be a highly cross-linked polyethylene-type polymer with some functional groups, and its peculiar way of formation (surface or interphase electrodic phenomenon), it remains uncertain at this moment the part that this or similar polymers may have played in pre-biochemical evolution.

Preliminary evidence for the formation of small-molecular-weight peptides was given by some of the two-dimensional paper chromatograms of Fig. 4. In particular *S*-3 and *S*-3-A showed two elongated spots close to the origin, which gave a brown colour on spraying with ninhydrin. This brown coloration changed very slowly into purple. Because of their low rate of migration and their characteristic way of reacting with ninhydrin, these compounds are probably peptides or polymers of amino-acids. Almost identical spots were observed in the reaction product from hydrogen cyanide–ammonia–water reaction mixtures[25], and it has been definitely shown by Lowe *et al.*[26] that polymers of amino-acids are formed in these experiments. The aforementioned ninhydrin-positive spots shown in chromatograms of *S*-3-A are supposed to correspond to the compounds *X* and *Y* which were observed to be eluted from a short ion-exchange column (Fig. 5).

Finally, it will be recalled that the gaseous and volatile products of experiments *S*-5 were condensed in two traps immersed in liquid nitrogen. After allowing the gases to diffuse back to the reaction flask, several droplets of a transparent pale yellow oil and a white viscous material were observed to remain in the trap adjacent to the flask. Both substances were radioactive and insoluble in water. The yellow oil was soluble in carbon tetrachloride. These materials were not analysed, but they suggest that the formation of lipophilic substances is possible in experiments with electric discharges.

I thank Prof. M. Calvin for providing the stimulus and laboratory facilities to carry out these experiments, and Dr. R. Lemmon for his advice.

This work was sponsored in part by the U.S. Atomic Energy Commission and by a grant (*NsG* 257–62) from the National Aeronautics and Space Administration.

ATTEMPTS TO ISOLATE INFECTIOUS NUCLEIC ACID FROM VACCINIA VIRUS AND VIRUS-INFECTED CELLS

By PROF. H. CURT BUBEL and DAVID A. WOLFF
Department of Microbiology, College of Medicine, University of Cincinnati

NUMEROUS plant and animal viruses yield infectious ribonucleic acid (RNA) on treatment by a variety of reagents and techniques[1–4]. Furthermore, a deoxyribonuclease-sensitive unit capable of infecting *E. coli* protoplasts was isolated by degradation of phage T_2 with concentrated urea[5]. The question now arose whether an infectious deoxyribonucleic acid (DNA) could be recovered from a DNA animal virus. Vaccinia virus was selected for investigation since it is known to contain DNA (ref. 6), is readily purified[7], can be accurately titrated and identified in tissue culture systems. It is the purpose of this article to describe attempts to isolate an infectious DNA from vaccinia virus or virus-infected cells, and direct attention to the possible biological significance of our findings.

Vaccinia virus (Lederle Laboratories strain) was propagated on a *KB* cell line (obtained from the Southern Research Institute, Birmingham, Alabama) grown in Eagle's basal medium (BME) with 10 per cent calf serum. Crude virus material for DNA extraction was prepared by treating 48-h infected *KB* cells and tissue culture fluids for 5 min in a 10 *KC* Raytheon sonic oscillator. Purification and concentration of vaccinia virus was effected by fluorocarbon (Genetron 113) treatment[7] and sedimentation at $37,000g$ for 1 h. Sedimented virus particles were dispersed by brief sonoration in an appropriate diluent for DNA extraction. Virus titres of these preparations ranged from 1×10^7 to 1×10^9 plaque forming units per ml.

Most of the DNA extraction procedures adopted in this investigation used phenol treatment as one step in the extraction procedure. The cold[1] and hot[8] phenol methods were used extensively, as were modifications of the former method which consisted of adding selected anions[9] and a surfactive agent[10] to the extraction mixture. *KB* cell monolayers for testing DNA extracts were grown in

250-ml. square dilution bottles and washed three times with solutions of either 0·5 M sodium chloride, 0·7 M sucrose, or versene buffer[11], *p*H 7·1, prior to adding DNA extracts. These washings materially reduced extracellular deoxyribonuclease (DNase) activity and the concentration of divalent cations necessary for DNase activity. A hypertonic environment as well as the presence of versene has been shown to increase the sensitivity of cells to infectious nucleic acids[11,12]. DNA extracts were diluted 1 : 1 in either BME without calf serum, 0·5 M sodium chloride, or 0·7 M sucrose solutions, and 1–2 ml. of the mixture incubated with *KB* cell monolayers 15–40 min at 37°. Fresh tissue culture medium was then added and incubation continued for 48 h. At this time the cells were disrupted by sonoration and at least one 'blind passage' made on fresh *KB* cell monolayers.

In some cases DNA extracts produced an observable cytopathogenic effect in the initial test cultures. To distinguish this effect from the cytopathogenic effect resulting from vaccinia infection, 2 ml. of a 1 per cent suspension of chicken red blood cells in 0·15 M sodium chloride were added to each test culture drained free of culture fluid. Susceptible fowl cells are rapidly adsorbed to *KB* cells infected with vaccinia virus, but not to cells showing non-specific cytopathogenic effect arising from cytotoxic materials in DNA extracts.

The inability of these procedures to release an infectious nucleic acid from either crude or purified virus materials prompted consideration of DNA extraction procedures relative to the structural complexity of vaccinia virus. Enzymatic digestion of vaccinia virus has been correlated with observable changes in the structural organization of the virus particle[13,14]. Consequently, purified virus material was pretreated 1–3 h at 37° with pepsin, trypsin or ficin prior to phenol extraction. Such procedures did not yield biologically active nucleic acid. A summary of typical experiments is given in Table 1.

Table 1. NON-INFECTIVITY OF VACCINIA VIRUS DNA EXTRACTS

Exp.	Virus material	Extraction procedure	Transmittable CPE on *KB* cells	CRBC hæm-adsorption to *KB* cells
1	CV, FPV	80–88% phenol, 0°	0	0
2	CV, FPV	80–88% phenol, 40–50°	0	0
3	CV, FPV	88% phenol, 0·15 M *p*-amino-salicylate, 0°	0	0
4	CV, FPV	88% phenol, 0·15 M tri-chloroacetate, 0°	0	0
5	CV, FPV	0·2–2% sodium dodecyl-sulphate, 88% phenol, 0°	0	0
6	FPV	0·02–0·2% pepsin, 0·1 M cysteine HCl, *p*H 3·5 37°; 88% phenol, 0°	0	0
7	FPV	0·001–0·1% ficin, 37°; 88% phenol, 0°	0	0
8	CV, FPV	0·25% trypsin, *p*H 7·2, 37°; 88% phenol, 0°	0	0

Abbreviations: CV, crude virus; FPV, fluorocarbon purified virus; CRBC, chicken red blood cells; CPE, cytopathogenic effect.

The failure to recover infectious nucleic acid from crude or purified vaccinia virus suggested the alternative approach that viral DNA might be recovered from virus-infected cells prior to its incorporation into virus particles. Saltzman[15] has shown that the majority of vaccinia virus DNA is synthesized by infected HeLa cells within 6 h after initiation of infection, and before the appearance of newly formed virus. This finding suggested that infectious DNA might be isolated from *KB* cells during the early stages of virus synthesis. In Table 2 are shown data from experiments with vaccinia virus-infected *KB* cells and homogenates of vaccinia-infected rabbit testicular tissue. In the latter instance the infecting virus was a testicularly adapted strain which could be propagated equally well in *KB* cells.

The extraction or homogenization of virus-infected cells entails the hazard of releasing cellular nucleases which rapidly inactivate infectious nucleic acid[16]. Therefore, in some of the extraction procedures for infected cells either a chelating agent (versene) was used to sequester magnesium ions, or an adsorbing agent (bentonite) which has been shown to inactivate nucleases during phenol extraction of tobacco mosaic virus (TMV) and contribute to the stability of TMV infectious RNA[17].

Table 2. DNA EXTRACTION OF VACCINIA-INFECTED *KB* CELLS AND TISSUES

Exp.	Material extracted	Extraction procedure	Transmittable CPE on *KB* cells	CRBC hæm-adsorption *KB* cells
1	*KB* cells, 6–8 h post-infection	88% phenol, 0°	0	0
2	*KB* cells, 6–11 h post-infection	88% phenol, 1 × 10^{-3} M versene, 22°, 0°	0	0
3	*KB* cells, 6–8 h post-infection	0·02–2% sodium dodecyl-sulphate, 88% phenol, 0°, 22°	0	0
4	*KB* cells, 6–8 h post-infection	0·15 M *p*-aminosalicylate, 88% phenol, 0°	0	0
5	*KB* cells, 6–8 h post-infection	0·15 M trichloroacetate, 88% phenol, 0°	0	0
6	*KB* cells, 6–8 h post-infection	0·15 M trichloroacetate, 0·02–2% sodium dodecylsulphate, 88% phenol, 0°	0	0
7	Homogenate, 3–5 day infected rabbit testicular tissue	0·15 M trichloroacetate, 0·02–2% sodium dodecylsulphate, 88% phenol, 0°	0	0

None of the extracts of infected *KB* cells contained biologically active DNA. The initial extraction of infected rabbit testes yielded a DNA preparation which caused a transmittable cytopathogenic effect on *KB* cells; this effect was shown positively to be caused by vaccinia virus. Since numerous attempts to repeat this finding were unsuccessful, it was impossible to apply strict criteria for the presence of an infectious DNA in testicular extracts. The results of the initial experiment may be explained by a carry-over of infectious vaccinia virus through the extraction procedure.

It appears, therefore, that neither purified vaccinia viruses nor virus-infected cells yield infectious DNA by the methods applied in this work. Suggested explanations for these results are: (1) the methods used in DNA extraction yielded a degraded, inactive product, or did not adequately release DNA from the virus particle; (2) the inability of extracted vaccinia virus DNA to initiate cellular infection because of some unique biological relationship with the host cell; (3) that some other component of the virus, in addition to DNA, may be involved in the initiation of cell infection.

It is noteworthy that the DNA extraction methods of Experiments 3 and 4 (Table 1) have released infectious DNA from the polyoma virus[18], as has cold phenol extraction of the Shope virus[19] and the SV_{40} agent[20]. The fact that infectious DNA can be recovered from these tumour agents and not vaccinia virus suggests a significant difference in the structural organization of the tumour viruses or perhaps the interaction of their nucleic acids with the host cell. It is also significant that the recovery of infectious DNA from such extensively studied, non-tumour agents as the adenovirus, herpes and pseudo-rabies viruses has not been reported.

Pertinent to this work are the results of Pfau and McCrea, who found that single-stranded DNA was released from vaccinia virus by phenol extraction[21], and that treatment of the virus with a protease and 2-methoxy-ethanol[22] yielded double-stranded DNA, both types being non-infectious. It is apparent, therefore, that DNA of strikingly varied physical properties may be derived from vaccinia virus, and it is reasonable to assume that the physical state of the extracted DNA would have some bearing on the biological activity of this material. Unfortunately there is no information available which might clarify the relationship between the physical state of animal virus DNA and the capacity of such DNA to infect cells.

That infectious DNA could not be recovered from virus-infected cells in the early stages of virus synthesis would suggest inactivation by cellular DNases released during extractions, although precautions were taken against this eventuality. Cairns[23] and others[24] have shown that vaccinia virus antigens appear in the infected cell simultaneously with viral DNA. It is conceivable that under such conditions viral proteins and DNA may form complexes or viral sub-units which cannot be artificially degraded to yield biologically active nucleic acid. The early-appearing nucleo-protein antigen of vaccinia virus may well represent such a complex.

Finally, consideration must be given to the possibility that the larger and more complex animal viruses such as vaccinia do not possess an infectious nucleic acid *per se*. Such an assumption predicates the existence of one or more viral components other than DNA which participate in the initiation of virus synthesis. That components of the pox viruses other than DNA play a part in the interaction of virus and host cell is indicated by the experiments of Joklik *et al.*[25], who showed that protein denaturants which do not harm DNA, completely destroy the reactivability of rabbit pox virus. Preliminary experiments with ultra-violet-inactivated vaccinia virus and DNA added to *KB* cell cultures simultaneously or at different intervals have not resulted in cell infection.

This work was supported by grant *E*-3536 of the U.S. Public Health Service.

INTERRELATIONSHIP BETWEEN GLUCOSE UTILIZATION OF BRAIN AND HEART

By Dr. R. VRBA, Dr. H. S. BACHELARD and Dr. J. KRAWCZYŃSKI

Medical Research Council, Neuropsychiatric Research Unit, Carshalton, Surrey

IT has been demonstrated[1] that brain can accumulate carbon-14 and retain it for a considerable period after the introduction of glucose-U-^{14}C into the circulation of the rat. The carbon-14 from glucose carbon which accumulates in the brain is rapidly converted into glutamic and aspartic acids[1]. Twenty minutes after subcutaneous injection of glucose-U-^{14}C, more than 70 per cent of the carbon-14 in the acid-soluble fraction from brain had already been converted into α-amino-acid carbon, but in liver only 10–15 per cent of the radioactivity was found in the α-amino-acid fraction[2]. The corresponding figure for heart (33–38 per cent) was intermediate between those for brain and liver, whereas in leg muscle it was lower than in any of the eight tissues investigated.

Heart has now been found to resemble brain in its ability to accumulate carbon-14 from labelled glucose *in vivo*. After the injection of glucose-U-^{14}C, the radioactivity in the brain-soluble fraction rapidly increases, despite the continuous decrease of radioactivity in the blood, and reaches levels much higher than that of blood[1]. As demonstrated in Fig. 1*A*, heart shows a similar increase. Leg muscle, on the other hand, does not appear to share this ability to concentrate the carbon-14 from blood glucose to values higher than the actual concentration of blood carbon-14 during the first 2 h after injection of glucose-U-^{14}C. However, after this period a retention of carbon-14 above blood-levels can be observed. The ability of the heart to accumulate carbon-14 from blood glucose has been considerably reduced after fasting (Fig. 1*B*).

The brain is known to be particularly sensitive to acute hypoglycaemia[3,4]. In cases of decreased availability of glucose, the possibility had to be considered that brain might utilize administered glucose (apart from glycogen reserves) at the expense of other organs. The following experiments were performed as part of a more extensive investigation which will be published in detail elsewhere.

Sixteen male Wistar rats of approximately the same weight were divided randomly into two groups. One group was deprived of food, the other was fed *ad libitum* on the normal laboratory diet (No. 41 *B*, J. Rank, Ltd.). Water was available *ad libitum* to both groups. After 24 h, all were injected subcutaneously with glucose-U-^{14}C (15 μc. in 0·3 ml. water in the presence of 0·037 mg of carrier glucose as supplied by the Radiochemical Centre, Amersham). The average weight (and *S.E.*) of the fed animals was 109 ± 1·4 g, and of the fasting animals was 92 ± 2·1. The concentration of blood glucose, as estimated with glucose oxidase[5], was 131 ± 6·2 mg/100 ml. for the fed group, and 77 ± 1·7 mg/100 ml. for the fasting group.

At various times (4 min–2 h) after glucose injection, the animals were killed by decapitation, and the blood (1 ml.) was immediately collected and deproteinized by the addition of 80 per cent (v/v) ethanol (8 ml.). Brain (whole, except for cerebellum), heart, liver and a sample of the gastrocnemius muscle were rapidly removed and frozen in liquid nitrogen. The time from decapitation to fixation of the tissues by freezing did not exceed 2 min. The tissues were stored in the frozen state at – 20° C until homogenization, which was done at 0° C in 80 per cent (v/v) ethanol (8 ml.) in a 'Teflon'-pestle homogenizer (A. H. Thomas Co.). Ethanol was used instead of perchloric or trichloroacetic acids because it extracts glucose, amino-acids, Krebs cycle intermediates and other substances, but not glycogen.

The homogenates were centrifuged at 0° C for 15 min at 2,500*g* (M.S.E., 'Major') and the residue was twice rehomogenized in 80 per cent ethanol (8 ml.). The combined supernatants from each sample were made up to 25 ml. with 80 per cent ethanol and plated in duplicate aliquots of 0·2 ml. and 0·4 ml. Counting was carried out at infinite thinness in a 'Nuclear Chicago' automatic Geiger counter. Duplicate counts of 1,000 were taken for each sample and activities were usually 10–100 times that of the background, for which corrections were applied. The results are shown in Table 1.

It may be seen that the carbon-14 content of the blood of all the fasting animals was considerably higher than in the fed animals. This indicates that the elimination

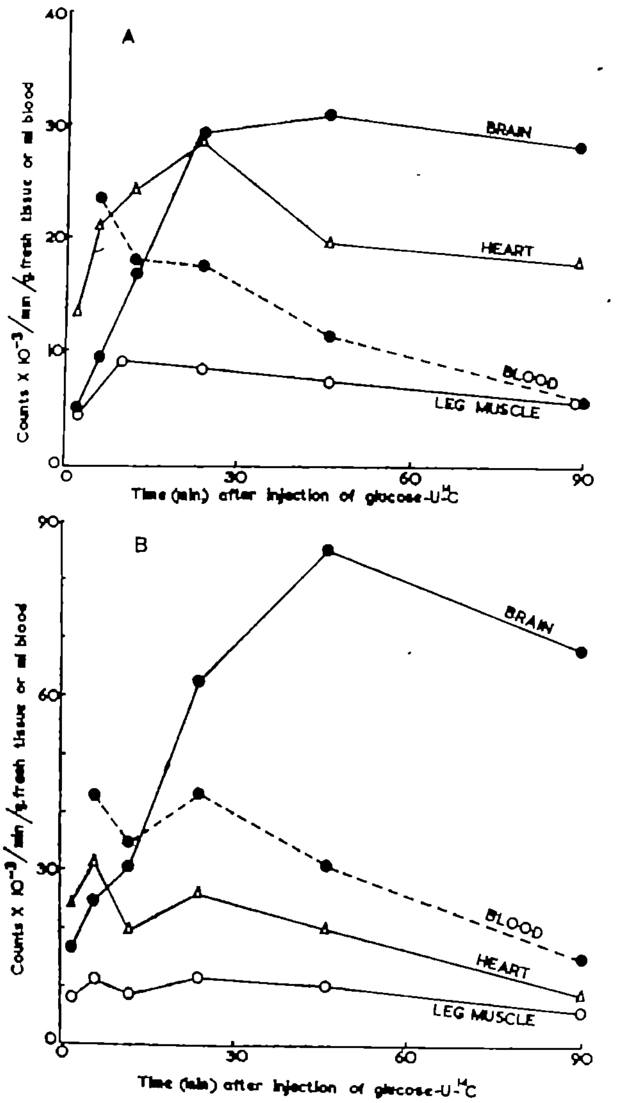

Fig. 1. Accumulation and retention of carbon-14 in ethanol-soluble fraction of rat organs after injection of glucose-U-^{14}C. Each point is the average of 2 experiments. *A*, rats were fed *ad libitum* until decapitation: *B*, food withdrawn 24 h before injection of glucose-U-^{14}C. For all other conditions, see Table 1

of glucose-carbon from fasting animals as carbon dioxide is slowed down, in accordance with the reports of similar investigations (for relevant literature, see ref. 6). As a consequence of the higher blood carbon-14 content in the fasting animals, the total amount of radioactivity in each of the tissues examined was increased (Fig. 1).

Table 1. ACCUMULATION AND RETENTION OF CARBON-14 IN ETHANOL-SOLUBLE FRACTIONS OF ORGANS OF FED AND FASTING RATS AFTER INJECTION OF GLUCOSE-U-^{14}C

Tissue	Nutrition	Time after injection of glucose-U-^{14}C 4 min	8 min	16 min	32 min	1 h
R.S.A. = 100						
Blood (counts/min/ml.)	Fed	30,875	16,504	19,504	15,625	7,569
	Fasting	60,781	24,250	44,968	41,468	20,343
R.S.A.						
Brain	Fed	34	50	130	215	376
	Fasting	54	66	99	197	425
Liver	Fed	197	73	137	128	164
	Fasting	87	87	98	146	205

	Fasting	79	60	54	67	62
Muscle	Fed	81	—	46	51	90
	Fasting	26	27	22	32	38

Male rats were injected subcutaneously over the left flank with 0·2 ml. of glucose-U-^{14}C (15 μc. in presence of 0 037 mg carrier glucose). Fed animals = animals fed *ad libitum* until decapitation. Fasted animals = food withdrawn 24 h before injection of glucose-U-^{14}C. Tissues were extracted with 80 per cent (v/v) ethanol as described in the text, and results expressed as relative specific activities (R.S.A.).

$$\text{R.S.A.} = \frac{\text{Counts/min/gm fresh weight of organ (ethanol-soluble fraction)}}{\text{Counts/min/ml. of blood (ethanol-soluble fraction)}} \times 100$$

Compared with the levels in the fed group, the relative specific activity in the brain and liver of the fasting group was almost unimpaired, whereas a considerable diminution of the relative specific activity was observed in the heart. The accumulation of carbon-14 in skeletal muscle, which in both groups was much lower than in heart, was even further decreased in the fasting group. Thus it appears that, under certain conditions of hypoglycaemia, the brain may accumulate and retain carbon from administered glucose at the expense of other organs.

It is conceivable that this mechanism, which seems to protect the vital functions of brain, may be, in suitable circumstances, detrimental to the functions of other organs, for example, heart. This could be relevant to the aetiology of heart disease. In this connexion, it is of interest that the tranquilliser, reserpine, 18 h after injection, has been observed in rats to cause a 55 per cent decrease in the uptake by heart of carbon-14 from blood glucose[7], while no effect on the ability of the brain or liver to accumulate carbon-14 from blood glucose could be demonstrated. Structural damage to cat heart after reserpine injection has been previously reported[8].

This work was carried out during the tenure by two of us (R. V. and H. S. B.) of Rockefeller Foundation grants, and by the third (J. K.) of a personal grant from the Polish Ministry of Health. We wish to thank Dr. Derek Richter for his interest and support.

POLIOVIRUS NEUTRALIZING PROPERTIES OF EQUINE AND OTHER SERA

By G. PLUMMER
Wellcome Research Laboratories, Beckenham, Kent

THE neutralizing or inhibitory action of some bovine sera to one or more of the three serological types of poliovirus has been described by a number of workers[1–4]. Bartell and Klein[3] found that this property was also possessed by the sera of certain horses, pigs and chickens, and that the activity was associated with the globulin fraction of the sera. McFerran[4] demonstrated that the bovine poliovirus inhibitors had much the same stability as poliovirus antibodies in human sera, and concluded, as did Bartell and Klein, that they were probably antibodies, the origin of which was obscure. In marked contrast were the conclusions of Takemoto and Habel[5] with regard to equine serum poliovirus inhibitors; they regarded the action of the serum as being not neutralization but a

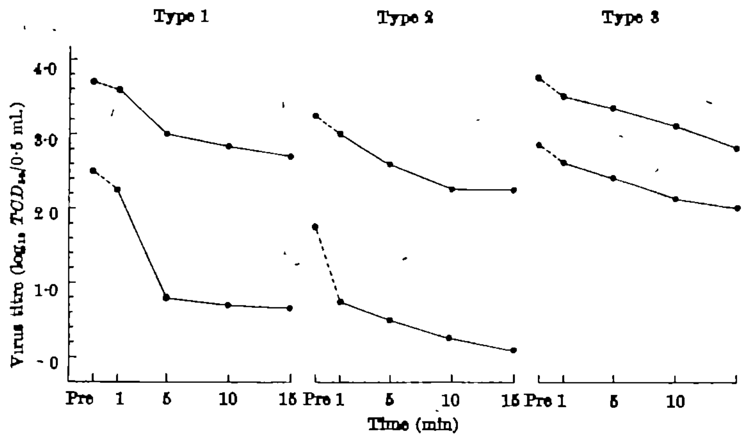

Fig. 1. Neutralization of polioviruses by equine inhibitory sera

reduction in the rate of adsorption and release of virus from the cells of the tissue culture system. Fractionation on the cellulose column, however, indicated that the activity was associated with the γ-globulin.

In this article, studies of poliovirus inhibitors of equine sera are presented and the frequencies of their occurrence analysed. A survey of inhibitors of sheep and monkey sera is also included, and suggestions as to the origin of poliovirus inhibitors are made. Monolayer monkey kidney tissue cultures were used for this work and were maintained on Earle's salt solution containing 0·5 per cent liver digest, 0·22 per cent sodium bicarbonate and penicillin and streptomycin. Poliovirus strains Brunenders, *MEF*-1 and Saukett were used unless otherwise indicated.

Adult horse, sheep and monkey sera were tested for inhibitors by mixing doubling serum dilutions with poliovirus (100 TCD_{50}/0·5 ml. of mixture), incubating 1½ h at 37° C, inoculating 0·5 ml. of each reaction mixture into four monkey kidney tube cultures and examining for cytopathic effect six days later. The percentages of sera showing inhibition are given in Table 1. In each case the type II inhibitor titres tended to be the highest and type III the lowest. Thus, in the equine sera the type II inhibitory action was sometimes detectable up to a serum dilution of 1/38; type I titres rarely exceeded 1/12 and type III 1/4. There was a statistically significant association between the presence in equine sera of inhibitors to polioviruses types I and II and between I and III, but no such marked correlation between types II and III. Monkeys are known to be to some extent susceptible to poliovirus infection; therefore, the findings for the monkey sera are presented with some reservation, particularly as the animals concerned had been held in contact with man for short periods.

Table 1. PERCENTAGE SERA FROM THREE ANIMAL SPECIES CONTAINING POLIOVIRUS INHIBITORS

Animal	No. of sera tested	Per cent sera containing inhibitors to polioviruses		
		Type I	Type II	Type III
Horse	203	17·2	33	4·9
Sheep	46	17	19	0
Monkey (*Cynomolgus* and rhesus)	699	1·1	2·0	0

The mode of action of equine poliovirus inhibitors was investigated in the following experiments. Undiluted serum was mixed with an equal volume of poliovirus suspension and incubated at 37° C, the virus being titrated before, immediately after, and at short intervals after, mixing. The titration dilutions were made in cooled medium immediately after each sample was taken. Such a test was done with two poliovirus concentrations of each of the three types. The results, which are given in Fig. 1, demonstrate a fall in virus titre during incubation, indicating that actual neutralization has taken place. This was confirmed by further experiments in which doubling dilutions of inhibitory serum were made. Part of each dilution was mixed with an equal volume of poliovirus suspension (100 TCD_{50}/0·5 ml. of mixture), incubated 1½ h at 37° C and inoculated into tube cultures, 0·5 ml./tube. Other cultures were inoculated with 0·25 ml. serum dilution and 100 TCD_{50} poliovirus contained in 0·25 ml. of medium without prior mixing and incubation. The inhibitor titres were 2–3-fold lower when prior mixing and incubation were omitted.

The heat sensitivity of the equine inhibitors is much the same as poliovirus antibodies prepared by hyperimmunization of horses, each type of inhibitor being stable up to 63° C. γ-Globulin precipitation by the method of Peterson *et al.*[7] brought about a complete removal of inhibitory activity from the supernatant; the resuspended γ-globulin neutralized poliovirus, although to a titre about two-fold lower than the original serum. The physical properties, therefore, of the equine inhibitors are rather similar to those of antibodies.

The susceptibility of the horse to poliovirus was of interest in view of the similarity of the inhibitors to antibody. No poliovirus has been detected in faecal samples and nasal swabs taken from 616 and 201 horses, respectively, over a period of 15 months; each sample was tested in monkey kidney tissue cultures. Further pertinent information was obtained during the hyperimmunization of horses with attenuated poliovirus. Two horses, the sera of which were free of type I poliovirus inhibitor, were each inoculated intramuscularly with 11·3 $\log_{10}$ $TCID_{50}$ Sabin attenuated type I poliovirus. Faecal samples were taken daily from each. Small quantities of type I poliovirus were found in the faeces taken from each animal 24 h after inoculation. No virus was detected in the subsequent faecal samples. Neither horse developed pyrexia or clinical reactions. Further type I poliovirus inoculations were given and antibody developed, but more sluggishly than might be expected if the virus were reproducing in the equine tissues (Table 2). Slow antibody responses were also obtained in other horses receiving a similar course of inoculations of Sabin attenuated type II and III poliovirus.

Table 2. ANTIBODY RESPONSE BY TWO HORSES INOCULATED WITH TYPE I POLIOVIRUS

Day of inoculation or taking serum	Log_{10} TCD_{50} poliovirus inoculated	Antibody titre
0	11·3	<1/4
14	11·0	Not tested
29	11·2	1/128
35	—	1/512

The properties of the equine poliovirus inhibitors are, therefore, very similar to those of antibody. They are apparently associated with the γ-globulin fraction and, like poliovirus antibodies prepared in horses, are stable to 63° C. The inhibitors neutralize the virus. This is contrary to the findings of Takemoto and Habel[8], who concluded that the type I poliovirus inhibitors they studied were not actually neutralizing the virus but reducing the absorption and release of virus from the cells. In their experiment inhibitory serum was mixed with high titre virus suspension (5·4 P.F.U./1 ml.), samples being removed and titrated at intervals after mixing. Little or no reduction in titre was demonstrable. However, equine poliovirus inhibitors usually have only low titres and in order to demonstrate neutralization in the type of test utilized by Takemoto and Habel it has been necessary to use poliovirus suspension of low titre. In preliminary experiments using between 5·0 and 7·0

$\log_{10}$ TCD_{50} per 0·5 ml. of serum/virus mixture, no neutralization could be detected. This is not surprising when the neutralization curves obtained with lower concentrations of virus are considered. Thus, in one of the type I neutralization curves the virus titre was reduced from 3·7 $\log_{10}$ to 2·7 $\log_{10}$, that is, 4,509 TCD_{50} were neutralized. Even allowing for a considerable elasticity in the neutralizing capacity of a serum containing antibody, the number of TCD_{50} which this serum sample would neutralize when mixed with 5·5–6·0 $\log_{10}$ TCD_{50}/0·5 ml. of poliovirus would not be readily detectable by ordinary titration techniques.

If these are antibodies, what are the antigens which stimulate their formation ? It is unlikely that polioviruses themselves form the stimulant, because: (*a*) the inhibitors reach only low titres; (*b*) poliovirus has never been isolated from horses; (*c*) horses seem to be insusceptible to poliovirus infection. Sabin and Fieldsteel[2] were also unsuccessful in their attempts to infect calves with polioviruses. It is therefore likely that the antigens are to be found in other viruses or micro-organisms. If this is so, there will probably be several, as it is unlikely that one single virus or organism can infect horses, cattle, sheep, swine, monkeys and chickens. Much evidence has accumulated for antigenic relationships between the three types of poliovirus[8–14] and between polioviruses and the various enteroviruses[10,15–18]. Among the polioviruses type II has antigens in common with type I and to a lesser extent with type III. These relationships can be emphasized by heating the antigens[9], by treating with formaldehyde[19] or by irradiating with ultra-violet light[20]. Such treatment probably alters the surface structure to reveal other antigens. Mayer *et al.*[21] and Hummeler and Hamparian[9] have demonstrated two distinct complement fixing antigens in poliovirus, one of which is 'exposed' by heating. The ability of type II poliovirus to stimulate antibodies common to the other serological types, particularly type I, could be explained by its deep antigens being more exposed. It is perhaps significant that in bovine, equine, sheep and monkey sera the type II inhibitors are most common and type III least common. It is suggested that these inhibitors are antibodies to the more deeply situated antigens common to enteroviruses, and are stimulated by various enterovirus infections experienced by the host during its life. The viruses in which these antigens are least concealed will most readily stimulate the formation of inhibitors and will be most sensitive to them when formed.

CONCEPT OF MULTIPLE MOLECULAR FORMS OF LACTIC DEHYDROGENASE

By DR. N. RESSLER, J. L. SCHULZ and R. JOSEPH

Department of Medicine, Wayne County General Hospital, Eloise, Michigan

EXPERIMENTS which have recently been reported by Conklin, Dewey and May[1] suggest that treatment with butanol may convert the various lactic dehydrogenase (LDH) isozymes in a tissue homogenate into a single form. For example, after starch-gel electrophoresis, seven LDH isozymes were detected in untreated rat kidney homogenate, but only a single band could be observed in a sample after butanol treatment. The explanation proposed by these authors is that the enzyme is associated with various lipoproteins or lipids which alter the electrophoretic mobility. The dissociation of these complexes by means of butanol would then permit all the LDH to migrate as a single band. Further corroboration, however, was felt to be necessary.

Since this theory questions the validity of the concept of multimolecular forms of enzymes, at least in regard to LDH, the effect of butanol on LDH activity was investigated further. The results, described here, demonstrate that increasing butanol treatment results in a progressive inactivation of the enzyme. Electrophoresis of purified isozymes provides no indication that butanol converts one isozyme into the form of another before complete inactivation.

Heart, liver and kidney tissue homogenates were prepared from both human and rat sources. Approximately 0·5 g of tissue was used per ml. of 0·25 M sucrose. All samples were subjected to both starch-gel[2] and agar[3] electrophoresis, since some proteins migrate differently in the two media. Preparative electrophoresis was conducted in agar. LDH activity was detected after electrophoresis by the nitro-blue tetrazolium-substrate solution described by Allen[4]. The butanol treatment was conducted by adding various amounts of butanol to a series of tubes. The same amount of tissue homogenate or isozyme was then added to each tube and the contents mixed. The butanol addition was thus varied, while the enzyme addition was constant. Total LDH activity was determined by the method of Cabaud and Wroblewski[5].

The results obtained with human tissues are shown in Fig. 1. Increasing amounts of butanol caused a progressive inactivation of the enzyme. Measurement of total enzyme-levels in corresponding samples, after butanol treatment, demonstrated a decrease in activity to approximately 10 per cent of the pre-treatment values.

Fig. 2 shows the results obtained with isozymes isolated from human liver. Since the fourth and fifth bands showed considerable overlapping, they were taken together as a single fraction. Sufficient butanol treatment caused an almost complete loss of activity of all the isozymes.

Fig. 3 presents the results after electrophoresis of rat tissues. The butanol inactivation, apparent from this figure, was also confirmed by the measurement of total levels in corresponding samples. The untreated liver tissue exhibited a band migrating towards the anode in the starch gel. This fraction had been observed by Conklin, Dewey and May only in the treated sample. The difference

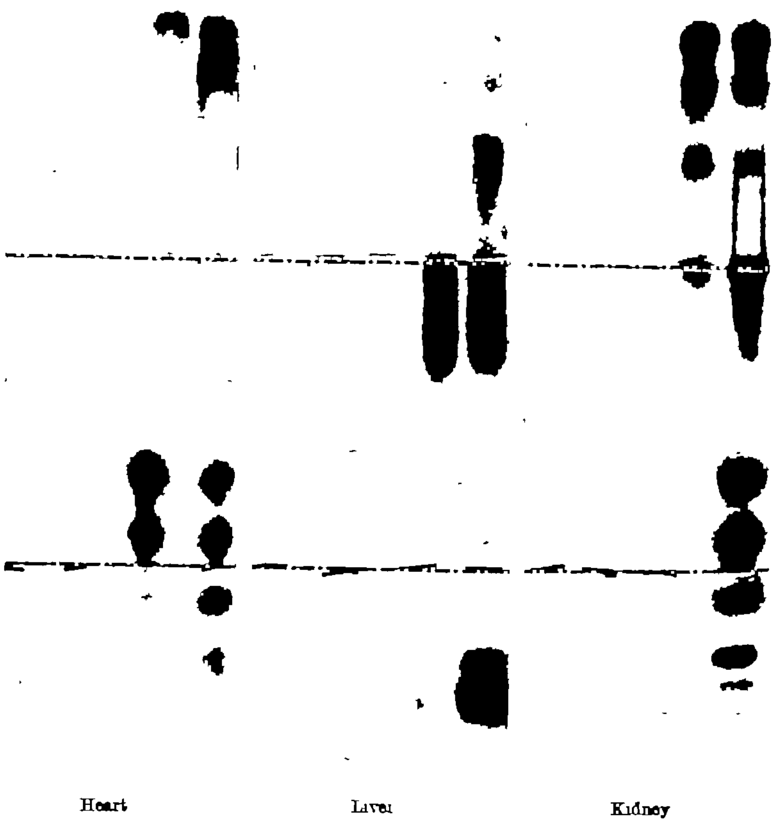

Fig. 1. Electrophoretic separation of LDH isozymes in human tissues. Migration towards the anode is upward. The origins are indicated by dashed lines. Starch-gel separations are above. The butanol additions per ml. of homogenate were, left to right, 0·50, 0·20, 0·10, 0·05 and 0·00 ml. Agar separations are below. The butanol additions per ml. of homogenate were, left to right, 0·50, 0·20, 0·10 and 0·00

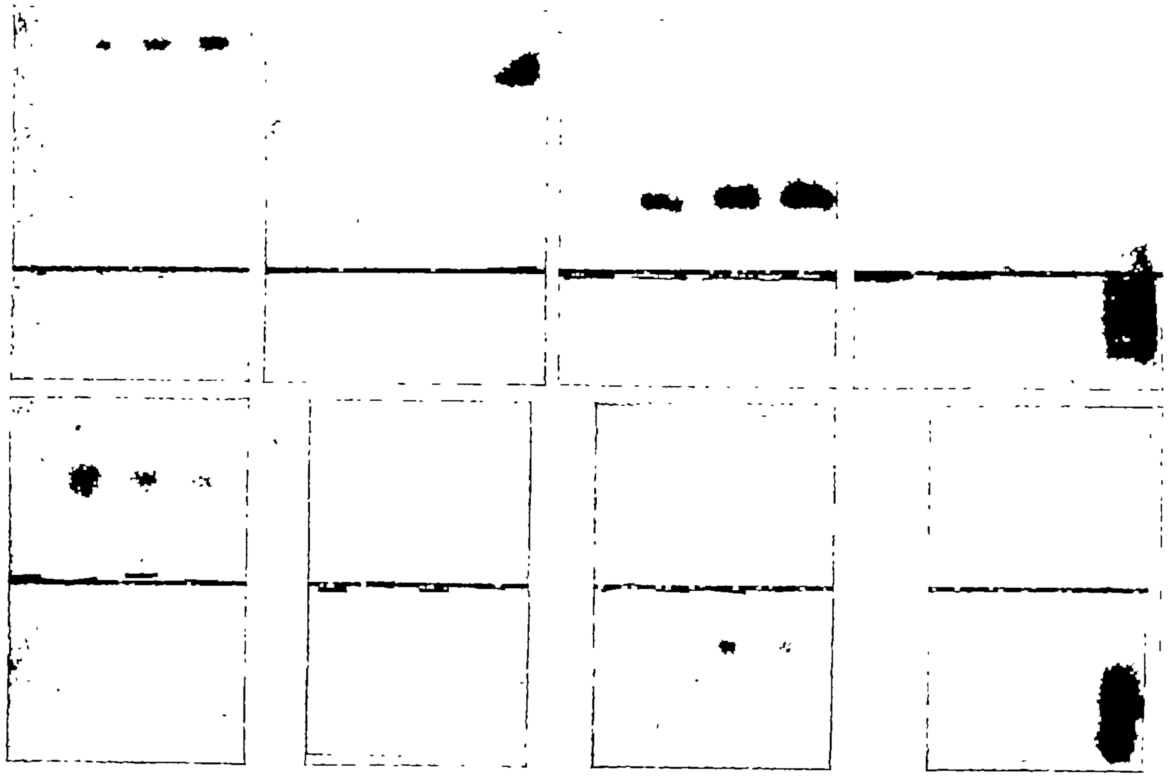

Fig. 2. Electrophoretic separation of isozymes isolated from human liver. The isozyme which migrates most rapidly towards the anode is on the left. Starch-gel separations are above, and agar separations are below. In all cases, the butanol additions per ml. of isozyme were, left to right, 0·09, 0·06, 0·04 and 0·00 ml.

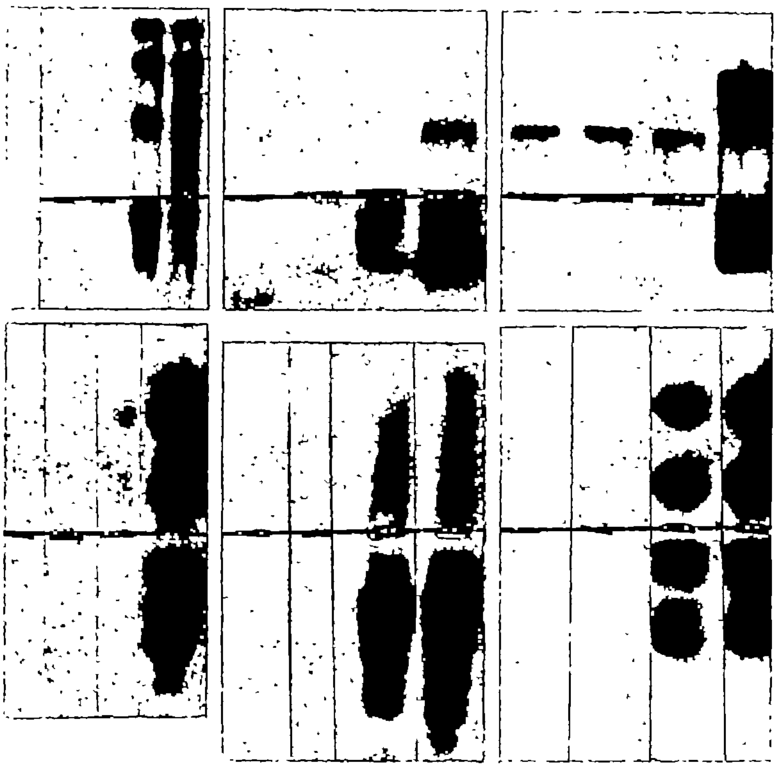

Fig. 1. Electrophoretic separation of LDH isozymes in rat tissues. Starch-gel separations are above, and agar separations are below. In each case, the sample on the left was an aqueous extract of a portion of the tissue which had been homogenized in butanol. The succeeding samples had been homogenized in sucrose. The additions of butanol per ml. of homogenate were, left to right, 0·45, 0·20 and 0·00 ml.

may be due to different quantities of enzyme applied to the gel. The corresponding band obtained after starch-gel electrophoresis of kidney tissue appears to be the only one remaining after butanol treatment. This is in agreement with the results of Conklin *et al.* The electrophoresis of the same samples in agar, however, revealed two bands in the treated kidney, corresponding in position to those of the untreated tissue. This discrepancy may possibly be related to an alteration of mobility by the starch gel.

Attempts were also made to detect specific lipids associated with the human isozymes by staining techniques, but none could be demonstrated. The conclusion which would appear most consistent with these experiments is that butanol treatment provides no reason to question the concept that LDH exists in different molecular forms.

This work was supported in part by grant No. *H*–3473 of the U.S. Public Health Service.

SOURCE OF THE GASTRIC MUCOSAL POTENTIAL DIFFERENCE

By J. G. FORTE*, P. H. ADAMS and PROF. R. E. DAVIES

Department of Physiology, School of Medicine, and the Departments of Animal Biology
and Molecular Biology, School of Veterinary Medicine,
University of Pennsylvania, Philadelphia

IT has been shown recently that the potential difference across frog skin is apparently the algebraic sum of sodium and potassium diffusion potentials on the outer and inner cell membranes in the cells of the stratum germinativum[1]. However, there is no agreement as to the source of the electric potential difference across the stomach wall which has been known since 1834 (ref. 2). The following experiments were designed to investigate this problem.

Bullfrog (*Rana catesbiana*) gastric mucosae were mounted between two chambers containing the following solutions. Nutrient side: sodium chloride, 85·3 mM/l.; potassium chloride, 3·4 mM/l.; calcium chloride, 1·8 mM/l.; potassium dihydrogen phosphate, 0·9 mM/l.; magnesium sulphate, 0·9 mM/l.; sodium bicarbonate, 17·6 mM/l. Secretory side: a similar solution with the sodium bicarbonate replaced by sodium chloride. Both solutions contained 0·2 per cent (w/v) glucose and were gassed with 5 per cent carbon dioxide and 95 per cent oxygen. In fourteen experiments the average transmucosal potential difference

---

* Postdoctoral Fellow of the Pennsylvania Plan to Develop Scientists in Medical Research.

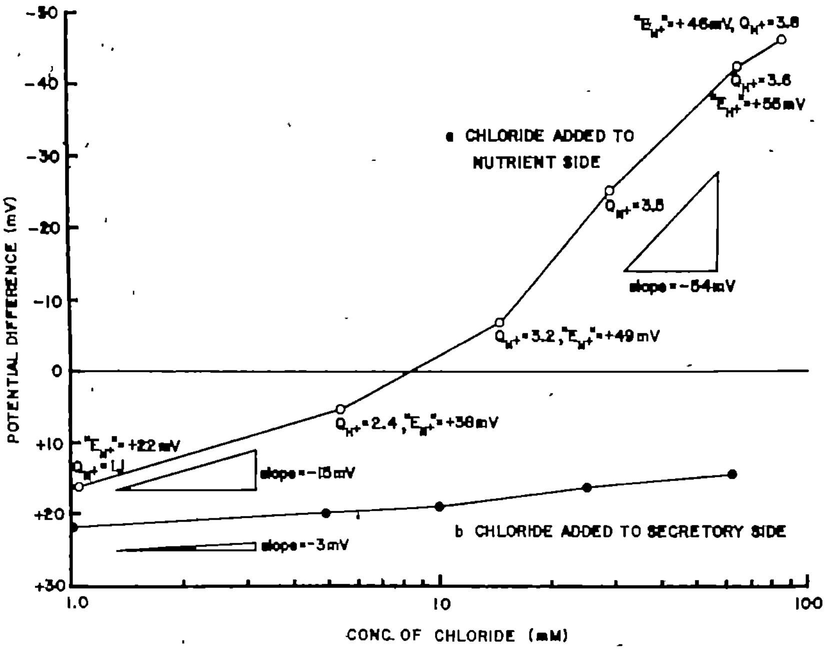

Fig. 1. Typical effects of serial addition of chloride to the nutrient side (*a*) ○; and to the secretory side (*b*) ● of a gastric mucosa bathed in isethionate Ringer's solution. The potential difference with no added chloride in the bathing solutions for the mucosa in (*a*) was + 24 mV and the rate of acid secretion (Q_{H^+}) was 1·0 µequiv./cm^2/h. After the chloride concentration was raised to 84 mM/l. on the nutrient side, the introduction of a similar chloride solution to the secretory side caused the potential difference to change from − 46 mV to a steady state value of − 33 mV. 'E_{H^+}' was calculated from the observed current of hydrogen ions times the mucosal resistance. For the mucosa in (*b*) the potential difference in the absence of chloride was + 27 mV and the Q_{H^+} was 1·1 and did not change significantly while chloride was raised in the secretory solution. Values for the slope are given as mV per ten-fold change in the concentration of chloride

at approximately 22° C was − 30·7 ± 6·6 mV (standard deviation). All values of the potential difference are given for the secretory side with respect to the nutrient side in an external circuit. The mucosal conductance was 2·9 ± 0·5 mmhos/cm^2, and the rate of acid secretion (Q_{H^+}) was 4·8 ± 1·1 µequiv./cm^2/h (1 cm^2 = 12 mg dry wt.). When all the chloride ions in the salt solutions were replaced by 2-hydroxy-ethylsulphonate (isethionate), the transmucosal potential difference changed from negative to positive and within a half-hour achieved a steady state value of + 22·2 ± 4·6 mV, while the conductance became 1·0 ± 0·4 mmhos/cm^2 and the rate of hydrogen ion secretion 1·0 ± 0·2 µequiv./cm^2/h. The electrical effects were similar in direction but much greater in magnitude than those observed when the chloride in the bathing media is replaced by sulphate[2-4] (which is less permeable than chloride and very inefficiently transported by the gastric mucosal pump[5,6]). The effects in isethionate solutions were completely reversible for at least 7 h.

Fig. 1 shows the changes in potential difference following serial addition of chloride to isethionate solutions on the (*a*) nutrient and (*b*) secretory sides. Fig. 2 shows similar changes during anaerobiosis and following the reintroduction of oxygen during conditions where acid secretion occurred or was inhibited.

The results support the view that there is a chloride diffusion potential across the nutrient (but not the secretory) surface, and that there are electrogenic hydrogen and chloride ion pumps at the secretory surface[4]. The evidence for this view is as follows.

The reversible change from a negative to a positive polarity when isethionate completely replaced chloride on the nutrient side shows that chloride is necessary for part of the naturally occurring potential difference. In isethionate solutions, with no external chloride, the rates of acid secretion were considerably less than those observed in the normal chloride solutions, presumably because the isethionate accompanying the hydrogen ion is at least ten times less permeable. Fig. 1 shows that for the change from 1–6 mM chloride on the nutrient side the Q_{H^+} more than doubled ($\Delta Q_{H^+} = 1{\cdot}3$) and the potential difference increased at the rate of − 15 mV for a ten-fold concentration change. However, for the change from approximately 15 to 60 mM chloride the ΔQ_{H^+} was only 0·4, but the rate of increase of the potential difference was − 54 mV for a ten-fold concentration change in chloride and thus approached the value of − 58 mV for a ten-fold change predicted by the Nernst equation for a diffusion potential resulting from an ionic concentration gradient. This suggests that there is a chloride diffusion potential

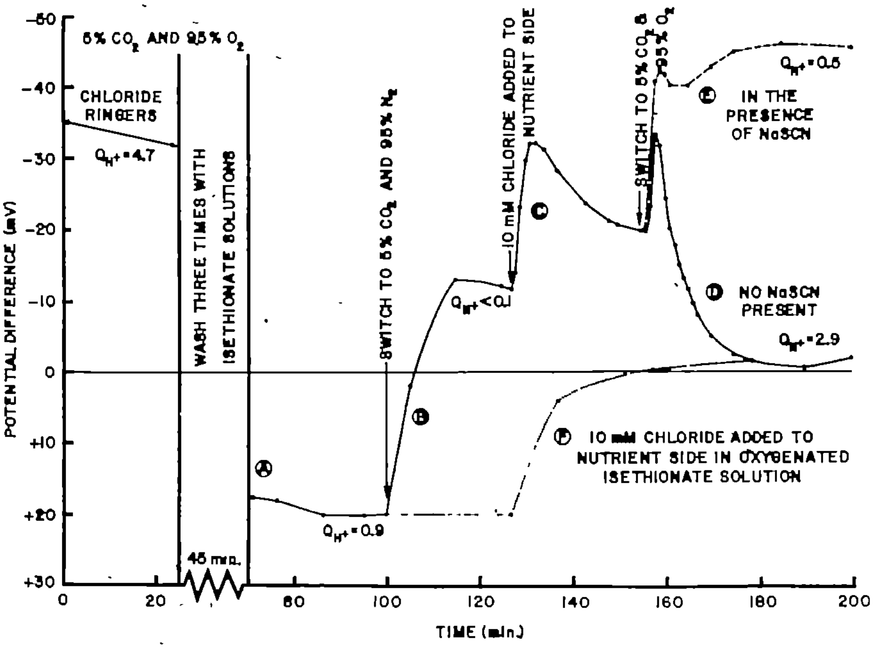

Fig. 2. Typical composite experiments showing effects of removal and reintroduction of oxygen and chloride from the solutions bathing the gastric mucosa. Conditions *b* and *c* of Fig. 3 obtain in normal chloride Ringer's, while in isethionate Ringer's condition *a* operates. *C* shows the transient chloride diffusion potential (Fig. 3*b*) which dissipates in the absence of oxidative metabolism. *E* represents the potential difference when 5 mM sodium thiocyanate has previously been added to the secretory side at time 127 min and shows that the chloride pump is re-established on the introduction of oxygen (Fig. 3*b*), while at *D* both the hydrogen pump and the hydrochloric acid pump (Fig. 3*a* and *c*) are operating. This latter state can be reached directly as shown in *F*.

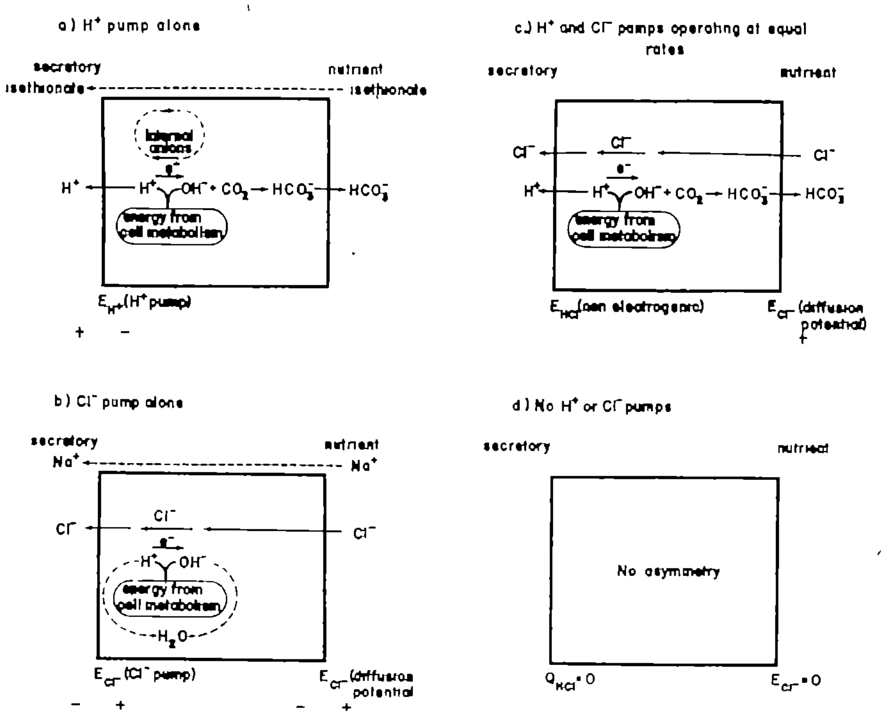

Fig. 3. Schematic representation of the mechanism of chloride and hydrogen ion transport under four operating conditions (see also Davies (ref. 14)). The secretory surface is probably relatively impermeable to hydrogen and chloride ions. The nutrient surface is permeable to chloride and bicarbonate ions. (*a*) H^+ pump alone in isethionate Ringer's. Note that traces of Cl^- remain in the mucosa even after many hours in this solution; (*b*) Cl^- pump alone, but no acid secretion, either naturally or in the presence of sodium thiocyanate; (*c*) the H^+ and Cl^- pumps are normally in operation during acid secretion; and (*d*) no H^+ or Cl^- pumps are in operation under conditions such as anoxia, 2,4-dinitrophenol, death, etc.

across the nutrient surface, but that normally it is masked by the positive potential caused by hydrogen ion secretion. Furthermore, the insensitivity of the potential difference to changes of chloride on the secretory side shows that no chloride diffusion potential is developed across this surface. The small changes in potential shown in Fig. 1*b* might be the result of slight leaks of chloride from the secretory to the nutrient solutions. Changes in the bicarbonate concentration from 5 to 30 mM in the nutrient solution were without significant effect on the potential difference, so it is unlikely that there is a bicarbonate diffusion potential across the nutrient surface (Fig. 3*c*).

Fig. 2*C* shows that a chloride diffusion potential at the nutrient surface can develop in the absence of oxygen although it dissipated as chloride entered the cells. On re-establishment of the energy supply (Fig. 2*D* and *E*) the cells were able to pump out the chloride which had accumulated in the absence of oxygen; thus they could restore the anionic concentration gradient and the resulting diffusion potential. These findings agree with the results of several authors that the chloride concentration within the oxyntic cells is normally low relative to the external concentration[7,8], and that the intracellular chloride concentration increases when oxidative phosphorylation is inhibited by 2,4-dinitrophenol[8] which also destroys the transmucosal potential difference[9].

The chloride pump causes a net flow of chloride through the secretory surface[10]. Since it can operate in the absence of acid secretion and with no exchangeable anion on the secretory surface, and since the chloride concentration within the cells is low, the chloride pump seems to be electrogenic, that is, capable of producing a net transport of electric charge.

It has been shown that the potential difference across the gastric mucosa in chloride Ringer's is unaffected by changes in *p*H from 2 to 7 on the secretory side[11]. In isethionate solutions we have similarly found that the potential difference is insensitive to the aforementioned *p*H changes. Thus, there is no significant hydrogen ion diffusion potential across the secretory surface. Since the secretory surface is relatively impermeable to hydrogen ions, the positive potential found during acid secretion in isethionate solutions (Fig. 2 *A* and *B*) is taken to be the result of an electrogenic hydrogen pump. This potential can be abolished by suitable inhibitors of acid secretion (anoxia or thiocyanate, Fig. 2 *B* and *E*). The magnitude of the measured hydrogen ion potential would depend on local short circuits through the mucosa which, in turn, are related to the permeability of the membrane. Thus in solutions containing isethionate, but no chloride, where the mucosal conductance was low, we have found that inhibition of acid secretion resulted in larger transmucosal potential changes than in chloride-containing solutions.

Fig. 3 is a schematic representation of the sources of the gastric mucosal potential difference under four different conditions. (It should be noted that states *b* and *c* are usually found together in any given mucosa.) Both the hydrogen and the chloride pumps are taken to be electrogenic in that if either of them operates alone it produces a separation of charge and hence an electromotive force. When the mucosa is secreting hydrochloric acid, the hydrogen pump and the chloride pump both operate, and, since the ions are equal and opposite in sign, there is no net charge transfer and hence no developed electromotive force associated with hydrochloric acid secretion *per se*. So long as the chloride pump is in operation, it maintains the intracellular chloride concentration at values below that of the bathing solutions, and hence a chloride diffusion potential develops across the nutrient side of the oxyntic cells. This causes a polarity across the mucosa—the secretory side being negative with respect to the nutrient side. In the absence of a permeable anion, such as chloride (or bromide, iodide, nitrate, etc.[12,13]), or in the presence of metabolic inhibitors which reduce or abolish the concentration gradient, the chloride ion diffusion potential is lowered or absent.

PRESENCE OF IODINE-127 IODOTYROSINES IN EXTRACTS OF NORMAL HUMAN SERUM

By Prof. SIDNEY C. WERNER and Dr. ILDIKO RADICHEVICH

Departments of Medicine and Biochemistry, Columbia University College of Physicians and Surgeons and the Presbyterian Hospital in the City of New York

WERNER and Block[1] observed a discrepancy between iodine-131 and iodine-127 content of iodotyrosines in chromatograms of serum of healthy human subjects given a labelling dose of iodine-131. No iodine-131 iodotyrosines were found, whereas in the same chromatograms, iodine-127 iodotyrosines, both diiodotyrosine (DIT) and monoiodotyrosine (MIT), constituted a sizeable percentage of the total iodine. The same group of workers further demonstrated that neither radioiodide nor labelled thyroxine (T_4*) was converted to labelled iodotyrosines by the extraction and chromatographic procedures originally used[2] or by several other methods. It was also noted that stable iodotyrosines were present in chromatograms of normal rat serum, and additional evidence was furnished[2-4] that the iodotyrosine titre in human serum extracts probably varied with pathophysiological change.

The present experiments were designed to determine further the identity of the iodine-127 iodotyrosines extracted from serum with standard compounds, MIT and DIT. Two techniques were adopted: isotope dilution and derivative formation by dinitrophenylation. With the isotope dilution method, small concentrations of iodocompounds were determined when dilution occurred of the appropriate standard compound of known specific activity added to the serum before processing. By dinitrophenylation, *bis*(2,4-dinitrophenyl)-derivatives of both DIT and MIT were formed which were then identifiable chromatographically by comparison with diphenylated standard MIT or DIT of known specific activity. Addition of either of these compounds to the serum prior to dinitrophenylation permitted both autoradiography and isotope dilution studies.

Blood for the experiments was secured from healthy medical students, and the sera therefrom pooled and used immediately. Iodine-131 diiodotyrosine and monoiodotyrosine (Abbott) of known specific activity were then added to separate aliquots of pooled serum and one of the two types of experiment mentioned here conducted. Several pools of serum were used during the study.

In all experiments, two-dimensional chromatography was performed with two different solvent systems. Radioactive areas were then identified by autoradiography, the appropriate areas of the paper cut out, and the radioactivities measured. Iodine-127 concentrations in these areas were determined either directly as DIT or MIT by the ceric sulphate–arsenious acid reaction, or in the case of the dinitrophenylated derivatives, as iodine-127 following combustion in oxygen.

Serum for the isotope dilution experiments was processed by the methods usually adopted in this laboratory[5], and the final extract chromatographed on paper. For dinitrophenylation, the iodotyrosines were first separated from the other iodinated compounds in serum by column or by paper chromatography, and the derivatives then prepared.

In all experiments, saline solutions containing 0·59 per cent sodium chloride, the average of human serum, were used as controls and processed the same as the serum. Full details of the procedures as well as the recovery and other salient data not presented here are being published elsewhere[6,7].

Tables 1 and 2 show the pertinent results. The wide range of individual values shown for the isotope dilution experiments was accounted for by several factors: (*a*) the amount of isotope added to the serum; (*b*) the serum sample used which may affect the chemical reaction used to quantitate iodine-127; (*c*) to a limited degree, the solvent systems. Since greater purification is achieved with the compounds to be dinitrophenylated, this probably accounts for the greater uniformity of the values for this part of the study. Also, the quantitation of stable DIT and MIT is more reliable with the combustion procedure than with the catalytic method used for the isotope dilution study.

Table 1. IDENTIFICATION BY ISOTOPE DILUTION OF IODINE-127-MONOIODOTYROSINE AND IODINE-127-DIIODOTYROSINE IN EXTRACTS OF NORMAL HUMAN SERUM

Solvent system	Isotope dilution (ratio of initial to final specific activities) MIT	DIT
BDA : 2 BA	2·3	*
2 BA : BDA	1·9	5·3
BDA : BAc	3·0	1·7
BAc : BDA	4·1	1·4
2 BA : BAc	5·6	8·6
BAc : 2 BA	2·8	2·1

* Value not determined

BDA, *n*-butanol : dioxane : 2N ammonia (4:1:5)

2 BA, sec.butanol : 1·6 N ammonia (3:1)

BAc, *n*-butanol : glacial acetic acid : water (9:1:2·5)

Table 2. IDENTIFICATION BY DERIVATIVE FORMATION THROUGH DINITROPHENYLATION OF IODINE-127-MONOIODOTYROSINE AND IODINE-127-DIIODOTYROSINE IN NORMAL HUMAN SERUM

Exp. No.	Isotope dilution (ratio of initial to final specific activities) MIT	DIT	Estimated serum content† MIT µg/100 ml.	DIT µg/100 ml.
A	7·5	4·3	1·21	0·48
B	*	7·2	*	0·86
C	14·4	8·9	1·31	1·01
D	*	10·7	*	0·74

* Values not determined.

† Corrected for losses during extraction.

The average concentrations of diiodotyrosine in the original serum before extraction have been estimated from the dinitrophenylation procedure (Table 2). The results agree reasonably well with those originally reported by this laboratory[1] and by Beale and Whitehead[8]. These latter used a double isotope dilution technique although the completeness of the chromatographic separation of the final products has been questioned. About a third of the extractable serum iodine appears to be present as iodotyrosines.

Proof that the compounds considered to be iodotyrosines do in fact contain iodine and hence that the catalytic reaction to measure iodine was not being produced by non-iodinated materials has been furnished by neutron-activation analysis. Both Stark and Knorr[9], and Dimitriadou, Turner, Slater and Fraser[10] have extracted normal human serum and identified the formation of iodine-128 in the iodotyrosine areas of the chromatograms. Their calculations of the amounts of iodine-127 present in serum correspond reasonably well with the original estimates of Werner and Block[1].

Dimitriadou *et al.*[11] later reported that the proportion of iodine-127 iodotyrosines in normal sera and in sera from thyrotoxic patients was less if a resin column was used for the extraction procedure. A similar observation has been made in our laboratory. Dimitriadou *et al.*[11] and Wellby and Hetzel[12], using different methods, also confirmed the fact that iodotyrosines are not formed during extraction from the other iodocompounds normally present in serum or plasma. The latter workers, however, were able to identify iodine-127 iodotyrosines in normal serum only when the serum protein-bound iodine values were at the upper limits of the normal range or were increased by pre-treatment of the donor with thyrotropin.

All in all, the evidence seems almost incontrovertible that iodotyrosines are extracted from normal human serum by the usual procedures for chromatography. The present investigation indicates that both DIT and MIT are involved. The materials extracted from serum and the appropriate standard compounds behaved identically on isotope dilution and derivative formation. It is improbable that two other iodinated compounds have been behaving in so many systems like DIT and MIT and yet are different.

If iodotyrosines are present in extracts of normal serum, the question remains whether they exist as such in the original serum. It is more probable that they do not, in view of the short half-life *in vivo* of several hours for these substances[13]. Rather they may be liberated from other compounds in the course of preparation for chromatography by splitting of bonds which are unstable at *p*H 3–4. This possibility is at present under investigation.

We are indebted to (the late) Dr. Richard J. Block and also thank Dr. Seymour Lieberman for his advice.

BINDING OF INSULIN TO A MUSCLE CELL MEMBRANE PREPARATION

By DR. P. M. EDELMAN, S. L. ROSENTHAL and PROF. I. L. SCHWARTZ

Department of Physiology, University of Cincinnati Medical College, Cincinnati, Ohio, and Medical Research Center, Brookhaven National Laboratory, Upton, New York

RECENT investigations[1-4] suggest that the primary action of insulin is on the permeability of cell membranes. This idea may account for the effects of the hormone in broken-cell preparations as well as in tissue preparations with intact cells if the concept of the cell membrane is broadened to include endoplasmic reticular extensions and the membranes of sub-cellular organelles.

Following on the initial demonstration that insulin was bound to muscle[7,8] and the elucidation of the structure of insulin[9,10], evidence was presented that this binding involves a sulphur–sulphur linkage between hormone and target tissue[11-13]. In the work reported here, skeletal muscle cell ghosts were prepared for use in studying the chemical nature of the attachment of insulin to a relatively pure cell-membrane preparation.

Sprague–Dawley female rats (150–200 g) were fasted for 18–20 h, killed by decapitation, and the femoral musculature removed. The intact excised muscles were then incubated in 15 ml. of phosphate–bicarbonate medium[14] containing 1–2 ml. of ^{131}I-iodoinsulin (specific activity 7·85 and 2·96 mc./mg, Abbott Lot No. *IN* 096–9, No. *IN* 099–22, respectively, and containing 0·05 mg insulin/ml.), at *p*H 7·4 and 37° C. 95 per cent oxygen and 5 per cent carbon dioxide were gently bubbled through the medium. The contralateral limb musculature was used for control studies.

After 30 min incubation, the muscles were removed from the medium, washed 3 times in normal saline, bathed in 10^{-3} M *N*-ethylmaleimide (NEM) for 3 min to bind available SH groups, washed 3 times in 0·01 N hydrochloric acid and then 6–8 times in a solution of 8 M urea in 0·015 N hydrochloric acid, after which the radioactivity in the supernate was at background levels.

The muscle was then sheared and shredded by a modification of the method of Wang[15] and membranes were prepared by a modification of the procedure of McCollester[16]. During the preparation, samples were inspected in polarized light[17] and the washings discontinued when half the muscle cell membranes appeared as hyaline tubules. The membrane suspension was divided into 4 equal parts in 4 separate tubes, and aliquots of the uniformly dispersed membrane preparations were assayed for protein by the method of Lowry[18] and for radioactivity in a well-type scintillation counter.

To free the preparation further of insulin bound in electrovalent linkage, these four tubes were shaken for 1 h at 37° C in a solution of 8 M urea and 0·1 M sodium bicarbonate (*p*H 8) under an atmosphere of nitrogen. After this and subsequent incubations, the membrane suspensions were centrifuged (1,200*g*) and the radioactivity and protein of the membrane and supernate determined. The membranes were then resuspended in 5 ml. of fresh media containing 0·1 M serine, 0·1 M methionine, 0·1 M cysteine or 0·1 M β-mercaptoethylamine in addition to 8 M urea, and 0·1 M sodium bicarbonate (*p*H 8). After replacing the air with nitrogen, the tubes were stoppered and shaken (100 oscillations per min) at 37° C. At 30-min intervals the tubes were centrifuged and an aliquot of each membrane preparation and the supernate derived from it were assayed for protein and radioactivity. The membranes in each of the 4 tubes were then redispersed in fresh aliquots of their respective suspension solutions, the tubes again gassed with nitrogen, stoppered, and the incubation continued with shaking at 37° C.

After 210 min of washing, the specific radioactivity of the membranes (defined as c.p.m./mg membrane protein) exposed to methionine or serine (the controls) reached a plateau at a level of 25 (±2 per cent) of their initial radioactivity. When these membranes were then incubated and washed with either β-mercaptoethylamine or cysteine, their specific radioactivity consistently dropped to a new plateau within 2 h; the residual labelling of the membranes now amounting to 5–8 per cent of the original (pre-incubation) level. Membranes that were washed in thiol compounds from the beginning also dropped to the 5–8 per cent plateau-level within 3 h (Figs. 1 and 2). (We observed that the thiol compounds caused a continuous dissolution of the muscle membrane which was minor but significantly greater than that noted in the control experiments. This phenomenon was, of course, taken into consideration in the calculation of the specific activity. It should be noted that the specific activity of the membrane preparation ultimately rises, indicating solution of unlabelled or relatively lightly labelled protein components.)

To determine the amount of ^{131}I labelling in each chain, an aliquot of ^{131}I–insulin was oxidized with performic acid[19,20] and the chains separated by counter-current distribution[20]. The *A* and *B* chains were found to have 56 and 44 per cent, respectively, of the total radioactivity.

Thus, when insulin was attached to muscle tissue under the conditions already described (and when the remaining free SH groups in the membrane were then reacted with NEM) it was found that, after the removal of the trapped and electrovalently bonded ^{131}I–iodoinsulin, a significant amount of radioactivity (25 per cent of the original level) remained bound to the membrane. This residual radioactivity was further reduced to 5–8 per cent of the original level when these membranes were subjected to thiol reagents, suggesting that this final reduction in membrane-bound iodine-131 was the result of cleavage of an SS bond between hormone and muscle cell membrane protein.

Since insulin possesses 2 S—S bonds linking the *A* and *B* chains, one must consider the possibility that it is these interchain S—S bonds which are cleaved by the thiol treatment. However, this possibility would allow a maximum 44 per cent release of additional radioactivity to be effected specifically by the final thiol treatment. The fact that a 67–80 per cent release of additional radioactivity occurred as a result of the thiol treatment strongly suggests that the initial hormone-tissue reaction involved the formation of an S—S bond between membrane protein and the half-cystine moiety in position 6 and/or position 11 on the *A* chain of the hormone.

Another possibility not excluded is that the *A* and *B* chains are involved in the separate attachment of these chains to the tissue. This alternative seems unlikely, however, because the individual chains are neither easily separated nor physiologically active[21].

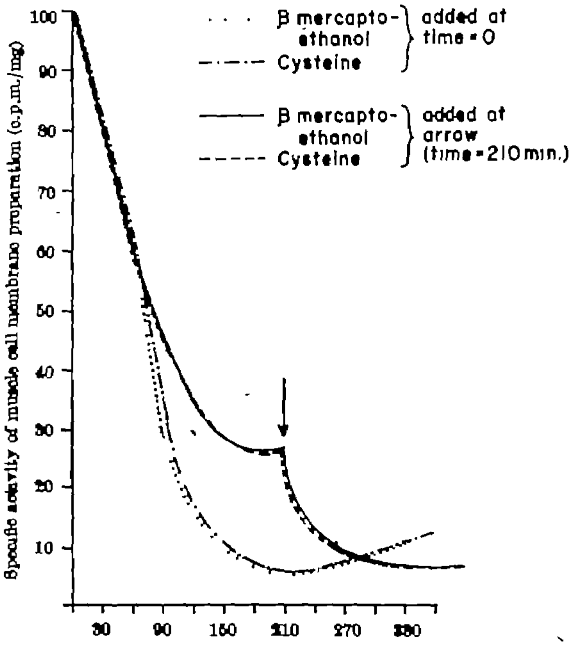

Fig. 1. The specific radioactivity of preparations of iodine-131-insulin-labelled muscle cell membranes at various times after incubation in media containing thiol reagents and in control media. The curves show data averaged from 10 experiments. Note the drop of the membrane specific activity after the addition (arrow) of the thiol reagents. The specific activity has been normalized to a zero time pre-incubation value of 100 c.p.m./mg membrane protein

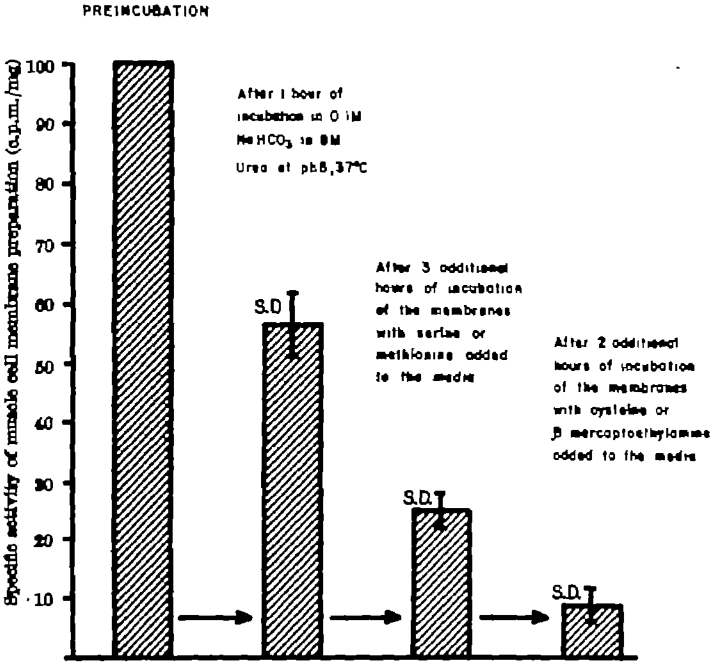

Fig. 2. Residual specific radioactivity of preparations of ^{131}I-insulin-labelled muscle cell membranes before and after incubation in various media. The specific activity has been normalized to a zero time pre-incubation value of 100 c.p.m./mg membrane protein. All incubations were performed with shaking at 37° C in media of 8 M urea in 0·1 M sodium bicarbonate to which the reagents were added

Whole muscle pretreated with 10^{-3} M NEM (to block SH groups) bound approximately 50 per cent less ^{131}I–iodoinsulin than did the control tissue which was not pretreated with NEM. This is in agreement with the findings of Cadenas *et al.*[11]. However, the amount of iodoinsulin bound in both the NEM-pretreated and the control whole muscle varied greatly; the bound iodoinsulin was apparently influenced by the amount of connective tissue present as suggested by Mirsky and Perisutti[22]. The specific activity of membranes prepared from NEM-treated muscle was 70 per cent of the specific activity of control membranes prepared from non-treated muscle. This relationship was maintained throughout the procedures designed to release electrovalently bound radioactivity. However, the thiol compounds reduced the specific activity of the control membranes and the membranes from NEM-pretreated muscle to the same level. This suggests that not all the membrane SH groups which may be serving as insulin-binding sites were chemically or physically available to NEM, but that the NEM which did reach and react with the muscle membrane indeed blocked hormone attachment at 30 per cent of the available sites. In view of the finding that the release of bound radioactivity was effected similarly from membranes prepared from NEM-pretreated and from control muscle, it appears that the mode of attachment of hormone to membrane may be qualitatively unaltered by the partial binding of NEM to the membrane as a whole.

Whole muscle boiled in saline for 3 min produced extremely variable results: the specific activity of the boiled muscle seemed to be in inverse relationship to the amount of connective tissue as determined by histological appearance. When moderate amounts of connective tissue were present, the boiled whole muscle bound approximately 75 per cent more radioactivity, a finding which corresponds to that of Mirsky and Perisutti[22] on whole muscle tissue. The muscle membranes obtained from boiled tissue had a specific radioactivity amounting to as much as 600 per cent of that of membranes prepared from the unboiled control muscle. However, the boiled membranes dissolved readily in the urea–bicarbonate media and even more so in the media containing thiol reagents. During the washing of the membranes to remove electrovalently- and disulphide-bound iodoinsulin, the specific activity of the 'boiled' membranes decreased at twice the rate (200 per cent) of the 'unboiled' control membranes. It appears, therefore, that boiling disrupts the membranes, causing a variably greater non-specific binding and trapping; the heat denatured membrane neither binds nor releases ^{131}I–iodoinsulin in a reproducible manner.

In summary, a relatively pure preparation of cell membranes was isolated from rat skeletal muscle which had been allowed to react with physiologically active iodoinsulin labelled with iodine-131. These membranes were found to be extensively labelled, the radioactivity being bound through both electrovalent and covalent (disulphide) linkages. These findings are consistent with the hypothesis that the action of insulin on membrane permeability is initiated by a thiol-disulphide interchange reaction involving the cyclic disulphide on the *A* chain and sulphydril groups on the receptor protein of the target tissue.

We thank Dr. Victor Bond of the Brookhaven National Laboratory for his interest and support, and Mrs. Linda Livingston, Miss Mary Anne Schoessler and Dr. Laura Rahm for assistance.

SPECIFIC METABOLIC REPRESSION OF INDUCED ENZYMES IN *ESCHERICHIA COLI*

By Dr. ELIZABETH McFALL and Dr. J. MANDELSTAM

National Institute for Medical Research, Mill Hill, London, N.W.7

INDUCTION and repression are two mechanisms which appear to have been evolved in bacteria to ensure that certain enzymes will be produced at a high rate only when they can function usefully in the chemical environment. The selective advantages of directed enzyme synthesis are obvious, and the fact that at least 100 enzymes may be controlled in this way[1] means that a substantial saving in protein synthesis is achieved. In general, repression is the control mechanism for biosynthetic enzymes concerned in the production of amino-acids, purines, pyrimidines and possibly co-factors. The inhibitory effect of amino-acids on the formation of enzymes involved in their own synthesis was first noted by Monod *et al.*[2], and later termed 'repression'[3]. The best-known example is that in which arginine, in *E. coli*, represses the synthesis of eight enzymes in the arginine biosynthetic pathway[4–6].

On the other hand, many degradative enzymes are controlled by induction, that is, they are not produced unless their substrates or chemically similar inducers are present. On the basis of genetic experiments with the β-galactosidase system the following explanation of induction was proposed (see Jacob and Monod[7]). The gene responsible for inducibility (i^+) causes the formation of a specific repressor (*R*). This prevents the functioning of the gene (*z*) which specifies the structure of β-galactosidase so that little or no enzyme is formed. If an inducer is added it reverses the action of *R*, and the enzyme is produced freely.

There is, however, an additional control on the production of β-galactosidase and other degradative-induced enzymes. This is commonly manifested as the 'glucose effect'; in which glucose prevents enzyme formation even in the presence of inducer. This is not a specific property of glucose; if any source of carbon and energy is made excessive (for example, by restricting nitrogen), it will exert a similar repression[8]. This is consistent with the earlier suggestion[9] that it is not glucose itself but metabolites derived from it which produce the effect.

We have examined the glucose effect to determine whether the repression is due to formation of greater amounts of *R*, or whether there is a separate metabolic repressor. If the metabolic repressor were the same as *R*, it should have the following properties: (*a*) it should not be formed at all by constitutive (i^-) strains because these have lost the ability to produce functionally active *R*; (*b*) its action should be reversed by adding sufficient inducer; (*c*) it should have no effect on the constitutive strains designated O^c. These are still i^+, that is, they still produce *R*, but have undergone a mutation which renders them insensitive to it.

An earlier investigation showed that the constitutive (i^-) strain was in fact susceptible to repression by glucose and all other carbon sources tested, and that even a moderate degree of repression was not reversed by adding large amounts of inducer[10]. Finally, we have confirmed Brown's observation[11] that the O^c mutants are also subject to carbon source repression. On all these criteria, therefore, the metabolic repressor is a separate control factor acting at some point which does not involve the three factors of the Jacob–Monod model: the *i* gene, the inducer or the O^c locus on the chromosome.

The next problem was to determine whether a common metabolic repressor exists for all enzymes showing the 'glucose effect' or whether there is a specific repressor for each. This was examined using three enzymes known to be subject to metabolic repression: β-galactosidase, D-serine deaminase and L-tryptophanase. When a culture of *E. coli* induced for the three enzymes was subjected to nitrogen- or magnesium-deprivation in a continuous-flow apparatus, it was often possible to dissociate the repression of β-galactosidase from that of the other two enzymes. The fact that the two latter enzymes behaved so similarly suggested that they had a common repressor which differed from that of β-galactosidase. This led us to test the effect of pyruvate, which is an end-product of enzyme action both for serine deaminase and for tryptophanase, and of galactose, an end product of β-galactosidase action. Pyruvate proved to be an even more effective repressor for tryptophanase than glucose while galactose was almost inactive (Fig. 1). Serine deaminase was examined in the continuous flow apparatus because a transient toxic effect of D-serine made the results of flask culture experiments difficult to interpret. Again, pyruvate repressed, while galactose did not. On the other hand, galactose was an efficient repressor for β-galactosidase (Fig. 2). In most experiments it was somewhat more effective than glucose itself, while pyruvate failed to repress at all (Fig. 2). Other carbon sources have been tested for repressor action but none was as efficient as galactose for β-galactosidase or as pyruvate for tryptophanase. These results are consistent with the assumption (see above) that glucose acts, not as such, but because it is rapidly metabolized and is thus capable of giving rise to large amounts of intermediary metabolites like galactose and pyruvate, which act as specific repressors for different enzymes. The validity of this interpretation and objections to it are considered in more detail elsewhere.

It appears, therefore, that inducible enzymes producing carbon and energy for the cell are each controlled by two specific repressors. Production of one repressor is controlled by the *i* gene, which determines the property of inducibility or constitutivity. The other repressor controls enzyme production both in constitutive and inducible strains, and seems to be the immediate end-product of the reaction or some closely related substance.

Other instances have been reported in which end-products repress the synthesis of degradative enzymes; see, for example, the effect of succinate on isocitratase production[12].

These findings suggest that end-product repression is a fairly general mechanism for controlling enzyme biosynthesis, and that it operates both in biosynthetic and catabolic pathways. However, in some of the latter induction provides an additional and independent control. The value, in terms of protein economy, of having this second type of regulation can best be appraised by considering what would happen if only one type of repressor were present. If the cells possessed the genetic, but not the metabolic, repressor, the enzyme would be produced in response to the substrate even in the presence of good carbon sources like glucose, which were already supplying sufficient carbon and energy. Conversely, if there were only the metabolic repressor, a state of carbon starvation would cause the synthesis of the previously repressed enzyme, whether its substrate were present or not. The possession of two repressor systems ensures that the enzyme will not be synthesized unless the substrate is present, and even then only if the level of intermediary metabolites has fallen to a low level.

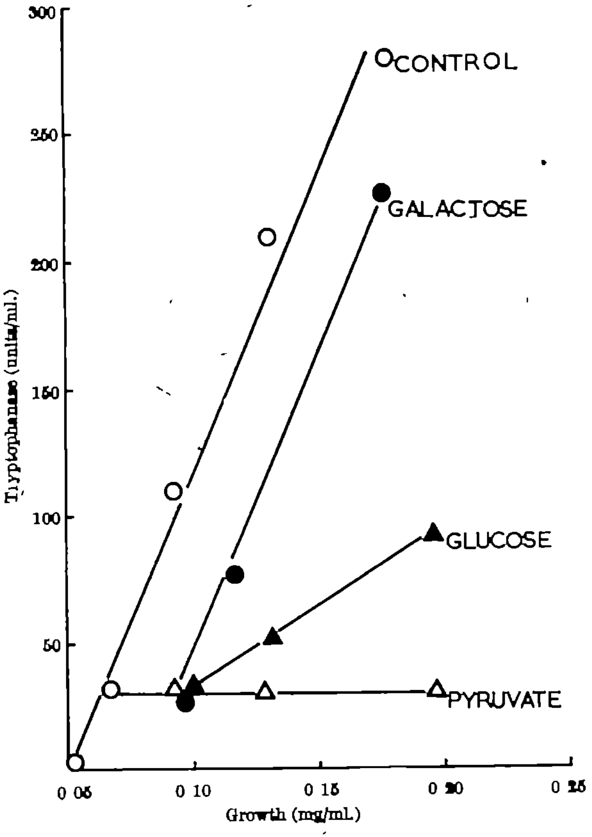

Fig. 1. Repression of L-tryptophanase by various carbon substrates. *E. coli* (K12) growing in 1 per cent glycerol–ammonium salts medium was induced with L-tryptophan (300 μg/ml.). The metabolites (5 mgm/ml. final concentration) were added to different portions of the culture. The rate of enzyme synthesis is given by the slope of the line. One unit of enzyme produces 1 mμmole indole/h from L-tryptophan

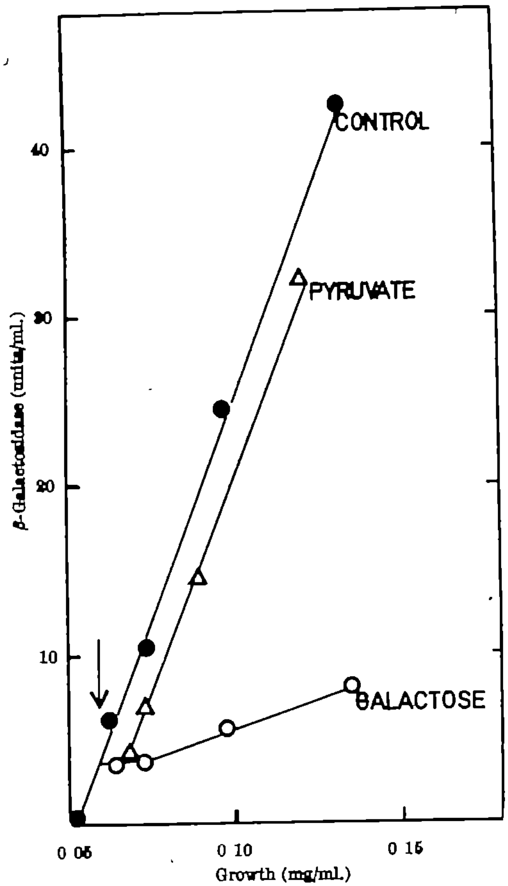

Fig. 2. Repression of β-galactosidase by carbon substrates. Medium and additions were as in Fig. 1 except that methyl-thiogalactoside was used as inducer and additions were made at the point indicated by the arrow. One unit of enzyme hydrolyses 1 μmole of *O*-nitrophenyl-β-D-galactoside/h

One of us (E. M.) thanks the U.S. Public Health Service for a special research fellowship.

ENVIRONMENTAL CONTROL OF FLOWERING IN *DACTYLIS GLOMERATA* L.

By D. M. CALDER

Welsh Plant Breeding Station, Aberystwyth

DACTYLIS glomerata has been shown to be a long-day plant[1], but before responding to long days it must be fully induced and there is some confusion over the nature of induction in this species. Some workers claim an inductive requirement of cold temperatures only[2], others short photoperiods[3], while still others suggest that both low temperatures and short days are necessary[4]. In a few instances[5,6] complete failure of induction has been reported.

In recent investigations at the Welsh Plant Breeding Station on the environmental control of flowering in *D. glomerata* certain aspects of behaviour have been revealed of which the following are significant: (1) germinating seed and young seedlings do not respond to cold vernalization; (2) plants grown from germination in continuous light fail to head; (3) plants grown in natural long days without any cold or short-day induction can head; (4) overwintered plants head more rapidly in continuous light compared with 16-h photoperiods.

These apparently confusing results may be explained by suggesting that from germination individual plants must pass through a number of developmental stages, each with its own environmental requirement for most rapid completion. The following three stages are postulated for *D. glomerata*: (1) juvenile, (2) inductive, and (3) post-inductive.

Juvenile. During this stage the plant is completely insensitive to environmental conditions which later promote flowering. It is believed to be a stage when the plant is increasing in size and weight but is not making any progress towards flowering. The existence of such a stage could account for the failure of seedling induction.

Inductive. On the completion of the juvenile stage plants enter the inductive stage during which they are sensitive to inductive conditions. It is suggested that darkness is the essential environmental factor for completion of induction, since plants of *D. glomerata* fail to head when grown from germination in continuous light, but will head in long days without exposure to cold temperatures or short photoperiods. It is possible that complete induction is achieved either by exposure to a certain number of hours of darkness, or by exposure to a certain number of diurnal cycles of light and dark. Temperatures during induction may influence the efficiency of the dark exposure.

Post-inductive. This state is achieved on the completion of induction, and during it *D. glomerata* behaves as a typical long-day plant.

It should be possible to test these postulates by growing plants for various lengths of time under continuous light conditions and then transferring them to long days and recording the number of days from germination to heading. Fig. 1 is the hypothetical graph which may be expected from the foregoing postulates when plotting time from germination to heading (Y axis) against length of time in continuous light (X axis). To achieve a graph of this form there must be a number of assumptions: (1) that there is a juvenile stage which, for the purposes of the present argument lasts, say, 4 weeks: (2) that continuous light is developmentally neutral when experienced before complete induction; (3) that darkness alone, as opposed to short-days, is necessary for induction.

In this hypothetical graph the time from germination to heading in plants which have had no exposure to continuous light (vertical line A) is taken up with the

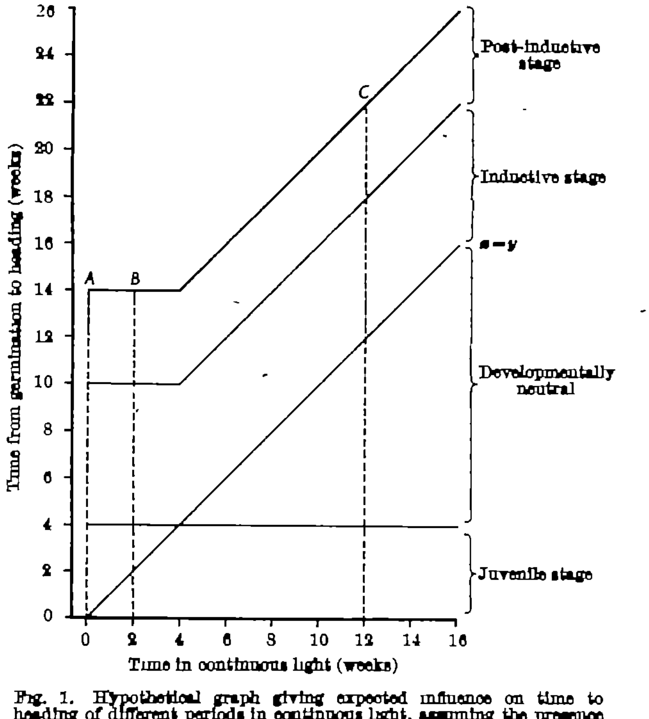

Fig. 1. Hypothetical graph giving expected influence on time to heading of different periods in continuous light, assuming the presence of a three-stage development as outlined

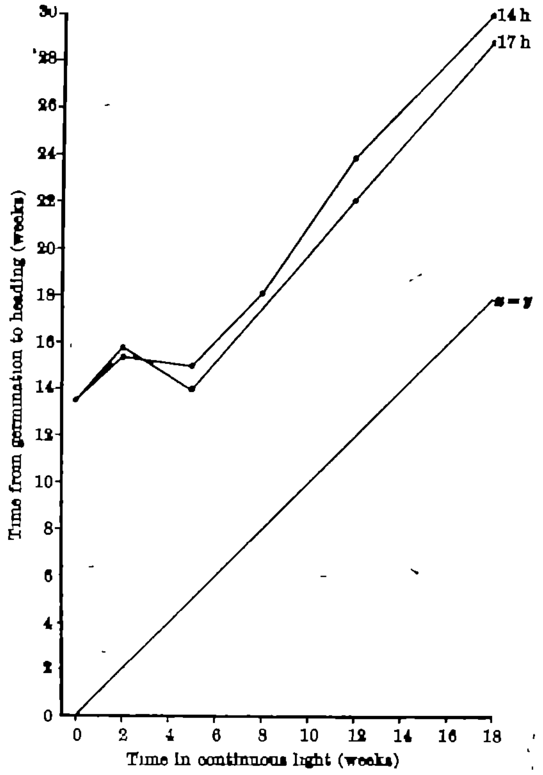

Fig. 2. The influence of increasing lengths of exposure to continuous light on time to heading in *D. glomerata*, variety *S.*143

length of the juvenile stage, plus the time taken for the plant to be fully induced (6 weeks), plus the time necessary for post-inductive development (4 weeks). After a period in continuous light shorter than the juvenile stage (vertical line *B*) the time taken to head is the same as for those plants which had no exposure to continuous light, because the juvenile stage is not completed while the plants are in continuous light and on completion of the juvenile stage these plants are in the inductive environment of long days. Thus for any period of time in continuous light shorter than the juvenile stage there should be no increase in the time taken to head. After a longer period in continuous light, say, 12 weeks, the time taken to head is longer (vertical line *C*). For the first four weeks in continuous light the plants are juvenile. On completion of the juvenile stage these plants cannot become induced since they are still in continuous light; they are increasing in size but are making no progress to flowering. On being placed in long-days they immediately respond to darkness, and head after induction and post-inductive development. Thus for every increase in exposure to continuous light after the completion of the juvenile stage there should be a similar increase in the time taken to head, resulting in a slope of 1. This proportional increase in time will hold, provided that exposure to continuous light does not inhibit later stages of development, provided also that there is no progress to flowering in continuous light, and that neither inductive nor post-inductive development is more rapid in older plants.

An experiment as outlined here was carried out using *D. glomerata* variety *S*.143. After various times in continuous light in a warm glasshouse the plants were placed in either a 17- or 14-h photoperiod. The results are seen in Fig. 2, each point representing the median days to heading of ten plants.

The correspondence between this graph and the hypothetical graph is close and it is evident that with increasing exposure to continuous light above 5 weeks there is a corresponding increase in the time to heading. Exposure to continuous light before the plants are 5 weeks old has apparently no effect. It is also evident that heading is more rapid in 17-h than in 14-h photoperiods.

On the basis of this experiment it is suggested (1) that *D. glomerata S*.143 has a juvenile stage which under the present conditions lasts about 5 weeks; (2) that there is no progress to flowering in continuous light prior to induction; (3) that continuous light before induction does not inhibit induction or post-inductive development; (4) that the time necessary for induction and post-inductive development is not altered by the age of the plant. The net effect of a 17-h photoperiod compared with one of 14 h is to decrease the time to heading, but since at present there is no known way of determining when induction is complete, apart from observing subsequent behaviour, it is not possible to say whether this effect is brought about by influencing the time needed for induction or post-inductive development.

Such a three-stage development has not been described previously in grasses and it may be general for *D. glomerata* since other varieties investigated behaved in a similar manner. It is believed that this rather complex relationship between stage of development and photoperiod could account for the varying interpretations of the nature of induction in this species. These investigations were carried out on the main tiller of each plant; whether later-formed tillers behave in the same way and, in particular, whether they have a juvenile stage has yet to be determined.

I thank Dr. J. P. Cooper for his advice, Prof. P. T. Thomas for providing facilities for this investigation, and the Agricultural Research Council for financial support.

RADIOACTIVITY IN LARGE MARINE PLANKTON AS A FUNCTION OF SURFACE AREA

By Prof. CHARLES OSTERBERG, LAWRENCE SMALL and LYLE HUBBARD
Department of Oceanography, Oregon State University, Corvallis

THERE are two sources of artificially produced radionuclides at present available to marine plankton in the north-east Pacific Ocean. The source of the first group is the Columbia River water used for cooling the nuclear reactors at Hanford, Washington. Trace elements in the water are activated by the high neutron flux in the reactors and ultimately returned to the river. The other source is the fall-out of fission products from nuclear weapons testing.

Two macroplankters, *Salpa* spp. and *Euphausia pacifica*, have been shown to concentrate zinc-65 (ref. 1), most of which originates at Hanford and reaches the ocean by way of the Columbia River[2]. Euphausiids are also known to concentrate fission products[3]. Because the organisms have a large total surface area, it was thought that adsorption should play a vital part in the uptake of radionuclides. Three experiments were designed to investigate this effect.

The animals used in the three experiments were collected with a 6-ft. Isaacs-Kidd midwater trawl off the Oregon coast, then preserved in formaldehyde, sorted by species, freeze-dried, pulverized, and packed into 15-c.c. spectrometer counting tubes. The samples were analysed with the low background anticoincidence spectrometer[4] at General Electric's Hanford Laboratories, Richland, Washington. Data reduction was carried out with an I.B.M. 1620 computer.

Since adsorption is probably related to surface area, the first experiment was to compare two species of pelagic crustaceans of different size, both from the same sample. *Euphausia pacifica*, which averages almost 20 mm in length, was compared for radioactivity with the copepod *Calanus cristatus*, averaging about 9–10 mm. The radioactivity per gram dry weight was found to be greater in the euphausiid (Fig. 1), despite its smaller surface area per unit weight, which would indicate that other factors are more significant than surface area.

The second experiment, a variation of the first, compared large adults with small adults and juveniles. Euphausiids from one particularly bountiful haul were separated into the two size groups. After fractioning, sub-samples were measured; the small euphausiids averaged 13·3 ± 2·3 mm in length, the large adults averaged 21·6 ± 2·6 mm. Assuming that the shape of the shrimp-like euphausiid approximates two cones (one long, one short) joined at their bases, this difference in length means that the smaller organisms have almost twice as much surface area per unit volume as the larger ones. Since weight varies directly with volume, the smaller euphausiids would have twice the surface area per unit

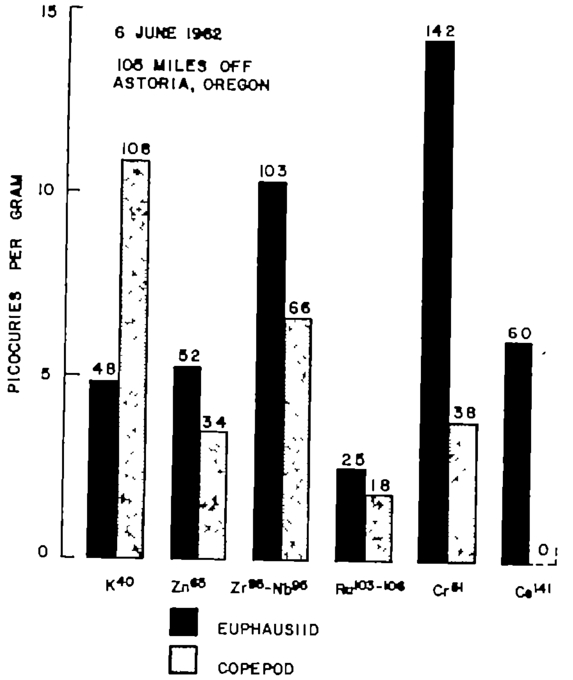

Fig. 1. *Euphausia pacifica* compared with *Calanus cristatus*
The heights of the bars are proportional to the radioactivity in picocuries ($\mu\mu c.$)/g dry weight. Zinc-65 and chromium-51 are from the Columbia River, zirconium-95–niobium-95, ruthenium-103 and cerium-141 are from fall-out, while potassium-40 is the natural radioisotope of potassium. Counting time was 30 min

weight. In general, our results (Fig. 2) indicated that the radioactivity per unit of weight was not greater in small euphausiids. The major exception, chromium-51, may be significant or it may merely be due to the particle size of chromium. However, not only do our techniques yield relatively poor data for chromium-51 (because of the nature of its nuclear decay scheme), but also its form and behaviour in the marine environment are uncertain. Zinc-65 and zirconium-95–niobium-95, on the other hand, are most amenable to the techniques of γ-ray spectrometry.

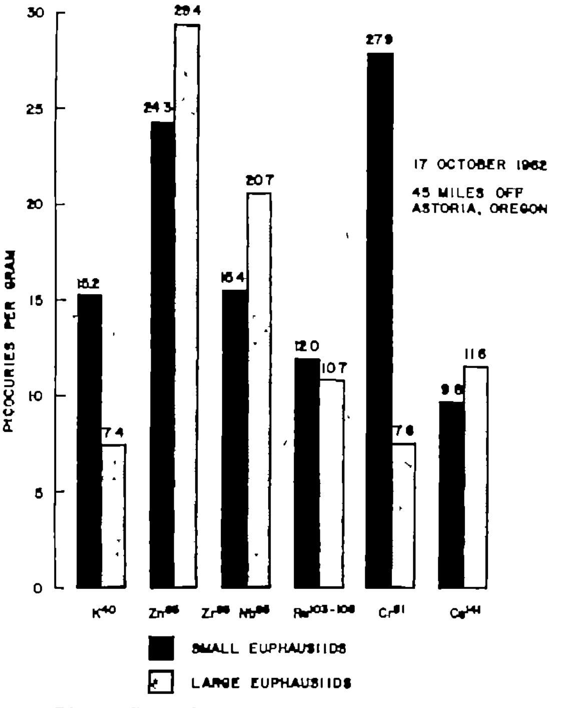

Fig. 2. Comparison of large and small euphausiids (see also legend to Fig. 1)

Pelagic tunicates, *Salpa* spp., were used in the third experiment, which compared the radioactivity of the internal organs with the external parts of the body. Salps are transparent, barrel-shaped animals with a central dark 'nucleus' which contains the digestive tract. In feeding, water is passed through the cylindrical transparent body and through a mucous filter on which particulate material is trapped and ultimately carried to the stomach in the 'nucleus'. Surface adsorption would occur on both the inner and outer walls of the transparent portion, since sea water is in contact with both. In our experiment, the 'nuclei' were removed from the transparent bodies of salps with a dissecting needle, and the radioactivities of the two fractions were compared (Fig. 3*a*). Fig. 3*b* is a similar comparison made of salps taken at a later date.

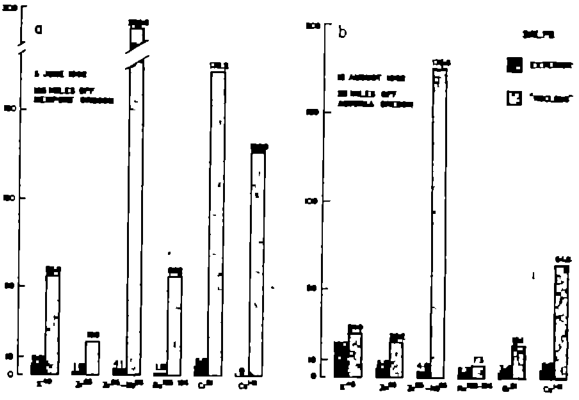

Fig. 3. *a*, Comparison of 'nucleus' and exterior of salp; *b*, similar comparison made at a different time and place (see also legend to Fig. 1)

A comparison of the radioactivity in the 'nucleus' to radioactivity in the transparent outer body (on a gram dry-weight basis) always revealed a higher concentration in the 'nucleus' (Fig. 3*a* and *b*). This is undoubtedly a direct result of feeding. The ratio of radioactivity in the 'nucleus' to radioactivity in the outer body varied, however, depending on the chemical species. Zirconium-95–niobium-95 and cerium-141, which are particulate in sea water[4], were most strongly concentrated in the 'nucleus'. Zinc-65 and potassium-40, which are in ionic form[5], show much smaller concentration ratios. After entering the digestive tract, zinc-65 and potassium-40 are probably somewhat mobile, while zirconium-95–niobium-95 and cerium-141 seem to be restricted to the gut. Preferential washing away of the particulate radionuclides from the surface might also be suspect here. However, Martin[7] has shown that washing with uncontaminated sea water did not remove radioelements (including zinc-65, zirconium-95–niobium-95 and ruthenium-106) from Foraminifera.

All three experiments lead us to the conclusion that, in general, surface adsorption plays a relatively insignificant part in the accumulation by macroplankton of these six radionuclides.

We thank R. W. Perkins of the General Electric Co., Richland, Washington, for the use of equipment and technical assistance.

LETTERS TO THE EDITOR

RADIO ASTRONOMY

Occultation of the Crab Nebula by the Solar Corona in June 1962

It has been established that the radiation from Taurus (*IAU 05N2A*) is profoundly modified every year around June 15 when this radiation passes through the solar corona. Extensive observations have been made in the metre wave-length range by the British, Russian, French, and Australian groups[1-4]. It has been found that there is a progressive increase of the angular diameter and a reduction of its intensity as the angular distance of the source from the Sun decreases. This has been attributed to the scattering by a non-uniform corona with randomly distributed irregularities of electron density.

The work reported here was undertaken to examine this effect at much shorter wave-lengths, namely, 25 cm and 10 cm. Preliminary observations were first made in June 1961 with the 84-ft. paraboloid at Sagamore Hill Radio Observatory, Hamilton, Massachusetts. The beam-width of the antenna is 35 min of arc in right ascension and 41 min in declination at 25 cm and 17·5 min of arc (approximately circular) at 10 cm. The observations in 1961 suggested a decrease in intensity of the source with decrease of its angular distance from the Sun. As such, these were repeated in June 1962 with an improvement in the technique of observation and reduction.

The object of these observations was to measure the temperature of the source and its angular diameter as a function of its radial distance from the Sun. This was carried out by taking successive drifts of Taurus in right ascension through the antenna beam. It was realized that, with the beam-width available, the solar contribution has to be carefully computed at least for the days when the source is close to the Sun. As such, at the end of the occulting period, the antenna was successively placed at the same relative right ascension and declination with respect to the Sun for each of the occulting days and a drift pattern was obtained. Each of these records was then normalized with respect to the corresponding solar temperature on the occulting day and the solar contribution was subtracted to give the antenna response due to the source alone. Records taken on June 14 and June 15 at 25 cm wave-length were rejected as the source contribution was less than 10 per cent of the total response.

The relative position of the source and the Sun is shown in Fig. 1 for each of the occulting days at 1700 G.M.T., which corresponded to the observation period. The plot of the intensity and the angular diameter of the source in the right ascension as a function of its radial distance from the centre of the Sun is shown in Figs. 2 and 3. This shows that there is a decrease of the intensity and an increase of the angular diameter of the source as the angular distance of the source from the centre of the Sun decreases. The difference in scattering between June 14 and June 15 at 10 cm, where the angular distance of the source is approximately $5\,R_{\odot}$, can be explained as we note that on June 14 the source was situated on the prolonged solar axis. If we assumed that there are field aligned irregularities then the geometry suggests that there will be more scattering in right ascension.

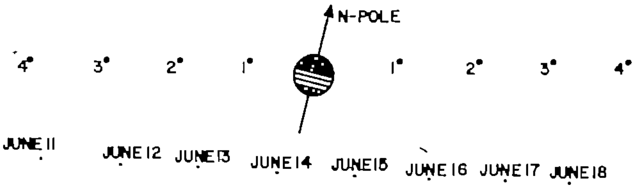

Fig. 1. Position of Taurus relative to the Sun at 1200 D.S.T.

Fejer[5] has made theoretical investigations on scattering of radio waves in a region of mean dielectric constant ε associated with a mean square deviation $\overline{(\Delta\varepsilon)^2}$, the scale of the deviations in any direction r being defined by the auto-correlation function $\rho(r) = e^{-r^2/l^2}$. It was shown that when a radiation of wave-length λ traverses a distance z through such a medium, the energy of the unscattered wave is:

$$Q = Q_0 e^{-B}$$

where

$$B = \frac{\overline{(\Delta\varepsilon)^2}}{\varepsilon^2} \frac{\pi^{5/2}}{\lambda^2} lz.$$

In the case of single scattering $B < 1$, and the angular spectrum of the scattered energy is given by:

$$P(\varphi) \propto \exp\left(-\frac{\pi^2 l^2 \varphi^2}{\lambda^2}\right)$$

However, in the case of multiple scattering $B > 1$, and the angular spectrum is expressed by the following relation:

$$P(\varphi) \propto \exp\left(-\frac{\pi^2 l^2 \varphi^2}{B\lambda^2}\right)$$

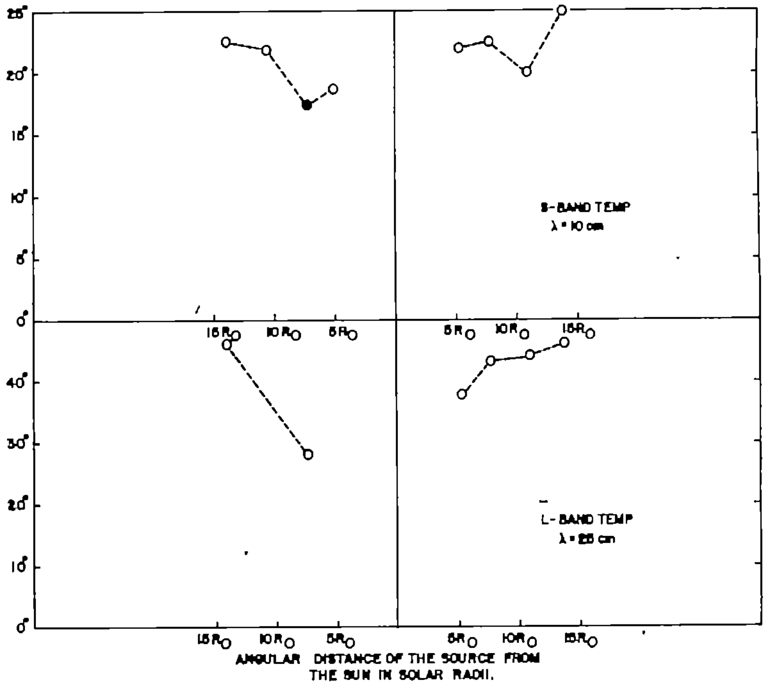

Fig. 2. Variation of the temperature of the source with angular distance from the Sun at $\lambda = 10$ cm and $\lambda = 25$ cm

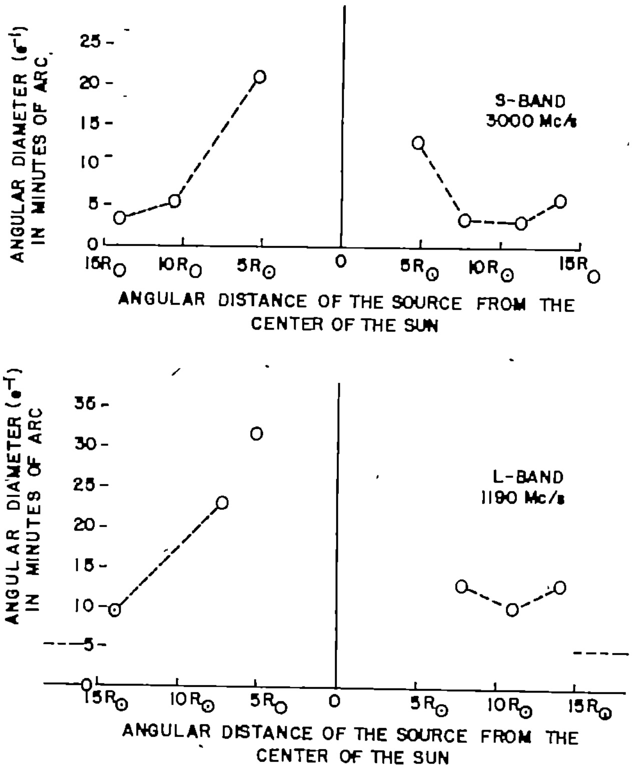

Fig. 3. Variation of angular diameter of the source with angular distance from the Sun at $\lambda = 10$ cm and $\lambda = 25$ cm

Hence the width (e^{-1}) of the angular spectrum is given by:

$$\varphi = \left[\pi^{1/2}\,\frac{z}{l}\,\frac{\overline{(\Delta\epsilon)^2}}{\epsilon^2}\right]^{\frac{1}{2}} \tag{1}$$

Considering the limiting case of multiple scattering when $B = 1$, we get:

$$\frac{\overline{(\Delta\epsilon)^2}}{\epsilon^2}\,\pi^{5/2}\,\frac{lz}{\lambda^2} = 1 \tag{2}$$

Combining (1) and (2), we get:

$$\varphi = \frac{\lambda}{\pi l}$$

or,

$$l = \frac{\lambda}{\pi\varphi} \tag{3}$$

It should be noted that this value of l is the minimum scale of irregularity consistent with $B = 1$. Further, it can be shown that:

$$\frac{\overline{(\Delta\epsilon)^2}}{\epsilon^2} = \frac{\overline{e^4(\Delta N)^2}}{\pi^2 m^2 f^4} \tag{4}$$

where,

$\overline{(\Delta N)^2}$ is the mean square deviation of electron density and e, m, the charge and mass of an electron in E.S.U.

Substituting (4) in (2), we obtain:

$$\overline{(\Delta N)^2} = \frac{m^2 f^4 \lambda^2}{\pi^{1/2} e^4 l z} \tag{5}$$

Hewish[1], assuming that z is equal to the minimum distance between the ray and the centre of the Sun, used equations (3) and (5) to arrive at the value of the minimum scale of irregularity $l = 0{\cdot}27$ km and $(\Delta N) = 70$ electrons/c.c. Considering June 14 data for $\lambda = 10$ cm, when we obtained the maximum scattering with $\lambda = 21$, calculations yield $l = 0{\cdot}52$ km and $\Delta N = 1{\cdot}7 \times 10^2$ electrons/c.c.

We thank Dr. Jules Aarons, chief of the Radio Astronomy Branch of Air Force Cambridge Research Laboratories, for his advice. We also thank Mr. C. Ferioli for help during observations.

RADIOPHYSICS

Focusing Effects in Spherical Earth Radio Propagation

The flat earth scattering theory[1] which explained many of the observed effects in relatively long-distance propagation of short radio waves has been extended to cover propagation around a spherical earth. The resulting formulæ may be expressed as here, using a co-ordinate system in which the transmitter is located at a pole; Λ is the co-latitude of the receiver, θ is the longitude of the receiver measured from the longitude of the direction of the maximum of the transmitted beam. The power polar diagram of the transmitter is assumed to be of the form $\exp(-B\theta^2)$. The distribution of received power in the direction ξ measured from the great circle direction between the receiver and the transmitter is then of the form:

$$P(\Lambda, \theta) \propto \exp - (L\theta^2 - M\theta\xi + N\xi^2)$$

where-

$$L = AB/D$$

$$D = A + \frac{\overline{n-1}^2 S_1^2 - S_{n-1}^2}{2S_1[nS_1 - S_n C_{n-1}]}\,B$$

$$M = \frac{2AB}{D}\cdot\left\{\frac{S_n C - nSC_n}{nS_1 - S_n C_{n-1}}\right\}$$

$$N = \frac{A}{D}\cdot\left\{B + \frac{2S_1 S_n^2 A}{nS_1 - S_n C_{n-1}}\right\}$$

n = number of equal steps (half-hops) between the transmitter and the receiver, each of angular length λ,

$$S_n = \sin n\lambda$$
$$C_n = \cos n\lambda$$

A = average ionospheric scattering factor obtained from a scattering function of the form $\exp(-A\xi^2)$.

The standard deviation of the spread of the incoming fan of waves may be interpreted as a measure of either the average power distribution or of the probability distribution of obtaining a particular bearing at any time. It is given by:

$$\sigma = \frac{1}{\sqrt{2N}}$$

The extent of the antipodal area[2] can be defined for an omnidirectional transmitter ($B = 0$) as the area within which $\sigma > \frac{1}{2}$ (that is, the standard deviation of the spread is greater than 30°, interpreting σ as sin(spread)). Then, approximately:

$$S_n = \sqrt{\frac{2n}{A}} = \sin^{-1} 10{\cdot}3° \text{ for } n = 16,\ A = 1.000$$

This is the angular size of the radius of the antipodal area which is centred on the point antipodal to the transmitter.

There is another position of interest. The spread becomes independent of B at a distance given by:

$$\tan \Lambda = n \tan \lambda$$

that is, at about 260° angular distance from the transmitter. There the spread is given by:

$$\sigma = \tfrac{1}{2}\sqrt{\frac{n-1}{A}}$$

Along this particular latitude line (measured from the transmitter), the deviation of the main incoming direction from the great circle is zero, irrespective of the beaming direction of the transmitter, or its beam-width or the ionospheric scattering coefficient. This arises since the deviation is given by:

$\xi \propto \frac{M}{2N}$ and M becomes zero at this distance. This is a long path but offers significant possibilities in separating ionospheric scattering effects from effects arising from the fact that the average ionosphere is eccentrically situated with respect to the centre of the Earth. It is proposed that the line at about 260° be called the reciprocal line to the transmitter.

Effect of the U.S. High-altitude Nuclear Explosion on Radio Wave Propagation

The U.S. high-altitude nuclear test at Johnston Island on July 9, 1962, when explosion occurred at a height of about 200 miles, offered a rare opportunity to observe the effect of the ionization caused by a nuclear explosion on the propagation of radio waves.

The 18·6 kc/s signals of the American very-low-frequency transmitter *NPG*, located near Seattle, Washington (38° 05′ N., 121° 35′ W.), the great circle connexion of which with Salisbury, South Australia (34° 43·9′ S., 138° 38·7′ E.), runs close to the site of the tests, have been monitored together with the 18 kc/s signals of *NBA* in the Panama Canal Zone (08° 22′ N., 79° 21′ W.), the 16 kc/s signals of *GBR* (52° 22′ N., 01° 11′ W.) and the 10 Mc/s signals of stations *WWV* and *WWVH* (39° 00′ N., 76° 51′ W. and 20° 46′ N., 156° 28′ W. respectively).

The beat frequency method, by which the beat between the received frequency and a suitable frequency derived from a stable local source is recorded in order to determine phase variations, has been used for the very-low-frequency signals, while only the signal strength was monitored on 10 Mc/s.

Fig. 1 shows the 10-Mc/s signal strength records of July 8, 9 and 10. The instant of detonation, which according to our timing occurred at 090009 u.t.2 (183009 local time) on July 9, is marked by *H* on the appropriate record. The signal strength dropped suddenly but recovered after about 15 min, to drop again at about 1900 h. After that it rose to a more or less steady value which was lower than that on the previous or following day and which would be expected here at this time of the year and day.

Fig. 2 shows the superimposed phase records of *NPG* during the three days in question. It is unfortunate that

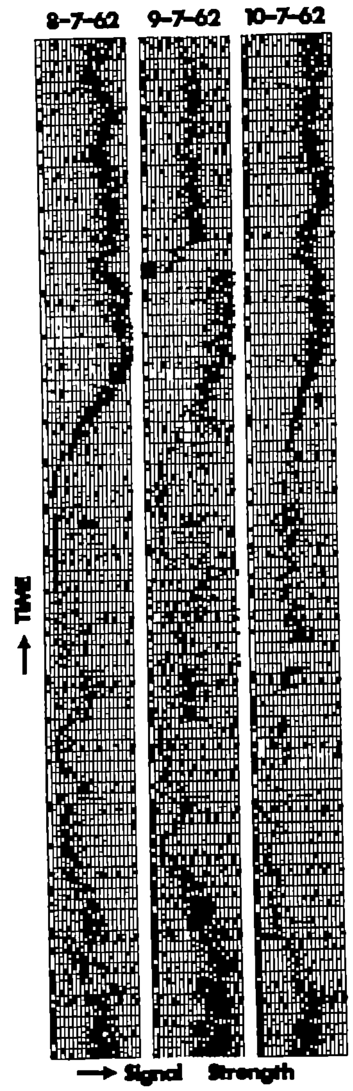

Fig. 1. Signal strength of *WWV* and *WWVH* on 10 Mc/s. Time-scale is Central Australian Standard Time, which is 9½ h ahead of u.t.2

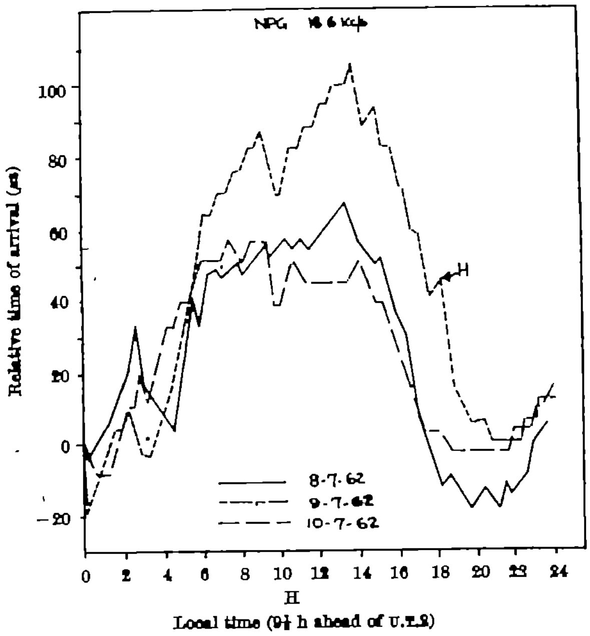

Fig. 2. Relative time of arrival of *NPG* signals

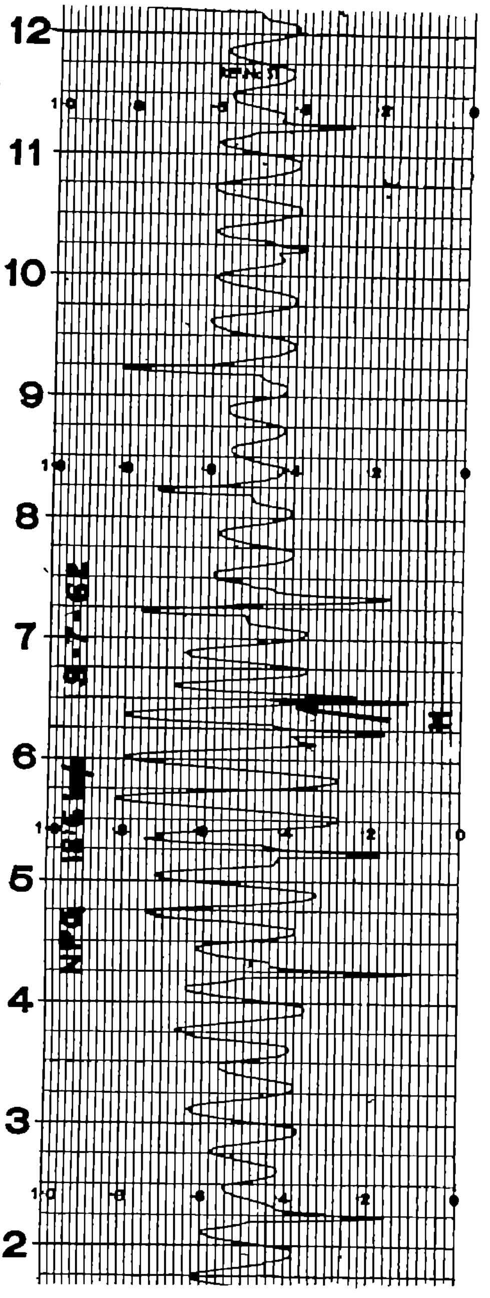

Fig. 3. Beat signal record of *NPG* between 1400 h and 2400 h C.A.S.T. on July 9, 1962

the explosion occurred at a time when the phase shift of the *NPG* signal is normally decreasing rather rapidly so that its effect is not readily discernible.

Fig. 3 is part of the beat signal record of *NPG* for July 9. A marked effect of the explosion on the phase is noticeable. This method of phase monitoring does not follow rapid changes of complete 360° and it is not known, therefore, whether a phase shift of such a magnitude has occurred. The receivers used for the reception of the very-low-frequency signals have a band width of 0·01 c/s approximately.

No effect was observed on the signals of *GBR*.

Fig. 4*a* and *b* show the variation of the relative signal strength of the signals of *NPG* and *NBA* for the three days of observation. It is interesting to note that the strength of the *NBA* signals has been also affected by the explosion although the great circle connecting the site of *NBA* with Salisbury is very far removed from the site of the tests.

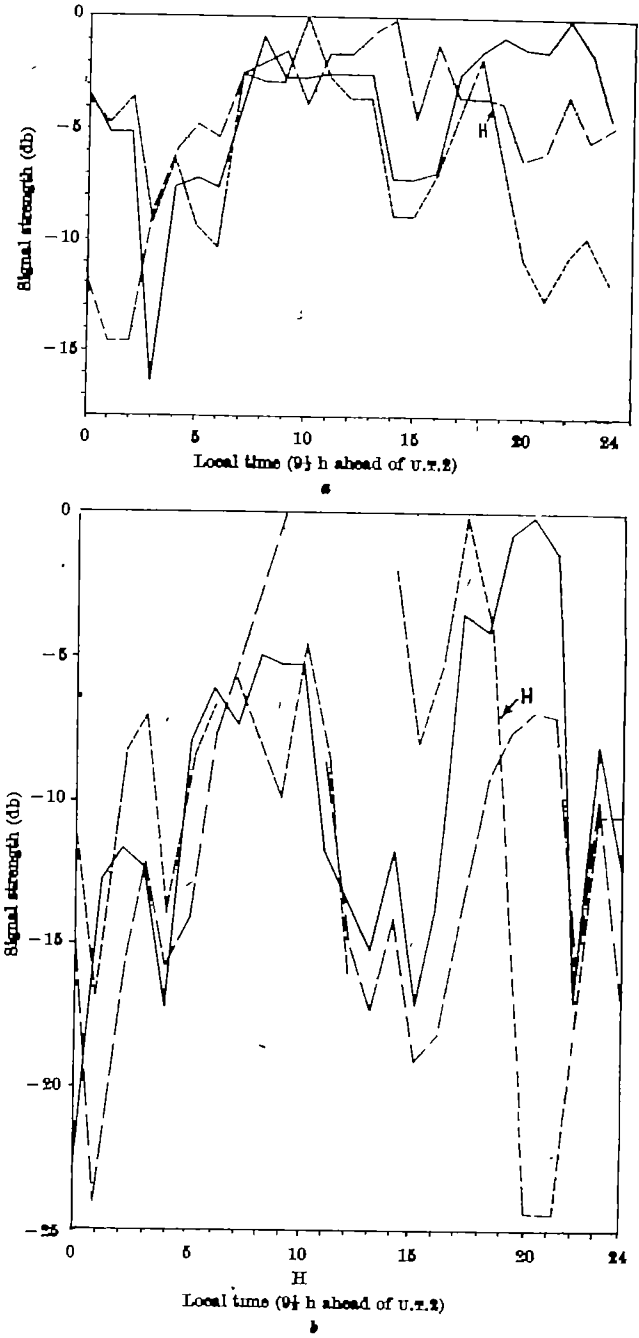

Fig. 4. *a*, Relative signal strength of *NPG*.; *b*, Relative signal strength of *NBA*. ——, July 8, – – –, July 9; —·—, July 10

GEOPHYSICS

Magnetic Anomalies over the Mid-Atlantic Ridge

The intensity of the Earth's magnetic field over the Atlantic Ocean has been measured on a number of flights organized by the Department of Mines and Technical Surveys of Canada and also under Project Magnet (U.S.

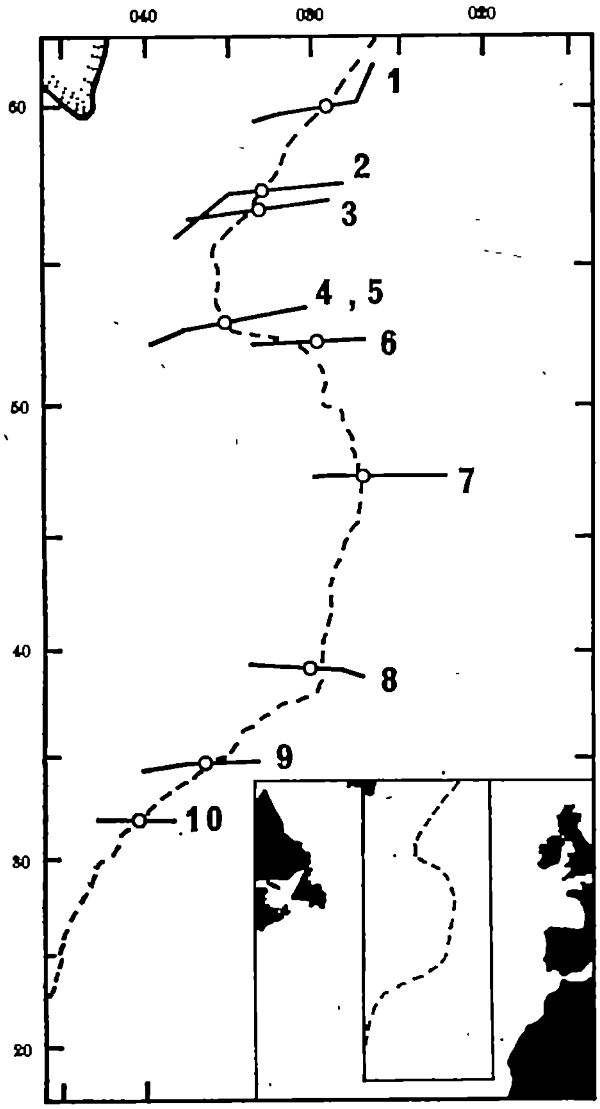

Fig. 1. Tracks of the flights. The heavy broken line is the approximate position of the crest of the Mid-Atlantic Ridge (see text). The circles correspond to the points on the centre line of Fig. 2

Hydrographic Office). Some of these flights passed over the Mid-Atlantic Ridge and the magnetic observations show that there are large anomalies associated with the crest of the Ridge in some crossings, but not in all.

Ewing, Heezen and Hirshman[1] have pointed out that work at sea has shown that the crest of the Ridge has a characteristic anomaly pattern associated with it, and Heezen, Tharp and Ewing[2] have published a profile of the total magnetic intensity across the Ridge, which indicates a positive magnetic anomaly flanked by two negative anomalies. M. N. Hill[3] has shown that the anomalies measured at sea-level in the area around 46° 50′ N., 027° 20′ W. range from about (+300) to (−500) gammas (one gamma is 10^{-5} oersted). Further work by his group in 1960 showed that the anomalies in the area of the median valley of the Ridge at 45° 50′ N., 027° 45′ W. range from about (−500) to (+500) gammas. The magnetic measurements made on the flights of the Department of Mines and Technical Surveys and under Project Magnet were therefore examined to see if anomalies occurred over the Ridge.

The flights were made at heights which varied from 8,000–15,100 ft. above sea-level. Measurements of all the magnetic elements were made but only the total intensity of the field is considered in this communication. Details of the parts of the flights which passed over the Ridge are given in Table 1. The values of the intensity found on the Department of Mines and Technical Surveys flights are values averaged over five minutes of flying time, which represents about forty kilometres in distance. The probable error of a single observation is about ± 50 gammas. The values found on the Project Magnet flights have been reduced from the original continuous strip chart records; the relative error between observations is not likely to be significant. The geographical positions at which the observations were made are likely to be uncertain by several kilometres.

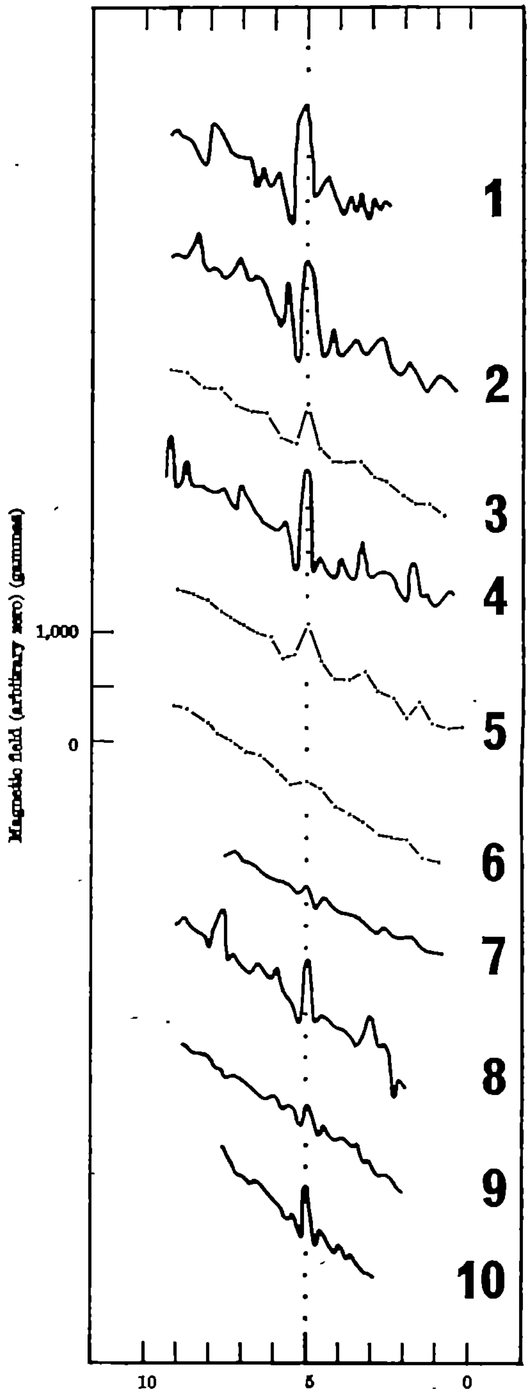

Fig. 2. Total intensity of the magnetic field. The profiles show the intensity of the field plotted against a scale of longitude. The zero values of the field are arbitrary; a scale in gammas is shown on the left-hand side. Numbers correspond to the flight tracks of Fig. 1

Table 1

Track No. on figs.	Dept of Mines and Tech. Surv. or Project Magnet No.	Height (ft.)	Position of points marked by circles
1	*PM* 008	11,000	60° 01′ N. 029° 00′ W.
2	*PM* 89	10,000	57° 35′ 033° 00′
3	*DS* 20 (*B*)	9,000–11,000	57° 02′ 033° 08′
4	*PM* 73	7,000	53° 02′ 035° 40′
5	*DS* 23 (*B*)	8,000–10,000	53° 10′ 035° 12′
6	*DS* 13 (*A*)	9,000	52° 25′ 029° 25′
7	*PM* 106	15,100	47° 24′ 027° 20′
8	*PM* 109	7,000–9,100	39° 08′ 030° 03′
9	*PM* 76	9,000	34° 38′ 036° 20′
10	*PM* 114	8,000–10,000	31° 56′ 040° 24′

Note.—Project Magnet lines marked *PM*, Department of Mines and Technical Survey lines marked *DS*.

The tracks of the flights are shown in Fig. 1, in relation to the approximate position of the central part of the Mid-Atlantic Ridge. This has been plotted from the map prepared by Heezen *et al.*[2] and from the British Admiralty Chart 1904. Track 8 is to the west of the Azores and track 7 passes over the Ridge at about 47° N. Two flights, 4 and 5, are close together and were made independently by Project Magnet and by the Department of Mines and Technical Surveys respectively.

Profiles of the total field along these tracks are shown in Fig. 2. There is a regional trend which has not been removed. The observations have been plotted against longitude and the points which lie on the dotted centre line of Fig. 2 correspond to the circles on the tracks of Fig. 1. There are peaks on the profiles of tracks 1–5 between 60° N. and 53° N., on track 8 at 39° N. and on track 10 at 32° N., and these vary in size from about 200 gammas to 800 gammas. The peaks on the profiles of tracks 1 to 5 and track 10, and one of the peaks of track 8 lie on or close to the central part of the Ridge. A flight adjacent to track 8, which is not shown, also has more than one peak on its profile in the area to the west of the Azores. There are no peaks on tracks 6 and 7 at 52° 25′ N. and 47° 24′ N. respectively. The peaks of tracks 4 and 5 are separated by several kilometres.

These results suggest that a magnetic anomaly is associated with some parts, but not all, of the central portion of the Mid-Atlantic Ridge, which agrees with the observations made by Ewing and others[1] and by Hill[3]. The apparent lack of coincidence of the peaks of the profiles with the exact centre of the Ridge is unlikely to be significant in view of the uncertainties in navigation.

I thank the Department of Mines and Technical Surveys of Canada and the U.S. Hydrographic Office for making their results available to me. This work was supported by the National Research Council of Canada and by the Defence Research Board of Canada.

OCEANOGRAPHY

Origin of Drift-logs on the Beaches of Hawaii

PACIFIC ocean currents can carry objects to the Hawaiian Islands not only from North America, but also from Western Pacific islands and perhaps from the mainland of Asia. This is our conclusion from a recent examination of logs that have drifted to beaches of all the main Hawaiian Islands.

We were stimulated to pursue this investigation by the forester's interest in the species and forest areas represented in these logs, but we have learned that our findings may interest oceanographers, botanists, and others concerned with the part that ocean currents have played in the development of the Islands.

Most of the logs were from the west coast of North America: Douglas fir, western red cedar, and redwood were most frequent (Table 1). The origin of some of these could be pinpointed by checking brands placed on the logs by west coast timber companies. But some logs were of species native to such far-away places as the Philippines, Japan, and Malaya.

Table 1. SPECIES, NUMBER, AND ORIGIN OF LOGS FOUND ON THE BEACHES OF HAWAII

Species	Common name	No. examined	Probable origin
Pseudotsuga menziesii	Douglas fir	75	W. North America *
Thuja plicata	Western red cedar	27	W. North America
Sequoia sempervirens	Redwood	25	California
Abies spp.	True fir	7	W. North America
Tsuga heterophylla	Western hemlock	4	W. North America †
Chamaecyparis lawsoniana	Port Orford cedar	4	W. North America
Pinus monticola	Western white pine	2	W. North America
Picea sitchensis	Sitka spruce	1	W. North America
Quercus sp.	Oak (red)	1	W. North America
Populus sp.	Cottonwood	1	W. North America
Shorea spp.	Several 'Philippine mahoganies'	6	Philippines
Parashorea bagtikan	'White Lauan'	1	Philippines
Cercidiphyllum japonicum	Kadsura	1	Japan
Dryobalanops sp.	Kapur	1	Malaya, Borneo or Sumatra
Melia sp.	—	1	Philippines or S.-W. Pacific ‡
Agathis sp.	—	1	Philippines or S.-W. Pacific
Albizzia sp.	—	1	Philippines or S.-W. Pacific ‡
Podocarpus sp.	—	1	S.-W. Pacific or Chile
Cybistax donnell-smithii	Primavera	1	Central America ‡

* Five logs carried brand from Gold River, Vancouver Island, British Columbia.

† One log carried brand from Coos Bay, Oregon.

‡ Possibly of Hawaiian origin.

It is quite certain that none of the logs listed in Table 1 arrived other than by drifting. The only logs Hawaii imports are monkey-pod (*Samanea saman*) from Fiji, and her forests grow only a few of the species listed. In all but three cases, Hawaiian forest trees could not produce logs as large as those found. Wood identification of the lesser known species was provided by the U.S. Forest Products Laboratory, at Madison, Wisconsin.

Since logs float very low in the water, they should be little influenced by wind action. The movement of drift logs is therefore probably due almost entirely to ocean currents.

PHYSICS

Multiple-beam 'Transmission-like' Fizeau Fringes in the Reflexion Interference System

MULTIPLE reflexions between close, nearly parallel surfaces of high reflectivity give rise to the well-known sharpened Fizeau fringes of equal thickness[1]. For two surfaces of equal reflectivity R and equal transmittivity T, neglecting absorption, the successive interfering beams in the transmitted system have intensities $T^2, R^2T^2, R^4T^2 \ldots = T^2 (1, R^2, R^4, \ldots)$. For the reflected system the intensities are $R, RT^2, R^2T^2 \ldots = R, RT^2(1, R^2, R^4, \ldots)$. As shown by Tolansky, the Airy summation of the corresponding amplitudes is valid for non-parallel plates provided certain conditions are met, and we thus obtain the intensity distribution of the transmitted and reflected fringe systems. It is found that, except for the term R

(and neglecting the *factor* R, close to unity for high-reflectivities), the reflected series is identical to the transmitted series. The term R represents the beams directly reflected from the upper surface. If these beams can be eliminated from the reflected system we are left with exactly the transmitted fringe system (reduced slightly in intensity by the factor R). That the usual reflexion fringes (minima on a light field) then become 'transmission-like' (maxima on a dark field) was shown by Lummer[1] for fringes of equal inclination at infinity. Tolansky[2] refers to the effect as "a property that can be exploited in special cases".

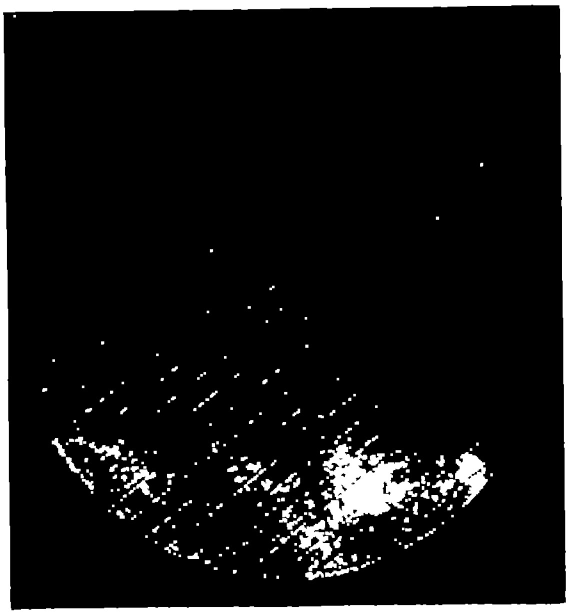

Fig. 1. Multiple-beam Fizeau fringes in *reflexion* for a flat ($R \approx 90$ per cent) against a surface of reflectivity close to 100 per cent. The fringes are 'transmission-like', that is, bright fringes on a dark field, having been reversed by intercepting the directly-reflected beams with a stop In the lower part of the field the directly-reflected beams are not intercepted and normal reflexion fringes result (minima on a bright ground). Ghosts are present due to interception of some of the higher-order reflexions. $\lambda = 5461$ Å

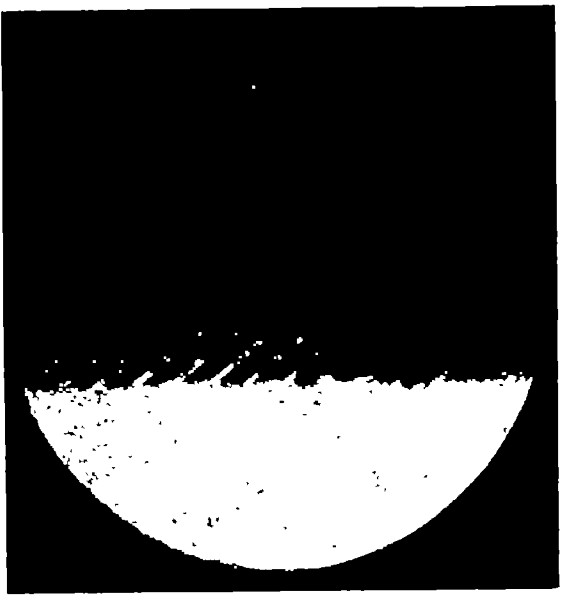

Fig. 2. Multiple-beam *reflexion* fringes produced by a linear wedge, using several wave-lengths (5461 Å, 5770 Å and 5791 Å). The contrast of the normal reflexion fringes is drastically reduced; that of the reversed reflexion fringes is scarcely affected. The bright fringe pairs come from the yellow doublet, the fainter fringes from the green line 5461 Å

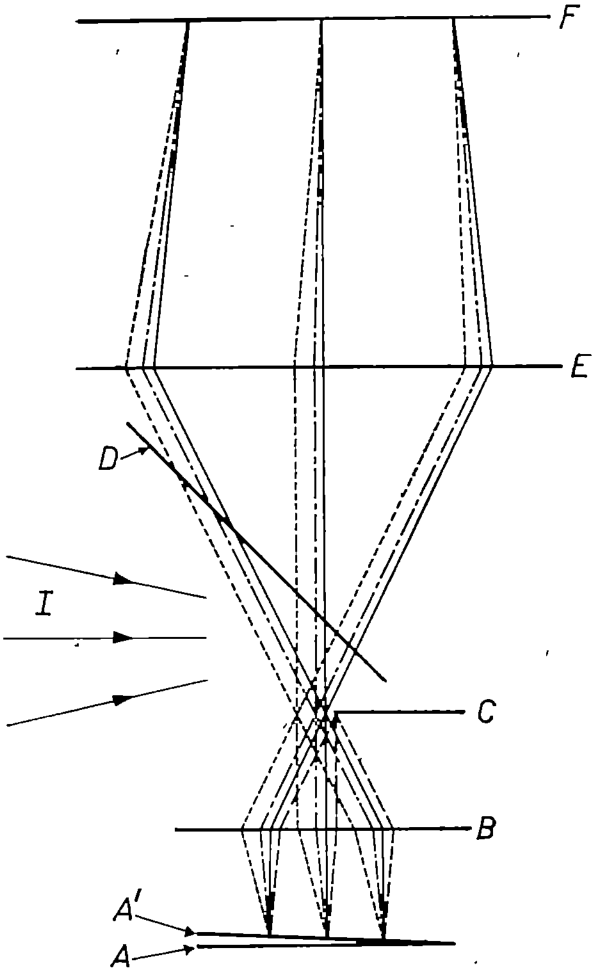

Fig. 3. Production of the reversed reflexion fringes. The diagram shows one of the possible configurations for intercepting the first reflected beams only. AA', interferometer wedge; B, objective lens; C, stop, intercepting the first reflected beams (— — —); D, half-silvered mirror; I, incoming convergent light, brought to focus in the back focal plane of B and producing collimated incident light on AA'; E, projection lens; F, plane on which the fringes are formed. The full lines represent the second set of reflected beams, the lines (- - -) the third set and the lines (---) the n^{th} set of reflected beams

It is possible to obtain this effect with Fizeau fringes of equal thickness. It seems remarkable that this fact has lain dormant until now, for 'reversed' Fizeau reflexion fringes can be useful in the examination of opaque surfaces. The accompanying photographs (Figs. 1 and 2) show topographic Fizeau fringes *in reflexion* for an upper flat of about 90 per cent reflectivity against an opaque highly-reflecting flat surface. Part of the field has been allowed to remain as normal reflexion fringes (minima on light field). Fig. 1 was made with the mercury green line 5461 Å; Fig. 2 with the three wave-lengths 5461, 5770 and 5791 Å.

The conditions under which reversal of the reflexion fringes was observed are outlined in Fig. 3. Collimated light falls nearly normally on the interferometer surfaces via a microscope objective. The light reflected directly from all points on the upper surface all comes to a single focus in or near the back focal plane of the objective. (In the microscope used the objective is used in conjunction with an auxiliary lens, E in Fig. 3, but this lens is not an essential feature in the present context.) The second and multiply-reflected beams all have slightly different directions, depending on the wedge angle, and are imaged at other locations in the back focal plane.

The directly-reflected beams are interrupted by a stop introduced in the back focal plane. Provided the upper surface is suitably oriented, the stop can be adjusted so as to intercept neither the incident light nor any of the multiply-reflected beams. If beams other than the first are intercepted the fringes are broadened, ghosts may develop and contrast may be affected. To obtain sharp reversed fringes over the whole field, critical adjustment of the stop and of the reflecting surfaces is required; it is not always possible to entirely avoid ghost formation or fringe broadening. However, these unwelcome effects may be suppressed or minimized if one is content with fringe reversal over only part of the field. In the interferograms shown there is nevertheless some ghost formation and fringe broadening. (The latter was found to be partly due to pressure broadening of the spectral lines of the source.)

Reversal of reflexion fringes also occurs when the upper flat has a metallic film of low reflectivity. This was first observed by Hamy[4] and further investigated by Holden[5]. This effect is due to the phase defect of the first reflected beams; but the fringes are necessarily broad and for this reason the effect has found little application.

The effect described here can be obtained with extremely sharp, narrow fringes and opens up the possibility of applying to opaque surfaces various techniques hitherto limited to transparent substances. Among these techniques are the use of two or more wave-lengths (for example, for order determination) and the use of low-dispersion crossed-fringes[6]. The very sensitive interference-contrast effect obtained with high dispersion, also described by Tolansky, seems to be impracticable here because the focus of the directly-reflected light is not sufficiently separated from the foci of the multiply-reflected beams when the wedge angle is small (as it must be for high dispersion). However, even with low dispersion, the reversed reflexion fringes appear to be more sensitive to certain surface features than either normal reflexion fringes or normal transmission fringes. For this reason some caution is necessary in the interpretation of details of reversed reflexion-fringe patterns.

GEOCHEMISTRY

Discrepancy in Age-determination Involving Radiogenic Isotopes of Lead

As is well known, the ages determined by the ratios $^{206}Pb/^{238}U$, $^{207}Pb/^{235}U$, $^{207}Pb/^{206}Pb$, and $^{208}Pb/^{232}Th$ are not always identical even for one and the same radioactive mineral. Wetherill[1] explained such a discrepancy as a result of chemical removal of radiogenic isotopes of lead from the mineral.

Where ages calculated from the aforementioned ratios do not agree with each other, it occurs most frequently that the age calculated from the ratio $^{208}Pb/^{232}Th$ is the lowest of all. This is believed to be due to the greater degree of deficiency or loss of lead-208 than those of other radiogenic lead isotopes lead-206 and -207. On the other hand, the acid-wash experiment conducted by Tilton[2] showed that there is a correlation between the isotopic composition of the lead removed by dilute acid and the mode of age discrepancy, and suggested that part of lead contained in the mineral exists in the loosely bound state. Kulp and Eckelmann[3] remarked that, for a given mineral, the isotopes of lead derived from decay of uranium must be in a different environment of lattice from the lead-208 derived from decay of thorium. However, any probable interpretation in terms of a basic parameter has not been successfully presented with respect to the genesis of loosely bound material and the different behaviours of radiogenic isotopes of lead on removal from the mineral.

Process of stepwise disintegrations complicates matters as compared with a process of single disintegration. Thorium-232 and uranium-235, the decays of which terminate in lead-208 and -207, respectively, are roughly similar to each other in the mode of disintegrations, while uranium-238 terminating in lead-206 differs somewhat from them. However, observed facts show that the behaviours of lead-206 and -207 on removal from a radioactive mineral are approximately similar mutually. This fact means that the difference in the scheme of disintegrations is not a leading factor in bringing about the difference in the degree of removal or loss of lead isotope. Therefore attention may be focused on the final stage of disintegrations and the stable lead isotopes which are the ultimate products of the concerned disintegrations.

The process of radioactive decay brings atoms involved in a limited range into the state of excited disorder and causes the ruptures of chemical bonds. But as the excitation of atoms abates with lapse of time, they will tend to compete for re-establishment of chemical bonds. However, the complete reversion to the initial orderly lattice is more or less impossible. That is, the disorder or defects in lattice and the half-satisfied bonds of atoms are thought to remain. It is reasonable to infer that at the stage of re-establishment of chemical bonds an important part is played by the difference in bond-strength of the oxide, because the easiness of re-establishment of bond can be inferred to depend on the bond-strength.

Table 1

	PbO	UO_3	U_3O_8	UO_2	ThO_2
Heat of formation at 25° C (kcal/mole)	52·4	302	898	270	292
Bond-strength (kcal/equivalent)	26·2	50·3	56·1	67·5	73·0

In this connexion the value obtained by dividing the heat of formation by twice the number of atoms of oxygen involved in molecular formula is used as a measure of bond-strength (Table 1). As seen in the bottom row of Table 1, the difference in bond-strength between Th-O and Pb-O is larger than between U-O and Pb-O. Accordingly, lead-208 in the radiation-affected zone where thorium co-exists can be expected to be prevented to greater extent from re-establishing a normally stable bond with oxygen than lead-206 and -207 in the environment where uranium co-exists. In other words, to formation of stable bond of lead with oxygen, the obstruction by thorium is expected to be greater than by uranium. This forms a greater potentiality for lead-208 to be segregated from phase of thorium oxide than for lead-206 and -207 to be segregated from phase of uranium oxide. Thus the structural damage caused by ejection of α-, β-, and γ-rays and the unstable existence of lead make ready the mobilization or removal of this element from host mineral. For a similar reason, on the other hand, it is conceivable that the distributional heterogeneity between thorium and its ultimate product which are contained in a microphase of a mineral is larger than that between uranium and its ultimate product. This can also be the condition parallel with the observed discrepancy.

According to the foregoing interpretation, the oxidation state of uranium bears on the instability of radiogenic lead, for bond-strength of oxide depends on the oxidation state. Very roughly, assuming that the relative instability of radiogenic isotopes of lead stands in the same ratio as the difference in bond-strength, the instability of lead-208 in thorium oxide might be 1·94 times those of lead-206 and -207 in UO_3, 1·53 times in U_3O_8, and 1·13 times in UO_2. These relative instabilities were calculated

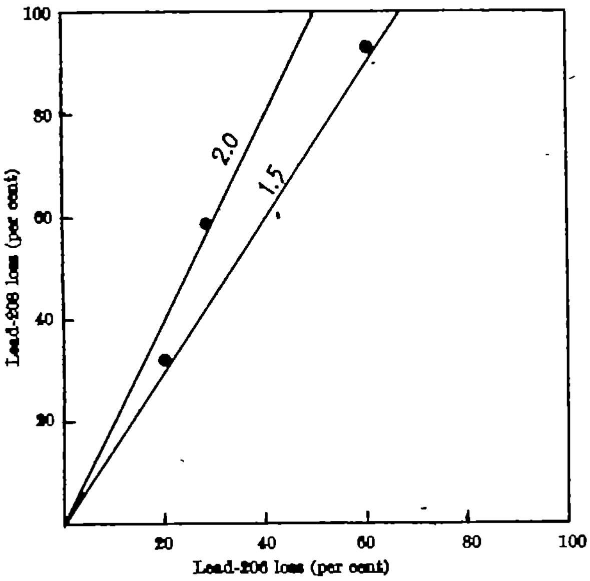

Fig. 1

as follows: for example, 1·94 was derived from (73·0–26·2)/(50·3–26·2).

Also the existence of other elements in the radiation-affected zone may have bearing on the problem under consideration. However, attention might be attracted to the fact that the ratios of lost percentage of lead-208 to lead-206 in specimens participating in Rhodesia pattern scrutinized by Ahrens[4,5] are about 1·5 and 2·0 (Fig. 1).

Age Determination of some Yugoslav Granites and Granodiorites by the Rubidium/Strontium Method

THE age of four samples of granitic rocks selected by the Establishment for Nuclear Materials (Beograd, Yugoslavia) has been measured by the rubidium/strontium method. All analyses were made on biotite fractions; the usual techniques of isotopic dilution were used for the determinations of rubidium and strontium, utilizing an *Atlas CH*4 mass-spectrometer equipped with a normal collector.

The following results have been obtained:

39025—*Stara Planina*. Granitic rock, coarse grained, with ipidiomorphic structure with a reddish coloration due to abundant large potassium feldspar crystals. The biotite frequently appears with idiomorphic crystals and seems rather fresh.

38772—*Biotite from a granitic rock of the same locality.* Stara Planina granite is considered to be one of the oldest Yugoslav intrusive rocks, and it seems very probable that this granite was formed during the Hercynian orogeny.

49438—*Dunye* (*Pelagonia—Macedonia*). Biotite from a rock intermediate between granite and granodiorite.

The sample comes from a geologically not well-known locality in which the rocks are characterized by a heavy metasomatic action and seem to form a para-series including gneiss, granitic gneisses, migmatites, etc. A pegmatite sample was analysed in a Russian laboratory. The age obtained on the muscovite by the potassium/argon method is 140 million years.

Table 1

Sample No.	Total Rb (p.p.m.)	Total Sr (p.p.m.)	Radiogenic ^{87}Sr (p.p.m.)	$\frac{\text{Radiogenic } ^{87}\text{Sr}}{\text{Total } ^{87}\text{Sr}}$	Age (m.y.)
39025	516 ± 9	9·17 ± 0·13	0·6474 ± 0·0160	0·50	300 ± 11
38772	642 ± 11	5·65 ± 0·08	0·7565 ± 0·0190	0·65	282 ± 10
59052	413 ± 7	8·40 ± 0·12	0·0542 ± 0·0077	0·10	37·3 ± 5
49438	708 ± 13	2·66 ± 0·04	0·3375 ± 0·0096	0·67	131 ± 5

59052—*Iastreboc* (*Central Serbia*). Biotite from a granodiorite with ipidiomorphic structure without any mechanical deformation. Biotite crystals, sometimes lightly chloritized, are very large.

The granodiorite intruded a Palæozoic series causing a strong contact metamorphism.

The results obtained for the samples 39025 and 38772 confirm the Hercynian age postulated for the Stara Planina granite.

The age of 131 m.y. for the sample 49438 agrees with that determined by the potassium/argon method, and is probably related to an ultrametamorphic phase concluded at the end of the Jurassic period.

The sample 59052 gives an Alpine age which agrees with geological information.

GEOLOGY

The Precambrian Atmosphere

IN his recent book on *The Geological Aspects of the Origin of Life on Earth*, Prof. M. G. Rutten has adopted as his central thesis the postulate that the Earth retained its primæval reducing atmosphere up to 1,500–2,000 million years ago. This conclusion is based on the premise that the gold–uranium ores of the Witwatersrand (South Africa), Blind River (Canada), and Serra de Jacobina (Brazil) are fossil alluvial deposits, in which the notionally detrital uraninite and pyrite are supposed to have survived weathering because the deposits reputedly accumulated under anoxygenic conditions. Nowhere in his work does Prof. Rutten mention that scores of papers have been written by geologists of international reputation to show that these ore-bodies ('bankets') have been formed within the Earth's crust long after the mother-rock sediments were laid down, by the infiltration of hydrothermal metal-bearing solutions. A lengthy review by Prof. J. D. Bernal[1] commends this book to *Nature*'s wide circle of readers as "a welcome fresh light on one of the most exciting problems of the day", the reviewer apparently being unaware that the origin of the Witwatersrand gold deposits has remained one of the most controversial issues of economic geology for more than half a century, and that since the discovery of commercial uranium in these ores the arguments have increased in number, vigour and acerbity. Most geologists will know that both sides of the question are recounted at length in the leading American, French and Russian text-books on uranium geology, as well as in the official publications of the South African, Canadian, and United States Geological Surveys. Other readers, however, should be warned that the validity of Prof. Rutten's conclusions is no greater than that of his fundamental premise, and that this is very debatable indeed.

The arguments against the hypothetical alluvial origin of these ore-bodies are much too numerous to be summarized here, and it will suffice to say that the placerist conceptions can only be sustained by a long series of perversions of chemical and physical laws[2]. It is relevant that in the Mozaan rocks of Swaziland deposited concurrently with the Witwatersrand strata, and in the Lorrain sandstones of Ontario almost contemporary with the Blind River conglomerates, heavy mineral assemblages completely of modern aspect are widely developed, indicating that the mineralogy of the banket ores cannot be explained in terms of abnormal atmospheric conditions. The latest work on the Serra de Jacobina ore-body shows clearly that this deposit is not alluvial, and that the mineralization was probably emplaced hydrothermally[3]. The recently discovered Russian deposits of banket-type gold–uranium ores[4], the locality of which has not yet been revealed, exhibit both sulphidic (pyrite–uraninite) and oxidic (magnetite–brannerite) phases in the same conglomeratic ore-body, demonstrating beyond a shadow of doubt that the mineral assemblages are of hydrothermal origin.

The orthodox geological conceptions on the history of the atmosphere have recently been reviewed by A. P. Vinogradov[5] in his Vernadsky Memorial Lecture, in which he concludes that the primæval atmosphere of methane, hydrogen and carbon dioxide (akin to the gases of meteorites and of terrestrial rocks of mantle origin such as kimberlites, carbonatites and dunites) lasted only a relatively short time. Probably it was lost in the 1,000 million years of the Earth's history before the earliest known rocks came into being. A. A. Polkanov[6] has lately observed that even for these earliest Katarchaean rocks of 3,500 million years ago, Lyell's principle of actualism may not, and should not, be rejected.

The origin of early Precambrian gold–uranium ore deposits has indeed been a controversial issue. But, as I stated explicitly in my book, I have become convinced that the features acquired by hydrothermal processes are due to younger alterations. These deposits are placers originally. The hydrothermal alterations have been important in enriching the original placers. They may even be at the origin of the money value of a given deposit, and consequently seen as the most important process by an economic geologist.

CRYSTALLOGRAPHY

Commination of Crystal Nucleation by a Precipitation Method

There are two ways to precipitate sediments of slightly soluble salts, namely, by simple mixing of the reagents or by the homogeneous method, that is, by developing the reagent *in situ* and thus precipitating the insoluble salt homogeneously in the whole bulk of the solution. In both cases no special care is taken with regard to nucleation and the parameter of time.

The formation of a sediment of an insoluble salt comprises two basic processes, the character of which is quite different: a chemical process involving the formation of a new compound of the ions existing in or introduced into the solution, and a physical process of solid phase formation. Different kinds of this general scheme, comprising extreme and intermediate cases, are being examined. The ionic process of chemical compound formation proceeds very fast. The physical process is rather slow and thus—depending on existing conditions—the solid phase is obtained as an amorphous body, that is, of poorly ordered crystal lattice or in the crystalline, well-ordered state.

The principle of the new technique which I have developed is to perform the chemical reaction as slowly as is necessary to obtain a well-ordered solid phase, that is, a crystalline form of the sediment. Under such conditions many new features, unknown until now, have been observed[1–3].

Now further work has revealed that:

(1) Crystallization proceeds on nuclei of symmetric shape and a mass of only 10^{-18} g or smaller.

(2) A great, but limited, number of crystallite shapes are obtained. The shape depends on the nucleus acting as a centre of crystallization.

(3) The different shapes are obtained simultaneously, which shows that just the specific properties of the nuclei are responsible for the shape and not the properties of the medium, for example, the concentration, surface tension, pH, etc. (Fig. 1).

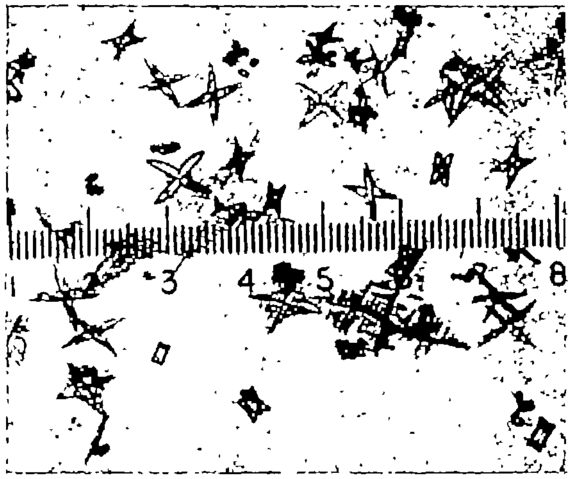

Fig. 1. × 400

(4) While introducing small quantities of foreign ions (the basic precipitate being barium chromate) crystallites of quite different shape are obtained. Because of the lack of separating methods it could not be established until now whether they were other compounds or other crystalline forms.

(5) A fractional precipitation performed with the aid of the new method removes the existing nuclei. On further precipitation the number of crystallite forms diminishes.

(6) In spite of their very delicate structure the crystallites are very stable. It has been stated that sediments do not change while in contact with the mother liquor for a period of even four years, showing that the solid phase has been formed under conditions enabling the building of an ideal crystal lattice, that is, a lattice of lowest energy.

(7) Observations have shown that nuclei formation proceeds possibly on amorphous matter of indefinite composition (hydroxides ?, silica ?).

I thank Mr. L. Trojanowski for assistance in performing the experimental work.

ENGINEERING

Role of Extreme Pressure Lubricants in Boundary Lubrication and in Metal Cutting

Rebinder *et al.*[1] have examined the effects of surface-active agents such as mineral oil solutions of oleic acid to alter the creep and fatigue character of metals. Observed changes are attributed to the adsorption of oleic acid by the metal, thereby hastening the strain-hardening of the metal's surface.

In metal cutting, the reduction of tool forces is attributed by Rebinder *et al.*[2] to the intensification of strain-hardening in the cutting zone by these agents, while the contributions made to tool force reductions as a result of the lubricant's action to reduce friction is regarded as unimportant[3].

Little attention has been paid by these investigators to liquids of other types, containing labile atoms of sulphur or chlorine, which are commonly regarded as effective metal-cutting fluids and extreme pressure or boundary lubricants. We have examined the effect of such liquids to modify the shear-strength of metals and a clearer picture of the part played by these liquids in boundary lubrication and metal-cutting has emerged from these studies.

The instrument used in these studies is shown schematically in Fig. 1*A*. A metal specimen ¼ in. × ⅜ in. × 2¼ in. made of steel, aluminium, etc., protrudes approximately ¼ in. above the surface of a split block, which clamps it tightly. The specimen yields plastically, as in a hardness test measurement, to form a V-shaped notch when the hardened tool-steel indenter, having $0{\cdot}25$-in.^{2} cross-section, is loaded hydraulically into the centred specimen at 2 in./min, Fig. 1*B*. The indenter's knife-edge overhangs the front and back of the specimen.

Shear-failure of cold-rolled steel takes place, with the production of a tiny chip (see Fig. 1*C*) when the applied load, which is increased continuously, reaches 4,400 lb. ± 2 per cent, provided that carbon tetrachloride saturates the specimen-indenter zone. No such shear-failure occurs in air, however, but only further deformation, as shown in Fig. 2, even at loads as high as 7,000 lb., provided that proper attention is paid to the cleanliness of the tool.

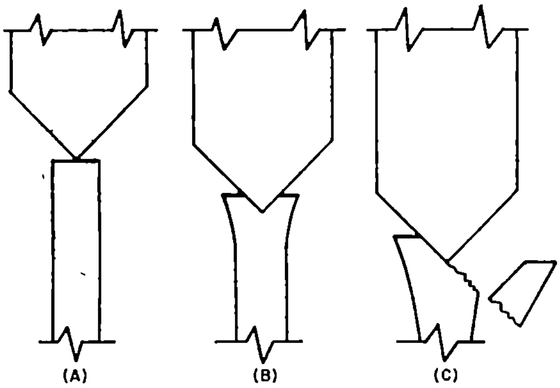

Fig. 1. *A*, Schematic diagram of shear-failure tester; *B*, plastic deformation of a specimen under load; *C*, shear-failure resulting from deformation in the presence of carbon tetrachloride

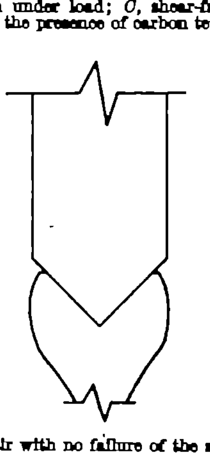

Fig. 2. Deformation in air with no failure of the specimen at 7,000 lb.

It is significant that the deformation of all specimens is the same, whether the deformation is conducted in air or in carbon tetrachloride, for loads up to at least 200 lb. short of the carbon tetrachloride shear-failure load. The deformation is judged both in terms of build-up of load compared with tool advance into the specimen, and from microphotographs of etched specimens that have been deformed.

For this and other reasons it has been concluded that the loading forces required to shear metal which has been strained is determined largely by the interaction between the environment and metal at points of maximum shear-stress. However, the process is not due to an acceleration of strain-hardening, as proposed by Rebinder, and is not due to the formation of a low shear-strength film along the tool-chip interface, as is commonly accepted in explaining reduced forces in problems of this nature which deal with boundary lubrication[3]. Rather, the source of activity arises from the generation of products, such as ferric chloride, formed during creation of fresh metal surfaces in the presence of lubricant, which stabilize micro-cracks generated prior to shear-failure in much the way liquid metals function in the embrittlement of aluminium[4]. This leads to shear at reduced stress-levels. The same mechanism applies in the case of surface-active agents.

Extreme pressure lubricants, therefore, because of their low-stress micro-crack stabilization factor, will reduce the friction, wear, and metal transfer of sliding surfaces by promoting the rapid shear-failure of welded asperities, of the type envisaged by Greenwood and Tabor[5], at reduced stress-levels, before build-up of the junction becomes extensive. Hence, cutting fluids reduce tool forces by promoting the shear-failure of the work-piece ahead of the tool-tip and the shear-failure of numerous welded asperities arising during chip-flow over the tool face, all at reduced stress-levels, with the former effect believed to be the more important.

RADIATION CHEMISTRY

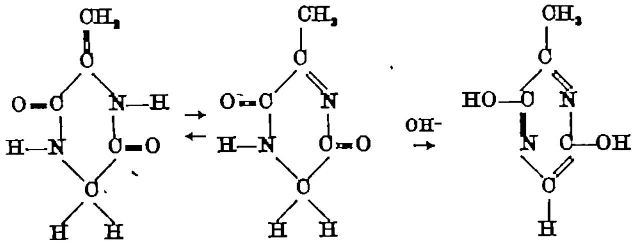
Dehydropeptide Production in the Radiolysis of Solid Peptides: a Radiolytic Synthesis of Pyrazine Derivatives from Cyclic Dipeptides

Among the chemical changes observed on radiolysis of compounds containing the peptide bond are those attributed[1-3] to the production of unsaturated linkages which may be represented in terms of the tautomeric structures, $\sim \mathrm{CON{=}C(CH_2}R) \sim \rightleftarrows \sim \mathrm{CONH{-}C({=}CH}R) \sim$. Compounds containing this type of chemical function have been designated dehydropeptides; such compounds are stable in water yet are readily hydrolysed to yield ammonia and a carbonyl product on heating in dilute mineral acid, $\sim \mathrm{CON{=}C(CH_2}R) \sim + 2\mathrm{H_2O} \rightarrow \sim \mathrm{COOH} + \mathrm{NH_3} + R\mathrm{CH_2CO} \sim$ (ref. 4). The experimental evidence for production of dehydropeptides in the radiolysis of proteins and simpler peptide systems has recently been reviewed[5]. Identification has been based primarily on studies of the formation of ammonia and carbonyl function during hydrolysis of the irradiated peptide system. For example, the hydrolytic production of ammonia and pyruvic acid from γ-irradiated acetylalanine (solid, evacuated) has been found to parallel very closely the hydrolytic degradation of authentic acetyldehydroalanine.

The cyclic dipeptides, such as glycine anhydride and alanine anhydride, also show an analogous post-irradiation production of ammonia and α-keto acid during acid hydrolysis[6]. We note, too, that the dehydropeptide derivatives of these cyclic compounds represent isomeric forms of the 2,5-dihydroxypyrazines. Quite recently, Sorkin[7] has given evidence that the dehydro derivative of glycylalanine anhydride, that is, 3-methylene-2,5-diketopiperazine (prepared by the classical chemical method of Bergmann and Miekely[8]), undergoes isomerization in alkaline solution to give 3-methyl-2,5-dihydroxypyrazine. We report here analogous evidence for the formation of pyrazine derivatives through γ-radiolysis of the amino-acid anhydrides followed by dissolution of the irradiated solids in alkaline solution.

Glycylalanine anhydride was synthesized after the method of Fischer and Scheibler[9]. Glycine anhydride and alanine anhydride were obtained from the Nutritional Biochemicals Corporation. The anhydrides were recrystallized three times from water, dried, and ground to a microcrystalline powder. Samples were evacuated on the vacuum line in 'Pyrex' ampoules for a minimum of 48 h. After irradiation (cobalt-60 γ-rays, $1\cdot7 \times 10^{18}$ eV/g/min), the ampoules were opened to the atmosphere and the contents were dissolved to a concentration of 0·1 M in 0·02 N sodium hydroxide under nitrogen aeration. Complete dissolution required 2–3 min. Changes in the absorption spectra of the oxygen-free solutions were followed differentially (against a 0·1 M solution of unirradiated anhydride) over the range 300–400 mμ.

Solutions of irradiated glycylalanine anhydride (3-methyl-2,5-diketopiperazine) show a rapid increase in optical density with time over the 300–400 mμ range with λ_{max} = 370 mμ. The spectrum is completely developed after about 2 h. Authentic 3-methylene-2,5-diketopiperazine[8] was found to exhibit almost identical spectrophotometric properties. The fully developed spectra obtained with irradiated glycylalanine anhydride and authentic 3-methylene-2,5-diketopiperazine in oxygen-free 0·02 N sodium hydroxide solution are shown in Fig. 1. Appearance of the absorption maximum at 370 mμ is attributed to the formation of the dihydroxypyrazine nucleus (II) via the isomerization reaction:



Ia Ib II

The absorption spectrum of an authentic dihydroxypyrazine (3,6-dimethyl) prepared after Karmas and Spoerri[10] is included in Fig. 1 for purposes of comparison. It is noted that the dihydroxypyrazines in alkaline solution are rapidly destroyed on exposure to air.

Isolation of 3-methylene-2,5-diketopiperazine (*Ia*, *Ib*) from irradiated glycylalanine anhydride has been accomplished. A methanolic extract of the irradiated solid was transferred to filter paper and chromatographed in parallel with authentic 3-methylene-2,5-diketopiperazine; butanol saturated with water was used as the developing liquid. The authentic methylene derivative is readily detected at $RF \simeq 0\cdot4$ under ultra-violet illumination; the irradiated glycylalanine anhydride also gives a strongly absorbing component at this RF value. The two areas were separately eluted and examined spectrophotometrically in oxygen-free 0·02 N sodium hydroxide. The characteristic growth in the 300–400 mμ region was observed in both cases and the final curves were essentially identical to those given in Fig. 1. The yield of 3-methylene-2,5-diketopiperazine from glycylalanine anhydride at the lowest dosage studied (5×10^{20} eV/g) corresponds to a G value of ~ 0·55.

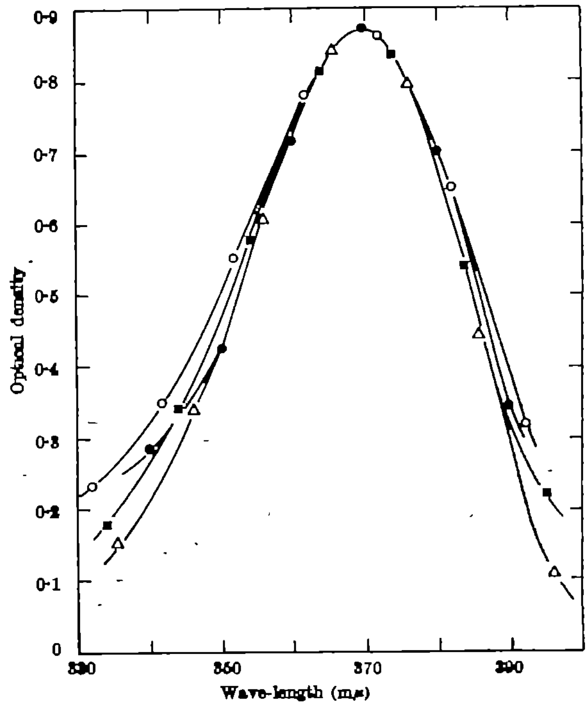


Fig. 1. Absorption spectra of irradiated cyclic dipeptides and authentic dehydropeptides in 0·02 N sodium hydroxide. ○, Irradiated glycylalanine anhydride; △, irradiated glycine anhydride; ■, authentic 3-methylene-2,5-diketopiperazine; ●, authentic 2,5-dihydroxy-3,6-dimethylpyrazine

The results obtained with alanine anhydride appear to be somewhat more complicated. In this case the development of the absorption curve is accompanied by a gradual shift in λ_{max} from 370 to 360 mμ. However, the spectra obtained within 15 min of the time of dissolution coincide with that given by authentic 2,5-dihydroxy-3,6-dimethylpyrazine.

Solutions prepared from irradiated glycine anhydride show the characteristic dihydroxypyrazine spectrum and on standing there is no detectable shift in λ_{max} from 370 mμ to shorter wave-lengths. However, glycine anhydride differs from both glycylalanine and alanine anhydrides in that the absorption spectrum shown in Fig. 1 is fully developed within the 2- to 3-min period required for dissolution. This behaviour may be interpreted as evidence for rapid isomerization of dehydroglycine anhydride, which must necessarily have only the endocyclic form as given by structure *Ib*.

Finally, we should like to comment on the fact that all three solid anhydrides develop a yellow coloration which is visually detectable at radiation dosages as low as ~ 5×10^{18} eV/g. The effect is most pronounced in the case of glycine anhydride. Coloration is not appreciably diminished by exposure to oxygen and remains visible in water extracts of the irradiated solids. This coloration, then, cannot be ascribed to an optical absorption by free radicals or ionic transients. It is noted that the authentic dihydroxypyrazines are yellow in the solid state and, although we have made only preliminary spectrophotometric studies of the irradiated solid anhydrides, the available evidence suggests that isomerization of dehydropeptides occurs to some extent in the solid state. A mechanism for the radiation-induced isomerization of the ~CO—NH~ linkage in solid peptide systems has recently been described[6]. A detailed report of the various aspects of the radiation chemistry of the cyclic dipeptides will be forthcoming.

CHEMISTRY

Binding of Xenon to Halogens, to Alkali Metals, and to Itself

THE existence of stable XeF_4 and XeF_2 molecules has recently been demonstrated[1]. A description of the binding and molecular geometry using the conventional electron pair model has been proposed[2]. Twelve of the XeF_4 electrons are assumed to be distributed in four electron pair bonds and two sets of lone pairs. This model is based on analogies with the chemistry and geometry of a large number of inorganic compounds. Simple chemical analogy must likewise predict that molecules such as $Xe(Cs)_4$ or $Xe(Rb)_4$ will not exist. Be_2 offers a partial analogy to Xe_2 and implies that the latter molecule will not be bound.

It is also important to understand XeF_4 in terms of approximate solutions to Schrödinger's equation, and an explanation based primarily on our knowledge of the electronic structure of isolated atoms and ions has been given[3]. The xenon fluoride bond is attributed to the atomic distortion[4] produced by electron correlation and the resultant opportunity for a xenon electron of one spin to partially fill the outer shell of a fluorine atom to a slightly greater extent than its partner of opposite spin.

However, in many quantum mechanical problems we find an inherent symmetry between systems possessing closed shells plus one electron and those possessing closed shells minus one electron, and thus we must examine the binding of $Xe(Cs)_4$ and $Xe(Rb)_4$ relative to that in XeF_4. In addition to numerous atomic calculations there exists one *ab initio* molecular calculation which can aid our discussion. This is a wave function for HeH determined by Harris[5], and we may use it as a model for the binding of xenon to an alkali metal atom. His wave function is particularly important because it was carried out by the full permutation group method, thus allowing different orbitals for different spins and building in the correlation induced orbital distortions that have been used to explain binding in XeF_4 (ref. 3).

Harris's HeH calculation shows no binding and we can interpret this through the properties of the constituent atoms. First, the noble gas atoms will have absolutely no electron affinity—even though there is a slight correlation induced separation of α and β spin there can be no stable orbit for an additional electron—so that the ease with which an alkali metal atom loses an electron has no influence on potential binding. Second, the electron affinity of both hydrogen and the alkali metal atoms is considerably less than fluorine. On the other hand, it might be argued that the unfilled *s* shell of hydrogen could provide as favourable a potential energy environment for a rare gas electron as does fluorine. This reasoning is incorrect, however, since not only is the electron affinity less but also the hole in the fluorine has a *p*-like angular dependence and the partially unpaired xenon electron which is most available for bonding also has a *p*-like angular distribution. Similarly, Xe_2 cannot exist because xenon shows no tendency to accept an electron.

One of the principal purposes in presenting this article is to point out the paucity of detailed theoretical knowledge available on the electronic structure of even small molecules, and short of very elaborate and extensive *ab initio* calculations (which are just now on the outer edge of feasibility for XeF_4 and XeF_2) it is not possible at present to give a thoroughly convincing theoretical prediction of inert gas compounds. In hindsight it appears that the geometry of XeF_4 is the same as ICl_4^- and thus empirical or semi-empirical model calculations bring out and tend to support the similarity in electronic structure of these compounds at their equilibrium separation[6]. However, there does not now exist any really adequate connexion between the effective Hamiltonians of the simple model schemes (such as the simple LCAO MO method) and direct solutions of Schrödinger's equation. Particularly at larger atomic separations, the xenon–fluoride bond involves subtle correlation effects and the partial breakdown of the simple idea of closed shells which are not directly represented in calculations with the simple models. Certainly a major reason for the lack of extensive investigations into inert gas compounds has been the overwhelming success of the Periodic Table based on free atoms along with the concept of closed shell configurations in organizing chemical experience.

I thank Dr. William de W. Horrocks for helpful advice.

Breeding of Nuclei

IN 1911 Miers[1] wrote: "I have many times noticed that when the appropriate crystal is introduced into a supersaturated solution, which is not strong enough to crystallize spontaneously, it may cause crystals to grow not only in actual contact with itself, but at some little distance in its neighbourhood". McCabe[2] has also discussed this subject: other references are rare. It is proposed to refer to this phenomenon as 'breeding' of nuclei. We have recently studied this question experimentally, using aqueous $MgSO_4 7H_2O$, and have concluded that various categories of breeding may be observed.

(1) If a crystal from a stock bottle is dipped into an under-cooled solution, a considerable number of small crystals appear after only a few seconds, usually on the bottom or surface of the solution. The breeding in this case is believed to be due to detached crystallites present on the surface of the crystal, which were produced either by rapid evaporation of solution when the crystal was dried, or by mechanical impact. This form of breeding will be called 'initial' breeding.

(2) If however the crystal, after removal from the bottle, is pretreated by growing at a low under-cooling (say 1° C)

and is then transferred directly to another solution, the phenomenon observed in (1) no longer occurs. But if the latter solution is strongly under-cooled (> 7° C) and if it is stirred, needles tend to grow out of the ends of the crystal, and these break off from time to time, and grow independently. This effect we call 'true' breeding.

(3) At the moment the aforementioned needles break off there is often also produced a shower of very small crystallites. This we call 'splinter' breeding.

(4) If the crystals growing in a stirred solution are free to collide with each other or with the walls fresh nuclei are very easily produced, even at low supersaturation, and with relatively gentle collisions. This we call 'attrition' breeding.

Results obtained with aqueous potassium bromide were generally similar to the above, but differed in some details. Fuller results will be published elsewhere.

Conduction in Nucleic Acid Components

In a recent paper[1] DNA was shown to possess a small semiconductivity in the dry state, the specific conductivity following the equation:

$$\varkappa = \varkappa_0 \exp(-\Delta\varepsilon/2kT),\ \Omega^{-1}\text{cm}^{-1}$$

with $\Delta\varepsilon = 2{\cdot}42$ eV, $\log_{10}(\varkappa_0\ \Omega^{-1}\text{cm}^{-1}) = 3{\cdot}4$. It was suggested that the conductivity was associated with the π-electron overlap of the paired bases, adenine–thymine, and guanine–cytosine. In the Crick and Watson double-helix for DNA structure these base pairs are arranged one on top of the other, with an interplane spacing of 3·4 Å, similar to that found in graphite[2]. A similar result was found for the electrical conductivity of RNA, which may now be related to its high content of double-helix structure[3]. We have examined the solid-state electrical conductivity of some of the component structures of the nucleic acid, using d.c. with the polycrystalline specimen compressed between nickel electrodes at 80 kg cm^{-2}, in a vacuum of 10^{-5} mm mercury. The bases adenine, thymine, guanine, cytosine and uracil were first examined. These gave very low conductivities, around $10^{-15}\ \Omega^{-1}\text{cm}^{-1}$ at 400° K, but sublimation (even in a nitrogen atmosphere) and thermal decomposition precluded the establishment of accurate Δε values. The nucleosides had conductivities of 10^{-11}–$10^{-13}\ \Omega^{-1}\text{cm}^{-1}$ and the nucleotides 10^{-7}–$10^{-13}\ \Omega^{-1}\text{cm}^{-1}$ at 400° K. The results are listed in Table 1.

Table 1. Nucleosides and Nucleotides

Substance	Δε, eV	$\log_{10}(\varkappa_0, \Omega^{-1}\text{cm}^{-1})$
Adenosine*	4·5	15
Yeast adenylic acid†	1·8	2·7
Muscle adenylic acid†	2·0	2·0
Adenosine triphosphate (DiNa, DiH salt)	2·0	2·5
Adenine phosphate	2·0	3·3
Uridine*	5·2	22
Uridylic acid†	1·3	0·6
Guanosine*	2·1	2·6
Guanylic acid†	1·5	1·8
Thymidine*	4·7	17·4
Cytidine*	4·9	19·4
Cytidilic acid†	2·2	1·6
Riboflavin	2·4	1·6
Riboflavin-5-phosphate (sodium salt)	2·2–2·3	5·0

*Denotes nucleoside †Denotes nucleotide.

We have to compare the following Δε values: (*a*) base + ribose (nucleoside) 4·5–5·2 eV; (*b*) base + ribose + phosphate (nucleotide) 2·0–2·2 eV; (*c*) RNA, DNA 2·4 eV.

It has been suggested that Δε for DNA corresponds to excitation of π electrons to the first excited state π→π* (or n→π*) followed by tunnelling of electrons and holes at right angles to the planes of the bases down the axis of the double helix[1]. This mechanism is made possible by the overlap of π-orbitals between the parallel-stacked bases[4], which stacking does not occur apparently in the nucleosides or nucleotides. It is suggested that to obtain electron tunnelling between the widely spaced bases in the nucleosides excitation of π electrons to the second excited state is necessary, π→π**. In nucleotides, in the specific case of cytidilic acid, the bases are connected by hydrogen bridges via phosphate groups[5]. If generally true for nucleotides, this may explain the Δε of 2 eV, since again the π→π* excitation would be adequate for electron tunnelling. Clearly, there may be other possible mechanisms for bridging of charge-carriers since guanosine has Δε = 2·1 eV, and riboflavin 2·4 eV, and an explanation of these low values, similar to the nucleotides, must await information on their crystal structure.

On band theory $\varkappa_0 \sim 4\mu$, where μ is the average mobility of electrons and holes. On this basis the observed values of μ are comparable for DNA and nucleotides, but the values for nucleosides, as for small aromatic molecules[6], are much too high to be interpreted in this fashion, and an alternative to band theory must be sought in such cases.

These substances obeyed Ohm's law accurately up to 3,000 V/cm, deviations at this voltage being adenine 5 per cent, uridine 7 per cent, thymidine 2 per cent, riboflavin-5-phosphate 5 per cent. This is a clear indication that we are not dealing with space-charge limited currents[7,8]. This interesting fact, which also holds for the proteins, also of very high resistivity[9], is not explicable on band theory.

Helix-coil Transmission and Electronic Conductivity of the Amylose–Iodine Complex

The first linear polymer of biological origin which was shown to exist in a helical configuration was amylose, the linear polymer of glucose. This polymer has long been known to exist in a helical form in its familiar blue complex with iodine[1–3]. Subsequent discoveries of the helical structure of other biological polymers such as polypeptides[4] and polynucleotides[5] have created great excitement and stimulated many detailed studies into the properties of these polymers. However, possibly because amylose fulfils a rather mundane biological function and is derived solely from plant origin, equivalent studies on this material have not been carried out.

One of the most interesting properties which has been intensively studied in the aforementioned polymers is their ability to undergo rather sharp transitions from a highly ordered helical rod to a disordered randomly kinked structure[6,7]. Furthermore, electronic conductivity has recently been reported for polypeptides and proteins[8,9]. In this communication I present results of experiments which show the iodine–amylose helical complex exhibits similar properties.

Fig. 1 shows the dependence on temperature of the adsorption maximum of the helical amylose–iodine complex in a mixed solvent of five parts water and one part dimethyl sulphoxide. No added ions are present. The molecular weight of the fractionated amylose sample was

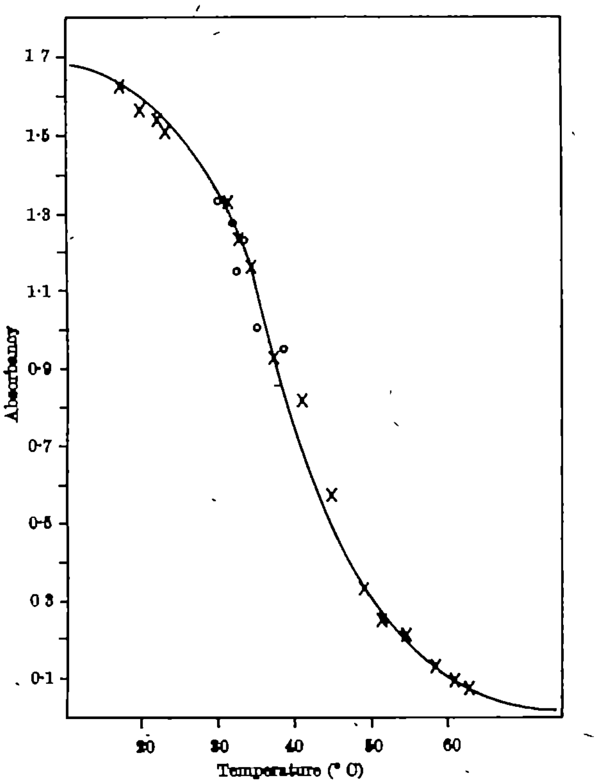

Fig. 1. The 6000 Å absorption band of the amylose–iodine complex as a function of temperature. The crosses were measured during the heating and the circles during the cooling-off cycle

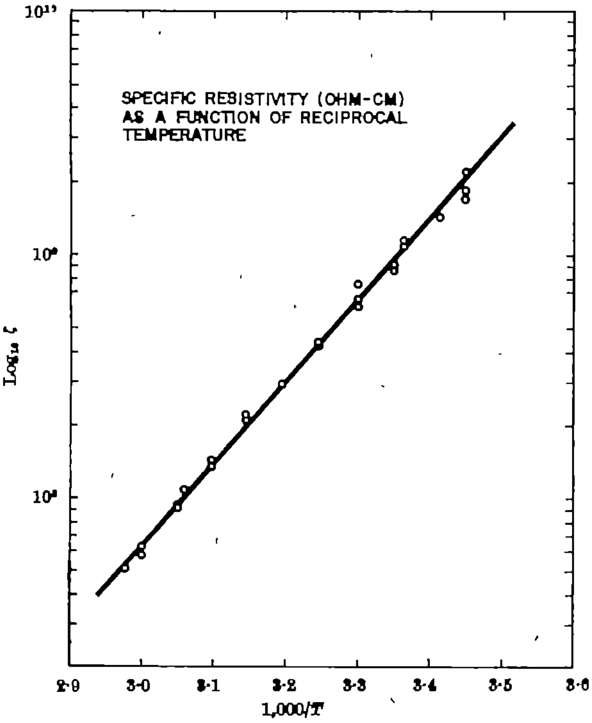

Fig. 2. Electric resistivity of a pressed sample of the amylose–iodine complex as a function of temperature

$1·6 \times 10^5$ and the concentration of iodine and amylose was $3·5 \times 10^{-4}$ g/ml. for each. This figure is in qualitative agreement with the statistical mechanical theory of such transitions[10–12] and shows the characteristic sigmoidal shape of such curves[6,7]. (A more quantitative evaluation is under way.)

Fig. 2 shows the resistivity, ζ, of a powder sample of amylose–iodine complex prepared in the following manner. Purified amylose and iodine were dissolved in dimethyl sulphoxide and then dialysed exhaustively against deionized water. The blue amylose–iodine complex will not form in dimethyl sulphoxide but forms sharply when the concentration of water reaches a critical value. The complex was dried by lyophilization and compressed into pellets for d.c. conductivity measurements by standard 4-pole methods. That electronic conductivity is involved seems assured by my experiments which show that the conductivity does not change with current flow. For any ionic mechanism one would expect an increase in resistivity due to polarization effects at the electrode.

My original observation led me to believe that this conductivity was evidence of the metallic behaviour of the iodine in this complex, which has been suggested theoretically by a number of investigators[13–15]. However, I afterwards found that this crystalline powder possesses a conductivity strongly dependent on the adsorbed water. In this respect it strongly resembles conductivity measurements of Rosenberg on hæmoglobin[9], who has shown that electronic conductivity increases in hæmoglobin with increasing moisture content.

Consequently, it is apparent that amylose–iodine helical complex possesses a number of the thermodynamic and electronic properties equivalent to those of other polymers of biological origin.

BIOCHEMISTRY

Capsular Polysaccharide of *Klebsiella pneumoniae* Type *A* (Strain 1265)

PREVIOUS investigations[1–3] have shown that the capsular polysaccharides of *Klebsiella pneumoniae* types *A* and *B* are glucose-containing polyuronides. Eriksen and Henriksen[3] have tentatively identified glucose, fucose and a uronic acid as components of type *A* capsular polysaccharide. Hitherto, little work has been directed towards elucidation of the structure of these polysaccharides and we now report briefly on the structure of the acidic polysaccharide of *Klebsiella pneumoniae* type *A* (strain 1265).

The bacterium was grown on a 2 per cent lactose–agar medium at 37° for 24 h, and the crude polysaccharide fraction precipitated from aqueous solution containing sodium acetate by 3 volumes of ethanol. After deproteinization, the polysaccharide fraction had $[\alpha]_D^{22}$ = −89°, N, 0·3 per cent, and was shown by hydrolysis to contain glucose, fucose, galactose, and a uronic acid. Earlier work[4] indicated that the galactose may result from contamination of the acidic polysaccharide with an intracellular galactan. The acidic polysaccharide was further purified by precipitation with cetyl pyridinium chloride[5] to yield a fraction, $[\alpha]_D^{20}$ − 102·5° (as sodium salt), containing uronic acid, glucose and fucose. A similar fraction, $[\alpha]_D^{20}$ − 107·8°, could be obtained by fractional precipitation with ethanol.

Hydrolysis of the acidic polysaccharide (700 mg) with 2 N sulphuric acid at 100° for 3 h yielded a uronic acid, glucose, fucose, and an oligosaccharide fraction containing uronic acid. The acidic sugars were absorbed on 'Deacidite *FF*' (CO_3^{2-}) and the neutral sugars (330 mg) chromatographed on a cellulose column to give D-glucose (180 mg), characterized as the *p*-nitroanilide dihydrate, m.p. and mixed m.p. 182–184° (ref. 6) and L-fucose (132 mg), $[\alpha]_D^{20}$ − 62·5°, characterized as the 2,5-dichlorophenylhydrazone, m.p. and mixed m.p. 206° (ref. 7). The acidic sugars (412 mg), after elution from the resin with N ammonium carbonate and conversion to the free acid forms, were chromatographed on cellulose to give a uronic acid fraction (254 mg), $[\alpha]_D^{20}$ + 12°, and a uronic acid-containing oligosaccharide(s) fraction (43 mg). The uronic acid was characterized as glucuronic acid by glycosidation and esterification with methanolic hydrogen chloride, reduction with lithium aluminium hydride, and hydrolysis. Chromatograms of the neutralized hydrolysate revealed a single component with mobility indistinguishable from that of D-glucose, and which was not detected after pretreatment of the hydrolysate with glucose oxidase. On hydrolysis the uronic acid-containing oligosaccharide(s) gave glucuronic acid, glucose and a sugar with the paper chromatographic and ionophoretic properties of lyxose. The reduced methyl ester methylglycoside of the oligosaccharide(s) fraction gave only D-glucose and lyxose on hydrolysis. The origin of the lyxose has still to be determined.

The polysaccharide rapidly lost the capacity to precipitate with antiserum after treatment with dilute alkali at room temperature. Approximately 45 per cent degradation resulted after exposure to 0·04 N calcium hydroxide solution under nitrogen for 96 h. Degradation was accompanied by the formation of saccharinic acids, including saccharinic acids derived from glucuronic acid and fucose. It has been established[8] that alkaline degradation of 1,3- and 1,4- linked glucans, and partially substituted reducing sugars, results in the formation of saccharinic acids. However, the formation of saccharinic acids is most rapid with 3-*O*- substituted derivatives[9]. The relatively rapid formation of saccharinic acids in this case suggests the presence of 1,3-linkages in the polysaccharide. This contention is supported by the fact that no uptake of oxidant was observed after prolonged treatment with periodate. The polysaccharide reisolated after treatment with periodate still precipitated with its antiserum using the gel precipitation technique.

The results of methylation studies also implied that 1,3-linkages predominated in the acidic polysaccharide. Reduction of the reducing end group with buffered sodium borohydride was necessary prior to methylation to avoid degradation of the polysaccharide under the alkaline conditions of methylation[10]. Hydrolysis of an incompletely methylated polysaccharide fraction ($[\alpha]_D^{20}$ − 92·5° in water) afforded components chromatographically indistinguishable from 2,4-di-*O*-methyl-L-fucose; 2,3,4,6-tetra-*O*-methyl-D-glucose (trace); 2,4,6-tri-*O*-methyl-D-glucose; and 4,6-di-*O*-methyl-D-glucose. The latter component probably arises from incomplete methylation of the polysaccharide as did two components resembling monomethylated glucose and 2-*O*-methylfucose in their chromatographic properties. However, the possibility of some branching in the polysaccharide cannot be excluded. A component showing similar mobility to glucuronic acid in acetate buffer at *p*H 5 indicated that it was a methylated glucuronic acid. The presence of 2,3,4,6-tetra-*O*-methyl-D-glucose in the hydrolysate implies that glucose comprises the non-reducing end unit of the polysaccharide. It is noteworthy that glucose is preferentially released, together with some glucuronic acid, on treatment of the polysaccharide with 0·01 N sulphuric acid at 80° for 30 min.

Sulphydryl Groups Essential for the Penicillinase Activity of *Aerobacter cloacae*

ALTHOUGH many enzymes possess sulphydryl groups essential for enzymatic activity there have been, so far as is known, no reports of these or indeed of any other types of essential group necessary for the enzymatic activity of a penicillinase. Evidence is given here to show that sulphydryl groups are essential for the penicillinase activity of a strain of *Aerobacter cloacae*.

Cells from an overnight broth culture of *Aerobacter cloacae* (laboratory reference No. 53) were collected by centrifugation, resuspended in 1/30 of their original volume with 0·025 M Sørensen's sodium phosphate buffer (*p*H 7·4) and disrupted, as described by Smith[1], in a liquid extrusion press. This suspension was centrifuged at 33,000*g* for 90 min to remove cell wall and other débris and the clear supernatant fluid stored at 4° C. This crude penicillinase preparation was diluted 1/100 with 0·025 M phosphate buffer and assayed against benzylpenicillin (2 mg/ml.) as described by Knox and Smith[2]. Penicillinase activity at different *p*H values was determined using 0·025 M phosphate buffer and ½ strength McIlvaine's[3] buffer. The *p*H optimum was found to lie between 5·2 and 6·2. Subsequent studies of penicillinase activity were made, using 0·025 M phosphate buffer, at *p*H 6·0, and as some penicillinases from other Gram-negative bacteria have been studied at *p*H 7·4 (ref. 4) the latter *p*H value was also used in order to make results obtained with this enzyme preparation comparable.

To investigate the effect of various enzyme inhibitors a penicillinase preparation was used which, in the absence of inhibitor, would hydrolyse about 20 µg/ml./min of benzylpenicillin. This was incubated with each inhibitor (2 mM) for 10 min at 37° C; an equal volume of benzylpenicillin solution was added and the enzyme assayed. The results (Table 1) show that, under these conditions, *p*-chlormercuribenzoate, which forms mercaptides with sulphydryl groups[5], was the only reagent which completely inhibited the penicillinase activity. Therefore the effect of *p*-chlormercuribenzoate was investigated more closely; and in addition *N*-ethylmaleimide, which forms, by addition, a thio-ether with sulphydryl groups[6–8], and iodoacetamide[9,10], which alkylates sulphydryl groups, were tested. *N*-ethylmaleimide and iodoacetamide reacted much more slowly than *p*-chlormercuribenzoate at concentrations

Table 1. EFFECT OF VARIOUS ENZYME INHIBITORS (2 mM) ON PENICILLINASE ACTIVITY

Inhibitor	Inhibition (per cent) At *p*H 7·4	At *p*H 6·0
2,4-Dinitrophenol	0	0
2,4-Dinitrofluorobenzene	17	13
Hydroxylamine	0	0
Sodium azide	0	0
Potassium cyanide	0	0
Ethylenediaminetetraacetate	0	0
Potassium ferricyanide	14	12
Ethyl urethane	0	0
Formaldehyde	0	0
Sodium fluoride	0	0
o-Iodosobenzoate	29	0
Phenylhydrazine hydrochloride	15	0
p-Chlormercuribenzoate	100	100

Table 2. EFFECT OF SULPHYDRYL GROUP REAGENTS ON PENICILLINASE ACTIVITY

Inhibitor	At *p*H	Concentration of inhibitor required to inhibit penicillinase activity by 50%	100%
p-Chlormercuribenzoate	7·4	2 μM	10 μM
	6·0	14 μM	60 μM
N-Ethylmaleimide	7·4	16 μM	200 μM
	6·0	2 mM	20 mM
Iodoacetamide	7·4	2 mM	20 mM
	6·0	> 20 mM*	—

* 20 mM iodoacetamide caused 10 per cent inhibition at *p*H 6·0; higher concentrations could not be tested under the conditions used.

producing equivalent inhibition and these inhibitors were therefore incubated with the penicillinase preparation for 90 min. The results (Table 2) show that *p*-chlormercuribenzoate was the most efficient inhibitor, *N*-ethylmaleimide had less effect and iodoacetamide had the least effect. Similar results showing that *p*-chlormercuribenzoate was more effective than iodoacetamide in inhibiting other enzymes containing sulphydryl groups have been reported[11]. All inhibitors were more effective at *p*H 7·4 than at *p*H 6·0; similar findings have been made[12,13] in the titration of the sulphydryl groups of egg albumin.

As the inhibition described here was caused by reagents which react with sulphydryl groups, various thiol compounds were tested to see if they caused reactivation. The results are shown in Table 3. With *p*-chlormercuribenzoate, when the enzyme preparation was incubated at 37° C with this inhibitor for 10 min then for 10 min with the thiol compound before benzylpenicillin was added, some reactivation occurred with all the thiol compounds tested. With *N*-ethylmaleimide or iodoacetamide, on the other hand, after the long period of incubation (90 min) necessary to complete the inhibitory process no reactivation occurred when any of the thiol compounds was added afterwards; though some reactivation did occur when the enzyme was incubated with these inhibitors for only 10 min at 37° C then for 90 min with the thiol compound before the addition of benzylpenicillin. Thus the inhibition caused by *p*-chlormercuribenzoate was more easily reversed than the inhibition caused by the other reagents. It is known that in general alkylating agents, in contrast to mercaptide-forming agents, combine irreversibly with the sulphydryl groups of enzymes[14].

Table 3. REVERSAL, BY CERTAIN THIOL COMPOUNDS, OF INHIBITION OF PENICILLINASE ACTIVITY

Concentration of inhibitor	Percentage of penicillinase activity in presence of inhibitor	*p*H value	Thiol compound	Percentage of penicillinase activity in presence of inhibitor + 5 times its molar concentration of thiol compound
4 μM *p*-Chlormercuribenzoate	28	7·4	Thioglycollate	96
			β-Mercaptoethylamine	44
			L-Cysteine	89
20 μM *p*-Chlormercuribenzoate	32	6·0	Thioglycollate	96
			β-Mercaptoethylamine	96
			L-Cysteine	96
20 μM *N*-Ethylmaleimide	35	7·4	Thioglycollate	78
			β-Mercaptoethylamine	35
			L-Cysteine	80
2 mM *N*-Ethylmaleimide	61	6·0	Thioglycollate	61
			β-Mercaptoethylamine	93
			L-Cysteine	91
2 mM Iodoacetamide	41	7·4	Thioglycollate	76
			β-Mercaptoethylamine	*
			L-Cysteine	†

* Under these conditions β-mercaptoethylamine caused further inhibition of penicillinase activity.

† Under these conditions L-cysteine destroyed benzylpenicillin.

Penicillinase preparation was incubated with *p*-chlormercuribenzoate for 10 min, thiol compound added and incubation continued for a further 10 min before penicillinase activity was estimated. Penicillinase preparation was incubated with the other inhibitors for 10 min, thiol compound added and incubation continued for a further 90 min before penicillinase activity was estimated.

The activity of this penicillinase preparation was found to be little affected by the oxidizing agents potassium ferricyanide and *o*-iodosobenzoate. It has been suggested[11,15] that sulphydryl groups in proteins can be readily oxidized only when two of them are sufficiently close for disulphide linkages to be formed. The resistance to oxidation shown by the penicillinase preparation may indicate that its sulphydryl groups occur singly or are not sufficiently close to allow oxidation. In any event, the finding that the penicillinase activity of this strain of *Aerobacter cloacae* can be inhibited by reagents which inactivate sulphydryl groups and that this inhibition can be reversed by thiol compounds suggests that sulphydryl groups are essential for activity. In this respect it seems to be unique among penicillinases so far described. It would be interesting to know if any other strains of bacteria, particularly of *Aerobacter cloacae*, possess a penicillinase with similar properties.

I thank Beecham Research Laboratories for gifts of penicillins. I also thank Prof. R. Knox, Dr. A. N. Davison and Mr. J. M. T. Hamilton-Miller for criticism and advice.

Occurrence of γ-Hydroxyarginine in Plants

AN examination of free amino-acids and related compounds in the genus *Vicia* revealed the presence of an unidentified ninhydrin-reacting guanidino compound in the seeds of 17 species (*V. alba*, *V. calcarata*, *V. cornigera*, *V. cordata*, *V. dumetorum*, *V. ferruginea*, *V. grandiflora*, *V. ludoviciana*, *V. monantha*, *V. nichouxii*, *V. onobrychioides*, *V. peregrina*, *V. pyrenaica*, *V. sativa*, *V. sepium*, *V. unijuga*, and *V. varia*).

This compound could be separated from arginine and homoarginine on paper in 17 h using methylethylketone/propionic acid/water (2 : 1 : 2 by vol.)[1] as solvent or in 72 h using butan-1-ol/acetic acid/water (12 : 3 : 5 by vol.)[2] as solvent. It gave a scarlet reaction with Sakaguchi's reagent[3], unlike the orange-red given by arginine and homoarginine, and behaved as an α-monoamino carboxylic acid when treated successively on paper with cupric nitrate and ninhydrin[4].

After extracting with water from seeds of *V. sativa*, and partially purifying by ion exchange chromatography, an attempt was made to isolate the compound as the monohydrochloride by acidifying the crude material (concentrated to a syrup under reduced pressure) with concentrated hydrochloric acid, removing excess acid with aniline and recrystallizing repeatedly from hot aqueous ethanol. During recrystallization the compound underwent transformation and the salt of a more basic compound (as indicated by its ionic mobility) was isolated in long colourless needles, m.p. 158° (uncorrected). This artefact resembled the original compound in giving a scarlet reaction with Sakaguchi's reagent but differed from it in giving a yellow and not a purple with ninhydrin. On standing in 0·1 N sodium hydroxide at room temperature the artefact reverted to the original compound in less than 17 h. These changes suggested the formation and subsequent hydrolysis of a lactone ring. The elementary analysis of the isolated salt was in agreement with it being the monohydrated dihydrochloride of a hydroxyarginine lactone (found: C, 27·72; H, 6·17; N, 20·40; Cl, 26·40; calc. for $C_6H_{12}N_4O_2.2HCl.H_2O$: C, 27·38: H, 6·08; N, 21·29; Cl, 27·00 per cent).

Although hydroxy derivatives of arginine have not been found previously in plant material, γ-hydroxyarginine, the derivative most likely to form a lactone, has been isolated from the sea-cucumber *Polycheira rufescens*[5] and the sea-anemone *Anthopholeura japonica* Verrill[6].

Using authentic γ-hydroxyarginine and γ-hydroxyornithine (kindly supplied by Dr. Y. Fujita) as markers, the original compound from *V. sativa* and the product obtained by refluxing it in 0·1 sodium hydroxide for 3 h were chromatographed on paper in six solvent systems and subjected to high-voltage ionophoresis on paper at pH 1·9 and pH 3·6. The R_F values and mobilities of the plant amino-acid and the product of its alkaline hydrolysis were, in each solvent system and at each value of pH, identical with those of γ-hydroxyarginine and γ-hydroxyornithine respectively. The plant amino-acid and γ-hydroxyarginine gave identical reactions with Sakaguchi's reagent as did the hydrolysis product and γ hydroxyornithine with periodic acid, and acetylacetone[7].

We thank Prof. H. Harris for his interest in this work and Mr. W. G. Mackenzie for his help in obtaining seed.

Enzyme Reactions with Phenolic Compounds[1]: Effect of O-Methyltransferase on a Natural Substrate of Fruit Polyphenol Oxidase[2]

PHENOLIC compounds constitute the natural substrates of the enzyme polyphenol oxidase (PPO). Of these, the major substrates of the enzyme in fruits are reported to be *o*-diphenols (catechols), for example, chlorogenic acid[3] (CGA), *l*-epicatechin[4], and dopamine[5]. If it were possible to modify irreversibly one of the catechol hydroxyl groups in any manner, this would have the following effects of preventing participation in PPO reactions by constituent phenolic compounds: (1) The modified catechols would themselves no longer be substrates of PPO[6], (2) the absence of catechols as primers of monophenolase oxidations could, in turn, eliminate the oxidation of constituent monophenols[7]. Even the first effect alone would eliminate the major proportion of PPO substrates in many plant tissues, as stated here[8].

The enzyme *O*-methyltransferase is capable of methylating the 3-position of 3,4-dihydroxy aromatic compounds[8,9] and *O*-methylation would be an irreversible modification of the type described. The substrates reported for rat-liver *O*-methyltransferase are such as to suggest a broad specificity, possibly including many of the plant *o*-dihydroxy aromatic acids. What would be the effect on PPO reactions after interaction of *O*-methyltransferase with PPO substrates? Methyl transfer was tested on two plant constituents, caffeic acid and CGA, after which their participation in PPO reactions was evaluated.

Synthetic caffeic acid[10] (3,4-dihydroxycinnamic acid) was used as a model compound because it was known to be methylated by the animal transferase[8] and the methylated product could be easily identified. The methylating enzyme was prepared according to Axelrod[8], taken through the ammonium sulphate precipitation step, dialysed against 0·001 M pH 7·0 potassium phosphate, and frozen.

Table 1. OPTICAL DENSITY CHANGES IN CGA AND ITS PRODUCT

Reaction time (h)	Optical density R_F 0·2 spot (CGA)	 R_F 0·6 spot (product)	O.D.—O.D. of control R_F 0·2 spot (CGA)	 R_F 0·6 spot (product)
(Boiled control)	0·228	0·057	0·00	0·00
1	0·170	0·112	−0·058	+0·055
2	0·154	0·147	−0·074	+0·090
5	0·071	0·263	−0·157	+0·206

O-Methyltransferase preparation (ref. 8) containing 8 mg protein was added to the following quantities of reagents (μmol/ml.): pH 9·5 potassium phosphate, 375; magnesium chloride, 10; sodium chlorogenate, 2·3; and *S*-adenosylmethionine, 15. Resultant pH, 7·7. The mixture was incubated at 38° C. 20 λ aliquots were spotted on paper at the designated times and the paper was chromatographed in 7 : 3 solvent mixture (see text). Excised spots were eluted by shaking in 5 ml. 70 per cent ethanol, and optical density was determined spectrophotometrically at 325 mμ. A control sample containing boiled enzyme was treated in the same manner.

Aliquots from a reaction mixture comparable with that shown in Table 1, except that sodium caffeate was used as substrate, were withdrawn periodically, spotted on paper, and chromatographed in chloroform/acetic acid/water, 2 : 1 : 1, lower layer[11]. During the incubation, caffeic acid decreased (R_F 0·1, detected by its ultra-violet fluorescence). A new fluorescent product, which increased in quantity with time, appeared at R_F 0·9. Its tested properties (R_F and absorption spectrum) coincided with those of ferulic acid (4-hydroxy-3-methoxycinnamic acid) as reported[8].

Chlorogenic acid (3-caffeoylquinic acid) isolated from green coffee beans[12] was subjected to the methylating system described in Table 1, and aliquots were chromatographed in several solvents, including a mixture of 7 parts chloroform–acetic acid–water (see above) and 3 parts methylcellosolve/acetic acid/water, 112 : 1 : 12 (ref. 13). This mixture was the only solvent system of many tried that distinctly separates CGA from its product substance. A fluorescent product appeared on the chromatograms; it increased in amount with time in proportion to the chlorogenic acid decrease (Table 1), suggesting their precursor–product relationship. The following properties were used to tentatively identify the product compound as 3-feruloylquinic acid, recently isolated from coffee bean and obtained through the kindness of Dr. J. Corse[14]: its R_F's in several solvents (for example, R_F 0·6 in the 7 : 3 mixture described here and R_F 0·7 in *n*-butanol/acetic acid/water, 4 : 1 : 2·2; as against R_F's 0·2 and 0·6, respectively, for chlorogenic acid), the bright blue-fluorescent colour of its spot on paper, and its 290–350 mμ absorption spectrum after elution from a paper chromatogram (procedure, Table 1).

In order to test the effect of PPO on the reaction products, caffeic acid and CGA reaction mixtures were chromatographed, and the chromatograms were sprayed with crude PPO prepared from peach or apple fruit according to the procedure of Siegelman[4]. When the sprayed papers were incubated at room temperature in a moist chamber, brown coloration soon appeared where

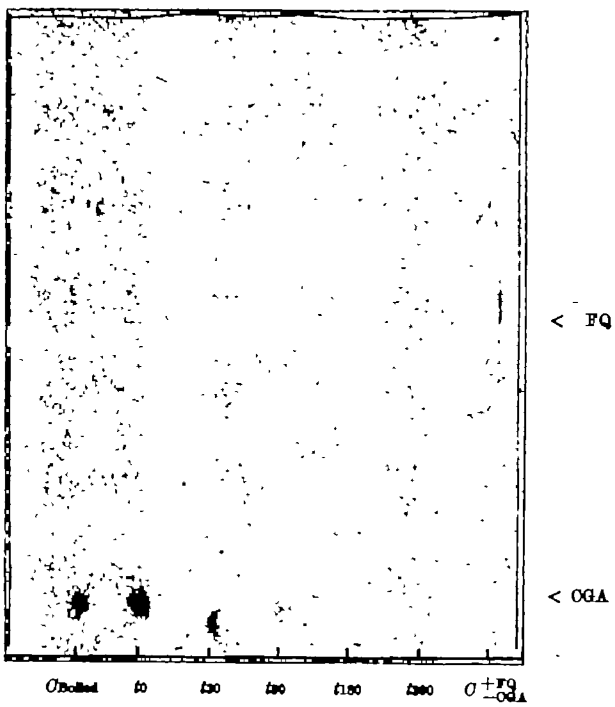

Fig. 1. Paper chromatogram of OGA reaction mixture, paper uniformly sprayed with PPO. Conditions of incubation and chromatography similar to those in Table 1 were used, except for an increase in enzyme concentration (40 mg/ml.). Aliquots were withdrawn at the designated times ($t_{\min}$). Two control mixtures are also shown: in C_{Boiled}, boiled enzyme was used; in C^{+FQ}_{-OGA}, feruloylquinic acid was substituted for OGA. R_F positions of the compounds are indicated at the right margin and by circling of the feruloylquinic acid control spot, visible when under ultra-violet light. (Note.—The migration of OGA is retarded somewhat by components of the incubation mixtures)

oxidizable substrates were present. Only caffeic acid, not methylated product, reacted to give a dark colour. Parallel effects, illustrated in Fig. 1, were obtained with OGA (R_F 0·2) and its methylation product (R_F 0·6). In each case, the methylated compound was no longer a PPO substrate. Similar results might be expected[6] with the enzymatically 3-methylated products of dopamine[8] and other *o*-diphenolic plant constituents.

Since enzymatic methylation of substrates of PPO prevents their oxidative reaction, the methylation would be of obvious interest with regard to the oxidative darkening of plant tissues. Interaction of *O*-methyltransferase with fruit tissues has given the expected effect on their PPO reaction, which will be reported elsewhere.

Tryptophan–Nicotinic Acid Metabolism in Subjects recently or long since recovered from Viral Hepatitis

In previous work we have shown that metabolic alterations in the chain of reactions leading from tryptophan to nicotinic acid are present in both experimental hepatitis by mouse hepatitis virus (*MHV*-3 virus)[1] and in human viral hepatitis in the acute stage[2].

We have now investigated the persistence of the aforementioned alterations in subjects clinically recovered from the latter disease.

The pattern of urinary metabolites involved in the tryptophan–nicotinic acid interrelation was examined in urine samples collected over a 24 h period from normal subjects and from 34 subjects who had recovered from viral hepatitis: 10 recovered for 2 months–1 year (group I); 12 for 1–5 years (group II); 12 for 5–15 years (group III).

For the chromatographic analysis of the aforementioned metabolites Dalgliesh's technique[3] was used. Identification of the compounds was carried out by examination of the fluorescence by ultra-violet light (3660 Å) and by the characteristic colour reactions. Several chromatographic analyses were carried out on different days for each subject.

Furthermore, in the same subjects the electrophoretic protein pattern, the flocculation or turbidity tests (Takata-Ara test and thymol–turbidity test), the activity of serum transaminases and the determination of serum bilirubin were carried out in order to discover whether the liver function of these subjects was altered or not.

Of the 10 cases of group I, we found kynurenine in 4, kynurenine and 3-hydroxykynurenine in 2 (only one of these presented a slight increase of γ-globulin and a partially positive Takata-Ara and thymol–turbidity tests).

Of the 12 cases of group II, we found kynurenine in 4, kynurenine and 3-hydroxykynurenine in 3 (the other tests were normal in all 12).

Of the 12 cases of group III, we found kynurenine in 5, and kynurenine and 3-hydroxykynurenine in 3 (only one of these presented a slight increase of γ-globulin and a partially positive Takata-Ara and thymol–turbidity tests).

The results obtained show that in a high percentage (about 60 per cent) of the completely recovered subjects examined (on the basis of clinical examination and of many tests for liver functions) a certain alteration of the tryptophan–nicotinic acid metabolism was still present. It seems that this lesion is connected chiefly with kynurenine oxidase activity.

Bacterial Transformation: an Antigen Specific for 'Competent' Pneumococci

The ability of a strain of pneumococcus to be transformed by deoxyribonucleic acid (DNA) isolated from another strain is termed 'competence'. The basis for 'competence' is not yet fully understood, but evidence has been obtained[1] that it may depend on the capacity of a cell to incorporate DNA. The finding by Hotchkiss[2] that non-transforming DNA inhibits transformation indicated that specific receptors for DNA are present in 'competent' cells. Schaeffer[3], after extensive investigation of this phenomenon, concluded that the receptor is on the surface of 'competent' bacteria.

The probability that the receptor on 'competent' pneumococci may be a protein[1,2] suggested that it might be antigenic. Immunization with 'competent' pneumococci accordingly should stimulate the production of antibodies which inhibit transformation, whereas antibodies to 'non-competent' cells should not inhibit transformation. The results of experiments designed to test this possibility are reported here.

All experiments were performed with DNA prepared from a strain of pneumococcus resistant to streptomycin, micrococcin, and erythromycin. The DNA was isolated from cells lysed with deoxycholate, deproteinized by shaking with chloroform and isoamyl alcohol, and precipitated with ethanol[3]. The procedures for transformation and the method of quantitation using anti-R serum were those described by Hotchkiss[2,3].

To prepare 'competent' cells for immunization, pneumococci were grown under conditions identical to those used for preparing a culture for transformation[3]. When 'competent' cells were presumably present, an aliquot was removed to test for transformability. Formaldehyde in a final concentration of 0·2 per cent was added to the remainder of the culture, and the pneumococci were kept at room temperature overnight. The cells were then separated by centrifugation and concentrated fifty-fold for immunization.

'Non-competent' cells were prepared in an identical fashion, except that bovine serum albumin was eliminated from the growth medium. It was usually necessary to transfer the culture several times in a medium lacking bovine serum albumin before a culture which gave no evidence of transformability could be obtained.

It had been found, in connexion with other investigations, that sera from presumably normal rabbits occasionally inhibit transformation. Consequently globulin fractions prepared by sodium sulphate precipitation[7] were used in these investigations. Such fractions do not inhibit transformation non-specifically.

The results of experiments in which three globulin fractions from the sera of rabbits immunized with 'competent' cells were compared with three corresponding fractions from rabbits immunized with 'non-competent' pneumococci are recorded in Table 1. All the globulin fractions obtained from the rabbits immunized with transformable pneumococci inhibited transformation for all three markers studied, whereas no inhibition was noted with the globulin fractions obtained from the animals immunized with 'non-competent' cells. In fact, the latter, for reasons not apparent, actually increased the yield of transformants as compared with the control tubes to which only the transforming DNA was added. The difference between the activities of the two sets of globulin preparations was not due to a difference in titre, because all six fractions had identical titres as determined by agglutination of either formalinized 'competent' or 'non-competent' pneumococci.

To eliminate the possibility that the results might be due to fortuitous variations among rabbit sera, globulin fractions prepared from pre- and post-immunization sera were compared (Table 2). Here, again, the inhibitory effect of fractions obtained from immunized rabbits is apparent, in contrast to the usual enhancement observed with globulin fractions obtained from the same rabbits before immunization.

Table 1. EFFECT OF GLOBULIN FRACTIONS FROM SERA OF RABBITS IMMUNIZED WITH 'COMPETENT' (C) AND 'NON-COMPETENT' (NC) PNEUMOCOCCI ON TRANSFORMATION

Globulin fraction	No. of cells transformed/ml. Streptomycin	Erythromycin	Micrococcin
$E6$–1 (C)	680	390	$1·0 \times 10^3$
$E6$–26 (NC)	$1·9 \times 10^5$	$1·4 \times 10^5$	$2·2 \times 10^5$
Control	$5·5 \times 10^4$	$1·0 \times 10^5$	$1·7 \times 10^5$
$E6$–2 (C)	$8·4 \times 10^2$	$4·2 \times 10^4$	$1·6 \times 10^4$
$E6$–27 (NC)	$1·3 \times 10^5$	$3·5 \times 10^5$	$1·8 \times 10^5$
Control	$8·6 \times 10^4$	$3·7 \times 10^5$	$1·8 \times 10^5$
$E6$–3 (C)	$1·4 \times 10^4$	$6·5 \times 10^4$	$2·7 \times 10^4$
$E6$–22 (NC)	$1·2 \times 10^5$	$4·5 \times 10^5$	$1·9 \times 10^5$
Control	$6·2 \times 10^4$	$3·2 \times 10^5$	$2·0 \times 10^5$

Table 2. COMPARISON OF GLOBULIN FRACTIONS FROM PRE- AND POST-IMMUNIZATION SERA OF RABBITS IMMUNIZED WITH 'COMPETENT' PNEUMOCOCCI

Globulin fraction	No. of cells transformed/ml. Streptomycin	Micrococcin
$E6$–35	0	0
$E6$–35s	$8·8 \times 10^5$	$2·7 \times 10^5$
$E6$–38	$1·5 \times 10^4$	$1·5 \times 10^4$
$E6$–38s	4×10^5	$3·3 \times 10^5$
$E6$–40	30	130
$E6$–40s	$2·2 \times 10^5$	$2·2 \times 10^5$
Control	$2·4 \times 10^5$	$2·2 \times 10^5$

s denotes pre-immunization sera.

The results provide direct evidence for the presence of an antigen associated with 'competence' in pneumococci. It is reasonable to assume that this antigen is the receptor that has been postulated to occur on the surface of transformable cells. This antigen must be lost or altered in the 'non-competent' cell, for if it were merely 'masked', that is, covered so that it was no longer on the surface, it should still be capable of acting as an antigen to stimulate the formation of inhibiting antibodies. Whether or not this antigen is responsible for the cyclical appearance of transformability in synchronously cultured pneumococci[4] remains to be determined. Obviously such variations in transformability could also result from changes in the ability of the cells to integrate DNA into their genomes, and bear no relation to a surface receptor or antigen.

The 'competent' pneumococci were grown in the presence of bovine serum albumin. As an additional control, therefore, globulin fractions prepared from the sera of rabbits immunized with bovine serum albumin were tested in the transforming system and were found to be without effect.

The sera, whether obtained from rabbits immunized with 'competent' or 'non-competent' cells, exhibited identical agglutinin titres with both types of cells. They undoubtedly contain a number of different antibodies, most of which are present in all the sera. It is not possible, therefore, to measure the specific antibody responsible for inhibiting transformation, but it has been found that only globulin fractions with relatively high titres (> 10,000) were active in this regard. Dilution by as little as ten-fold eliminated their capacity to inhibit transformation, indicating that the specific inhibitory antibody probably is present in small concentrations in comparison with antibodies directed against other cell components. Despite this complication, it is hoped to use such antisera as a guide to the isolation of the 'competent' antigen by fractionating transformable pneumococci and determining which fractions absorb the inhibiting activity.

PHYSIOLOGY

Rate of Restitution and Self-regulation of Contractility in Mammalian Heart Muscle

In a suitable environment a heart muscle preparation stimulated at a fixed rate maintains a steady-state strength of contractions for long periods. The muscle thus completely recovers between two successive beats. However, the recovery does not occur immediately with repolarization of the membrane. The recovery or restitution of contractility lags behind that of excitability[1] and it is not instantaneous but progressive, as revealed by the premature and delayed beats (Fig. 1): if the interval is shorter, the amplitude of contraction is smaller, that is, the restitution of contractility is not complete. If, on the other hand, the interval is longer than the regular one, the contraction is higher, the restitution of contractility being even more complete.

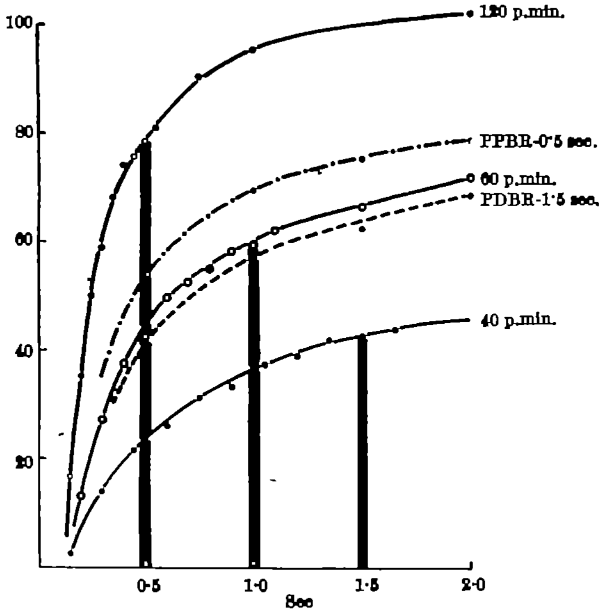

Fig. 1. Restitution of contractility in guinea pig atrium at 32·2° C and at basal rates of 40, 60 and 120 per min, as revealed by the strength of premature and delayed contractions (ordinate). Abscissa: interval preceding the measured contraction. The steady state amplitude for each of the 3 frequencies is marked by a black column. *PPBR*, post-premature beat restitution—accelerated (potentiated) restitution following a premature beat (interval 0·5 sec); *PDBR*, post-delayed beat restitution—slowed restitution following after a single delayed beat (interval 1·5 sec). Ordinate, amplitude; abscissa, interval. Differences between the two upper (120 per min and *PPBR*) and two lower (*PDBR* and 40 per min) curves indicate the effects due to cumulation (single and repeated intervals of 0·5 and 1·5 respectively)

Moreover, besides this change in the amplitude of the irregular contraction, the change of a single interval causes an augmentation of the next beat, even when it follows after a regular interval, that is, without a compensatory pause (post-extrasystolic potentiation)[2]. In our experiments it was possible to show that within certain limits—at medium rates—the velocity of contractility restitution, which follows the premature beat, is increased (Fig. 1, *PPBR*). On the other hand, a longer interval causes a decrease in the rate of restitution. It looks as if the speed of contractility recovery were set according to the length of the preceding interval. A shorter interval between contractions accelerates the restitution of contractility so that the amplitude of the following beat reaches a higher level than previously during the same time period (Fig. 1, *PPBR*); a longer interval causes just the contrary (Fig. 1, *PDBR*).

If not only one but all intervals are shortened, that is if frequency is increased, the speed of the restitution process gradually increases and this change results in gradual augmentation of the contractile force or shortening (staircase phenomenon). The speed of restitution of contractility is thus set progressively to a higher level corresponding to the final steady-state of the new frequency. The change of frequency in the opposite sense, its slowing within the limits of medium rates, results in a progressive decrease of restitution velocity to a new lower steady-state level (negative staircase).

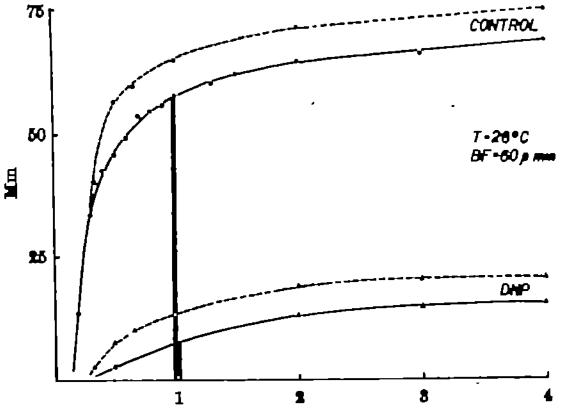

Fig. 2. Restitution of contractility in guinea pig atrium at 28° C and basal frequency 60 per min before and after 1 h exposure to 2,4-DNP ($7\cdot5 \times 10^{-5}$ M)

Solid line, normal restitution curve; broken line, post-premature beat restitution. Steady-state amplitudes indicated by dark columns. Elevation of the curve due to single inotropic effect of premature beat is unchanged, but its maintenance on the higher level is abolished. Note the two phases of restitution development: an initial rapid, followed by a slow phase. The change in rate of restitution occurs almost entirely in the initial phase (cf. also Fig. 1)

This cumulation of the individual inotropic effects of premature or delayed beats seems due to a certain inertia in the return of the restitution, deviated from its steady rate. It may be observed on several beats after a premature or delayed contraction: the initial change is abrupt, but the return only gradual.

Potentiation thus seems to be essentially a change which accelerates or facilitates the process of restitution of contractility. The immediate effect due to a premature contraction, and the cumulative effect brought about by an increase of frequency, are closely related; but they are not identical. The difference between them is well revealed by anoxia or some metabolic inhibitors (fluoroacetate, dinitrophenol), which first suppress the cumulation, leaving the immediate effect almost unchanged (Fig. 2). It is affected only later, when, owing to the progressing metabolic lesion, the mechanical response of the heart muscle is greatly altered. Thus the immediate effect is largely independent of energy-yielding metabolic reactions, while cumulation requires integrity of the whole system of oxidative reactions.

It is to be noted that the change which results in potentiation may be elicited by very premature stimuli which are not followed by any mechanical response and is therefore connected rather with the membrane phenomena and with the process of activation than with some mechanical event of contraction[3], and may therefore be called inotropic effect of activation[4].

Some special problems arise from the behaviour of the heart muscle at very low and high frequencies, at various temperatures, and there are also some species differences in the form of the frequency-strength relationship, most important in the rat myocardium. Their implications will be discussed elsewhere.

The nature of the restitution of contractility and of the mechanism of its 'setting' is so far not clear. We know, however, that these phenomena are closely connected with the membrane depolarization and with the process of excitation–contraction coupling on one hand, and on the other with the processes of transformation and conversion of the stored energy into an available form and its utilization for the mechanical process of contraction. Recent evidence shows that many variations of contractility are related rather to changes in the efficiency of the utilization of chemical energy and its conversion to mechanical energy than to changes in the actual amount of the chemical energy used per beat[5]. This conception does not seem inconsistent with our interpretation of present results. Further research is needed, however, to elucidate the underlying processes.

The fact that the activation, besides triggering the contractile mechanism, modifies at the same time the rate of contractility restitution, and with it the strength of contraction according to the length of the preceding interval, may be of definite physiological significance in a muscle adapted to rhythmical activity. It leads to the idea of self-regulation in the heart muscle, of an efficacious mechanism—and perhaps the only possible one—allowing for a gradation of mechanical response in rhythmical activity.

Effect of Œstradiol on Spinal Cord Convulsions in Developing Rats

Spinal cord convulsions can be elicited by direct spinal cord stimulation in 1-day-old rats[1]. In contrast, the tonic–clonic seizure pattern of adult rats produced by electroshock stimulation of the brain[2] usually does not appear until the 21st day of age. Thus, the spinal cord matures more rapidly, functionally, than do higher centres of the nervous system.

Previous investigations in this laboratory have demonstrated that œstradiol in adult rats increases brain excitability, as measured by a decrease in electroshock seizure threshold and by facilitation of the tonic phase of the maximal electroshock seizure[3]. In view of the part that spinal reflex systems play in determining the seizure pattern[4], the question arises whether or not œstradiol exerts a significant action on these systems.

In a preliminary investigation, Heim and Timiras[5] have found that in rats treated with œstradiol from the 8th to the 11th days after birth, the time of appearance of the ability to exhibit a tonic–clonic seizure was hastened by two days over that of the controls. These authors have suggested that œstradiol induces precocious maturation in the brain. However, the role of spinal reflex systems should be considered.

The following experiments were performed to examine the effect of œstradiol on spinal cord convulsion patterns in rats during maturation.

Œstradiol dipropionate in a dose of 1 mg/kg (in 0·01 ml. 'Mazola' solution/g body-weight) was administered to rats daily from the 8th to the 11th days after birth. Control animals received 0·01 ml./g body-weight of 'Mazola' for the same period. Spinal cord convulsions were elicited in both control and œstradiol-treated rats on the 12th and 21st days of age. The technique for direct spinal cord stimulation was that described by Esplin and Freston[4] and modified by Vernadakis[1]. The animals were decapitated at the cervical region and the stimulating electrode (cathode) was inserted 4–5 mm into the cord. The anode was attached to exposed tissue of the neck. Square-wave stimuli 1 msec in duration and of 100 pulses/sec frequency were delivered by a Grass stimulator at a stimulus intensity of 30 V. Spinal cord stimulation of 10-sec duration was applied 15 sec after decapitation. The end points of hind-limb flexion and extension were measured by an electronic timer. The duration of flexion is utilized as a standard index of seizure intensity; the shorter the duration of flexion the more severe is the convulsion[6].

The duration of flexion in control and œstradiol-treated rats 12 and 21 days of age are presented in Table 1. In both ages the duration of flexion in the œstradiol-treated animals is significantly decreased; the decrease in 12-day-old œstradiol-treated rats is more marked than that in the 21-day-old. These results illustrate that œstradiol administration increases the reflex excitability of the spinal cord and that this increase in excitability persisted during the experimental period; they are in agreement with previous studies[2,3] showing that œstradiol has long-lasting effects on developing rats.

Table 1. Effect of Œstradiol* on Spinal Cord Convulsions in Rats during Development

Age: days after birth	Duration of hind-limb flexion (sec)	
	Control	Œstradiol
12	1·58 ± 0·18†	0·99 ± 0·04 (< 0·001)‡
21	1·32 ± 0·13	0·95 ± 0·004 (0·05–0·02)

* Œstradiol was injected subcutaneously from the 8th to the 11th days after birth. 8–16 rats were used in each age period.

† ± *S.E.*

‡ Number in parentheses is *P* value for comparison to control.

It has been suggested in previous investigations[5] that œstradiol, given at a critical period of development, enhances the appearance of the full tonic hind-limb extensor seizure by inducing precocious maturation of the higher centres of the nervous system. In the present investigation œstradiol given at a critical period of the development of higher centres increases the level of activity of spinal reflex system. Thus, it may be suggested that the enhanced appearance of a full tonic–clonic seizure in œstradiol-treated developing rats can be attributed in part to an increased level of spinal reflex excitability.

Permeability of Dermal Connective Tissue in Normal and Scorbutic Guinea Pigs

Recent work has shown that the permeability of capillary blood vessel walls does not seem to be affected by scurvy[1] despite the presence of hæmorrhages. However, capillary resistance was shown to decrease[2–6] and the corresponding capillary fragility increased[6,7]. No investigations of the influence of scurvy on the permeability of dermal and connective tissue have been made.

To examine the effect of scurvy on dermal and subcutaneous tissue, we used young guinea pigs weighing 250–400 g, fed *ad lib.* on Wayne guinea pig diet containing 420 mg of vitamin C (added) per 100 g of diet. To induce scurvy, the guinea pigs were placed for 15–17 days on Wayne 'Lab Blox' (mice and rats), which contained practi-

Table 1. Effect of L-Ascorbic Acid (1 mg/ml. in Saline) on the Rate of Diffusion of Evans Blue Dye in Normal and Scorbutic Guinea Pigs

	No. of animals	Weight (g)	Spread area (mm²) with: Dye alone	Spread area (mm²) with: Ascorbic acid	Increase (per cent)	Average values (males and females) Spread area (mm²) with. Dye alone	Average values (males and females) Spread area (mm²) with. Ascorbic acid	Average values (males and females) Increase (per cent)
Normal animals	3 ♂	350 ± 21	121 ± 14	144 ± 21	18	141 ± 20	162 ± 30	15
	7 ♀	430 ± 50	147 ± 11	168 ± 22	14			
Scorbutic animals	6 ♂	285 ± 42	123 ± 9	148 ± 24	20	137 ± 33	164 ± 23	20
	6 ♀	203 ± 15	151 ± 17	179 ± 22	19			

cally no ascorbic acid. On this diet, they lost an average of 22 per cent of their body-weight and at autopsy showed severe hæmorrhages of limb joints, chondrocostal junctions and of the intestines. The adrenals had increased in weight.

Modifications of Duran-Reynals's spreading test[8] and of the constant pressure infusion test of Hechter *et al.*[9-11] were used for measuring permeability. In the spreading test, 0·05 ml. of a 4 per cent Evans blue solution in saline (*p*H 7·3) with or without ascorbic acid (1 mg/ml.) was injected intradermally into the abdominal regions of animals. The areas of the spots thus produced were recorded by tracing on semi-transparent paper after 30 min.

In the constant pressure infusion method a 27-gauge needle attached to a constant pressure burette with rubber tubing was introduced into the dorsal calf region of guinea pigs. Saline (0·154 M) adjusted to *p*H 7·3 was allowed to flow into the animal for 15 min at an infusion rate of 0·4–0·6 ml./min. After the first 5 min, 0·5 ml. of ascorbic acid (1 mg/ml.) in saline was injected into the bleb. The flow-rates of the saline during the first and third 5-min periods were measured. The permeability was measured as the volume (× 100) of saline infused during the third 5-min period divided by the volume infused during the first 5-min period. Generally, two tests (on left and right calves) were made on each animal. The control ratios were obtained by injecting 0·5 ml. of saline into the bleb. (Details of these techniques will be described elsewhere.) Both methods, spreading and infusion tests, were used on normal and scorbutic guinea pigs. Before the tests, the animals were anæsthetized by use of aqueous solution of sodium nembutal ('Pentobarbital sodium', Abbott) (60 mg/ml.), diluted 1 : 4 with saline; 0·4 ml. of this dilution was injected intradermally per 100 g of body-weight.

The results of the application of the dermal diffusion method using Evans blue with or without ascorbic acid is shown in Table 1 for male and female guinea pigs. Ascorbic acid caused an increase in the spreading of the dye. However, both normal and scorbutic animals showed about the same increase. The size of the spots for dye alone was also similar for the normal and scorbutic animals. Female animals had somewhat larger spots than males, an observation found in our earlier work for both rats and guinea pigs. A similar sex difference for rabbits using indian ink and hæmoglobin as the test substances has been reported by Lurie and Zappasodi[12].

Table 2. Effect of L-Ascorbic Acid (1 mg/ml.) in Saline on the Rate of Infusion for Normal and Scorbutic Guinea Pigs

	No. of animals	Body-weight (g)	Ratio: ml. in third 5 min × 100 / ml. in first 5 min		Permeability increase (%)	
Normal animals						
Controls (with dye alone)	9 ♂	*	95 ± 13	93 ± 13†	—	
	8 ♀	*	90 ± 12		—	
With ascorbic acid	8 ♂	300 ± 20	110 ± 13	111 ± 12	15	20‡
	7 ♀	280 ± 48	114 ± 12		27	
Scorbutic animals	9 ♂	292 ± 33	101 ± 11	105 ± 12	6	18
	5 ♀	254 ± 51	113 ± 16		25	

* Animals of 250–350 g.

† The same values were also used as controls for scorbutic animals.

‡ Average.

As shown in Table 2, the increase in rate of infusion of saline was enhanced by ascorbic acid to about the same extent for normal and scorbutic animals.

These results suggest that the permeability of dermal and subcutaneous tissues is not altered in scurvy when measured by these methods.

Diet and Histamine in the Ruminant

The presence of histamine in normal rumen liquor has not been proved decisively, and the part played by this substance in acute indigestion in ruminants has not been well established.

Dain *et al.*[1] were unable to detect histamine in normal rumen contents, whereas Shinozaki[2] found histamine base values between 2·9 and 5·6 μg/ml. rumen liquor. In both investigations the sheep were fed on hay. Dain *et al.*[1] detected histamine in ingesta of experimentally overfed sheep, levels higher than 70 μg histamine base per ml. being obtained. They also reported good correlation between increase in histamine-level, lowering of the *p*H, due to fermentation of great amounts of carbohydrates, and severity of indigestion. Tyramine was also present.

It has been established that intravenous injection of histamine in sheep will cause rumen paralysis[1,3-5] and cessation of eructation[1]. On the other hand, orally administered histamine does not influence the physiological condition of the rumen[2]. This has been attributed to poor absorption of histamine through the rumen epithelium. The consensus of opinion has been that the histamine in the rumen is of endogenous origin.

In our experiments histamine was extracted from the rumen liquor of sheep by passage through an 'Amberlite *IRC*-50' column according to Bergstrøm and Hansson[6]. After elution with hydrochloric acid, histamine was assayed conventionally on isolated atropinized guinea pig ileum. The acetyl-conjugated histamine was determined as the increase in free histamine which occurred on acid hydrolysis. All histamine values refer to the diphosphate.

Fig. 1 shows the diurnal variation of histamine concentration in the rumen liquor when the morning ration consisted of hay and concentrates and the afternoon ration

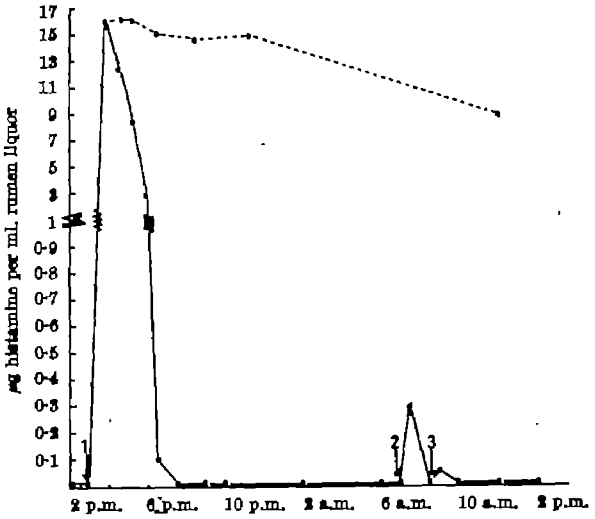

Fig. 1. Variation in the concentration of histamine in rumen liquor. ——, *In vivo*; – – –, *in vitro*; the *in vitro* sample of rumen contents was provided after ingestion of silage. Fed at hours indicated by arrows: 1, silage; 2, concentrates; 3, hay

of formic acid grass silage (460, 500, and 270 g, respectively). A large increase occurred after ingestion of silage. When the feeding schedule was altered, similar increments always occurred subsequent to silage feeding, independent of the hour of the day. The increase was of short duration, as in 3–5 h the histamine concentration in rumen reached pre-feeding levels. A moderate but distinct increase also occurred after feeding with hay or concentrates.

The quantities of preformed histamine were determined in silage, hay, fresh grass, and concentrates using the ether extraction method of Block[7]. The histamine was afterwards extracted twice from the ether with equal volumes of distilled water. By this procedure approximately 99 per cent was transferred to the water phase. When large amounts of histamine were expected, the assay could be performed directly, since small amounts of ether did not interfere. When small amounts were expected, however, the ion-exchange method was used, serving both the purpose of removing the ether and concentrating the solution.

Table 1. Content of Histamine in the Feeds used

Grass silage				
Unfractionated (μg/g dry weight)	Press juice (μg/ml.)	Hay (μg/g dry weight)	Concentrates (μg/g dry weight)	Fresh grass (μg/g dry weight)
1,110–3,000	620–1,230	0·2–0·3	0·4–0·6	0·5–0·9

Silage was found to contain large amounts of histamine, while the quantities present in the other feeds were minimal (Table 1). In samples of grass silage from 7 other farms (preserved with either HCOOH or H_2SO_4–HCl) the histamine concentration varied between 26 and 900 μg per ml. press juice.

To identify the tested substance we first showed that its effect on guinea pig ileum was completely counteracted by small amounts of antihistamine. Secondly, the ether extracts were subjected to paper chromatography (Whatman No. 1, diethyl-ether/ethanol/water/conc. ammonium = 5 : 4 : 1 : 0·1). The active compound had the same R_F value as histamine standards, and reacted positively on the Pauly reaction[8]. The chromatograms also revealed that tyramine was a component of these feeds (unpublished results).

Fig. 1 demonstrates a pronounced discrepancy between the *in vivo* and the *in vitro* disappearance of histamine in rumen contents after ingestion of silage. This indicates that micro-organisms of the rumen are not responsible for any substantial part of the metabolization. The rate of fluid transport from the rumen to more distal parts of the alimentary tract[9] does not seem to be sufficiently rapid to account for the fast disappearance from the rumen. This suggests that a considerable proportion of the histamine is absorbed. Furthermore, analysis of faeces revealed that neither free nor acetyl-conjugated histamine ever reached high levels after ingestion of silage. In urine, on the other hand, a large increase in the excretion of acetylhistamine occurred, whereas the increment of free histamine was minimal.

Table 2. Metabolism of Histamine (μg Histamine/g Wet Weight/h) *in vitro* by Liver Slices, Rumen Epithelium and Mixed Rumen Muscle

	Liver tissue	Rumen epithelium	Rumen muscle
No. of observations	28	21	8
Mean and *S.D.*	115 ± 23·4	3·1 ± 0·7	5·2 ± 1·1
Range	64–153	1·9–4·5	3·4–6·7

It is evident from Table 2 that moderate quantities of histamine can be metabolized in the rumen wall. However, after ingestion of silage its metabolic capacity will be far exceeded. Table 2 demonstrates that liver tissue possesses an activity sufficiently high to metabolize even these excessive amounts of histamine. Thus it seems likely that the absence of symptoms of intoxication and the minimal increments in free histamine in urine can to a great extent be attributed to detoxication in the liver. Further studies of these problems are in progress.

Effect of Tetraethyl Ammonium Ion on the Electrical Activity of Smooth Muscle Cell

Tetraethyl ammonium (TEA) ion is known to be one of the most effective ions for maintaining the electrical activity of excitable tissues in sodium-free media[1]. It is also known that TEA is capable of lengthening the action potentials in crustacean muscle[2,3], crustacean nerve[4], vertebrate striated muscle[5] and in certain nerve fibres and cells[6,7]. The work reported here was planned to elucidate the effect of TEA on the smooth muscle cell, which is assumed to be different in membrane properties from many other excitable tissues.

Action potentials were recorded from the taenia coli of the guinea pig by means of intracellular microelectrode. TEA–Krebs solution, similar to the normal Krebs solution except that various amounts of sodium chloride in solution were replaced by equimolar amounts of TEA, was used.

At small concentrations of TEA (6 mM), the rate of spike discharge increased slightly but the shape of spike potential was not different from that obtained in normal Krebs solution. At relatively high concentrations of TEA (15 mM or more), its action is diphasic, causing an initial increase in spike frequency followed by the decrease in its frequency, and in the latter phase the marked prolongation of action potential was observed (Fig. 1). That is, the action potentials had shapes similar to those characteristically obtained from the cardiac muscle[8]. However, when the preparation was immersed in TEA–Krebs solution for a longer period, the resting potential tended to fall and the action potential magnitude

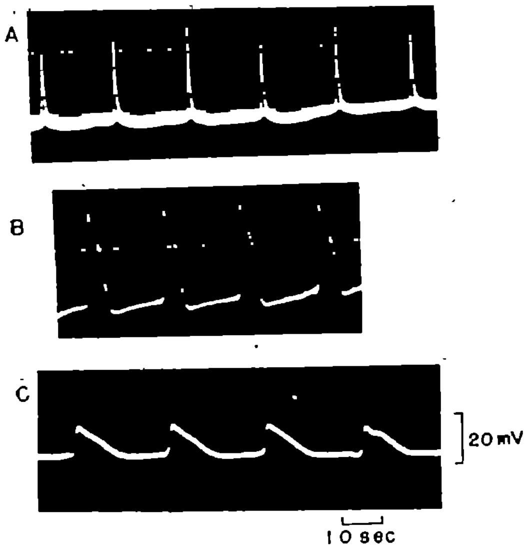

Fig. 1. The effect of TEA (38 mM) substituted for equimolar sodium in Krebs solution

A, action potential in normal Krebs solution; *B* and *C* obtained after 3 min and 30 min exposure in TEA–Krebs solution respectively. In *B* and *C*, the duration of action potential is prolonged. Note: marked depolarization in *C*

decreased. In such a depolarized condition, action potential still showed delayed repolarization. Those effects of TEA became more prominent when the amount substituted for sodium increased, but there was a variation in the degree of lengthening among individual cells of each preparation. The effect of TEA was usually reversed by washing in normal Krebs solution.

Recently, Burnstock and Prosser[9] and Barr[10] reported that barium chloride prolongs the action potential of intestinal smooth muscle. But there is not sufficient evidence to decide whether those two prolongations of action potential caused by TEA and barium chloride are similar in mechanism or not.

Effect of Dilution of the Diet with an Indigestible Filler on Feed Intake in the Mouse

Adolph[1] and Warkentin *et al.*[2] showed that dilution of rat diets with varying proportions of indigestible filler, including cellulose, brought about an adjustment of feed intake by the animal, so that intake of digestible feed energy per day was the same on concentrated and bulky diets.

In experiments with mice at Leeds, different levels of food intake have been achieved by diluting a standard mouse food with varying amounts of cellulose meal. All diets were pelleted and fed to appetite.

Table 1. MEAN LITTER WEIGHT (g) AT WEANING (25 DAYS OLD)

Generation	Normal diet	15% Diluted	30% Diluted
0	80·46 ± 3·64 (34)	82·65 ± 3·64 (26)	60·87 ± 3·29 (46)
1	66·85 ± 4·41 (26)	68·44 ± 3·95 (30)	49·73 ± 3·25 (30)
2	84·68 ± 2·91 (40)	83·96 ± 3·97 (38)	55·14 ± 3·03 (34)

Figures in parentheses denote the number of observations for each mean.

The performance of the stock (Table 1) maintained on a normal undiluted diet and on diets diluted with 15 and 30 per cent of cellulose for 3 generations showed that, at low levels of dilution (15 per cent), performance measured by litter weight at weaning had not been impaired.

None of the differences between the means was statistically significant at $P = 0·05$. It appeared that 15 per cent dilution of the diet with cellulose was equally as effective as the normal diet.

Digestibility studies carried out showed that digestibility did not differ in the main dietary constituents between the diets, and there were limited results to show that mice on the diluted diets consumed more feed.

Recently this aspect has been pursued further in feed intake trials over a wider range of dietary dilutions using cellulose meal (Table 2).

Table 2. ANALYSIS OF DIETS USED IN FOOD INTAKE TRIALS

Diet	Dry matter (%)	Crude protein (%)	Crude fibre (%)
Normal (undiluted)	91·1	16·2	5·3
15% Diluted	91·4	14·2	14·1
30% Diluted	92·6	11·5	24·2
50% Diluted	93·5	7·7	33·4

In these trials, mean feed and water consumption per head per day were measured using 3 mice per cage. Feed wastage was recorded by sieving of waste feed and fæces. No bedding was provided in the cages. Results from male and female mice were recorded separately, but as the differences in feed consumption between sexes were small and not consistent, the values quoted refer to means of both sexes.

Trial 1. Mice were fed, some on a normal diet and others on the same diet diluted with 30 per cent cellulose meal by weight, for three continuous periods each of 7 days, commencing at 8–9 weeks of age (3 mice per cage). Feed and water consumption was expressed per gram of body-weight per day. The mice on each diet were from stocks that had been maintained on each diet throughout a long-term experiment for 20 generations. The results are expressed as the percentage extra food and water consumed by the mice on the diluted diet compared with the normal undiluted diet (Table 3).

Table 3. PERCENTAGE EXTRA FOOD AND WATER CONSUMED BY MICE ON A 30% DILUTED DIET COMPARED WITH A NORMAL DIET (PER G BODY-WEIGHT PER DAY)

Period (7 days)	No. mice per diet	$\frac{\text{30\% Diet–Normal}}{\text{Normal}} \times 100$ Food (g)	$\frac{\text{30\% Diet–Normal}}{\text{Normal}} \times 100$ Water (c.c.)
1	18	+27·6	+22·0
2	18	+17·8	+17·9
3	18	+23·1	+13·4
Mean	18	+22·8	+17·8

The animals attempted to compensate against dilution of the diet and ate 22·8 per cent more food than those on the normal diet. This compensation, however, resulted in an intake of only 86·0 per cent of the undiluted ration as eaten by the mice fed on the normal diet.

Trial 2. In this trial, mice of 8–9 weeks of age (3 per cage) were fed on diets diluted with 15, 30 and 50 per cent by weight of cellulose, and their intakes were compared with mice fed on a normal diet (Table 4).

The mice were all from stocks previously maintained on a normal diet for 20 generations and the trial extended over 35 days divided into 5 periods each of 7 days.

The intake of the animals on the 30 per cent diluted diet in Trial 1 was greater than that in Trial 2. This could be due to the different source of the animals for each trial. Adaptation of the stock to the diet for 20 generations prior to Trial 1 could have brought about a change in

Table 4. Percentage Extra Food and Water consumed by Mice on a 15, 30 and 50 per cent Diluted Diet compared with a Normal Diet (per g Body-weight per Day)

		$\frac{\text{15\% Diet–Normal}}{\text{Normal}} \times 100$		$\frac{\text{30\% Diet–Normal}}{\text{Normal}} \times 100$		$\frac{\text{50\% Diet–Normal}}{\text{Normal}} \times 100$	
Period	No.	Food (g)	Water (c.c.)	Food (g)	Water (c.c.)	Food (g)	Water (c.c.)
1	12	+15·1	+27·2	+5·6	+2·9	+14·6	+28·7
2	12	−2·4	+29·8	+16·6	+24·8	+27·3	+39·3
3	12	−4·8	−2·7	+8·5	+16·5	+26·3	+41·0
4	12	+4·6	+2·8	+12·9	+7·3	+32·1	+35·6
5	12	+4·8	+17·5	+16·4	+23·1	+34·4	+49·9
Mean	12	+3·5	+14·9	+12·0	+14·9	+26·9	+39·1

intake response, compared with the animals on the same diet in Trial 2 which had not had a similar adaptation period on the diet. Further work is required on this aspect.

The extent to which the animals on the diluted diets were successful in their attempts to compensate against lowered nutrient content of the feed is presented in Table 5. This shows the percentage intake of undiluted feed as fed on the normal diet, after the mouse had attempted to compensate.

Table 5. Percentage of Undiluted Feed consumed by Mice in Trial 2 after Attempts at Compensation

	Normal diet	15% Diluted	30% Diluted	50% Diluted
Effective nutrient intake	100	88·4	78·4	63·5
Deficiency	—	11·6	21·6	36·5

No definite conclusions could be drawn from water consumption except that it was directly related to food intake.

Dilution of the diet of the mouse with an indigestible filler, for example cellulose, is an effective means of lowering nutrient intake despite attempts by the animal to compensate for the lowered nutrient content of the diet by increased food consumption.

I thank Prof. T. L. Bywater for his interest in this work.

HÆMATOLOGY

Hæmoglobin and Transferrin Types in the American Buffalo

When O. Smithies[1] published his first results obtained by starch-gel electrophoresis of human sera, an additional field was opened for investigations of genetic polymorphism. Consequently, a large number of investigations dealing with genetic variation in the serum proteins of several animal species have since then been reported. Smithies's technique can also be used with advantage for the purpose of examining electrophoretic patterns of hæmoglobins.

In this communication we describe results obtained by starch-gel electrophoresis of blood samples from 113 American buffalo (*Bison bison*). Sixty-five of these came from Wichita Mountains Wildlife Refuge, Cache, Oklahoma. The remaining 48 came from the U.S. Fish and Wildlife Service, National Bison Range, Moise, Montana. Blood samples were collected into tubes containing sodium citrate solution. On arrival at the laboratory, plasma samples were taken off after centrifugation and afterwards frozen. The red blood cells were washed three times in saline and then lysed by adding distilled water. The ratio of red cells to distilled water was 1 to 40.

The samples were subjected to electrophoresis in gels made from Connaught's potato starch. In the electrode vessels the *tris* buffer described by Gahne *et al.*[2] was used (20·2 g Sigma 7–9, 2 g EDTA and 1·5 g boric acid per litre). For preparing the gels a *tris* buffer similar to that described by Poulik[3] was used (Sigma 7–9, 9·196 g, citric acid 1·050 per litre). (The results showing the various types of hæmoglobins in Fig. 1 were, however, obtained by using the technique described by Gahne *et al.*[2].) The samples were inserted on filter paper and run horizontally for approximately 3·5 h at a voltage gradient of 7–8 V/cm.

In Fig. 1 is shown a photograph of the results obtained when running hæmoglobins from two bison. For comparison, the three types of cattle hæmoglobins first reported by Cabannes and Serain[4] in 1955 for Algerian hill cattle are also shown and by them called Hbα, Hbβ, and Hbα + Hbβ. These three samples here shown were from Jerseys. All the other 111 bison showed the same type of hæmoglobin as the two shown in Fig. 1; namely, two components which migrate at slightly different speeds. The slower-moving component corresponds to the hæmoglobin type of cattle now usually called *AA*. The faster-moving component moves with approximately two-thirds of the speed of hæmoglobin *BB* of cattle.

Fig. 2 is a photograph of results obtained on starch-gel electrophoresis of six bison plasma samples and three cattle serum samples. As may be seen, all six bison samples produced the same pattern. The remaining 107 samples gave this same pattern. One of the three cattle samples was from a *DE* animal; the other two were from an *AA* animal (nomenclature of Smithies and Hickman[5] and Ashton[6]). It can be seen that the cattle albumin and β-globulin bands are somewhat thicker than the bison bands. The reason for this is that the samples from cattle were serum samples and as such were not diluted, in contrast with the plasma samples which were diluted with the sodium citrate solution.

As indicated in Fig. 2 there was no difference between the β-globulin pattern of bison and the *AA* transferrin pattern of cattle. Therefore, it is concluded that these protein bands of bison are transferrins and that they are indistinguishable from the *AA* transferrin bands of cattle.

That these 113 samples of bison blood showed no polymorphism of β-globulin is in contrast with results obtained in studies of domestic animals where genetic variation in serum proteins has been the rule. Another wild species in which no genetic variation in β-globulins has so far been detected is *Alces alces*[7], but only 27 individuals were examined.

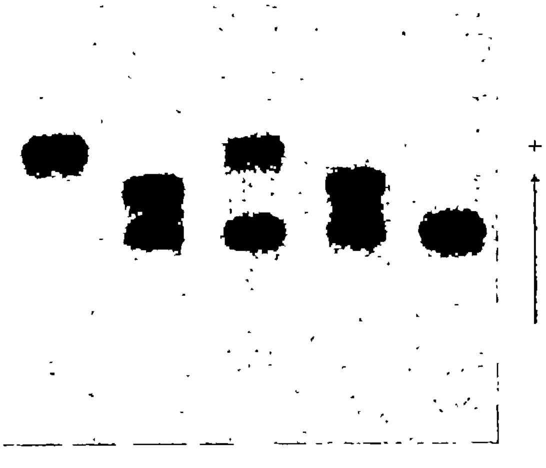

Fig. 1. Comparison between electrophoretic mobilities of bison and cattle hæmoglobins

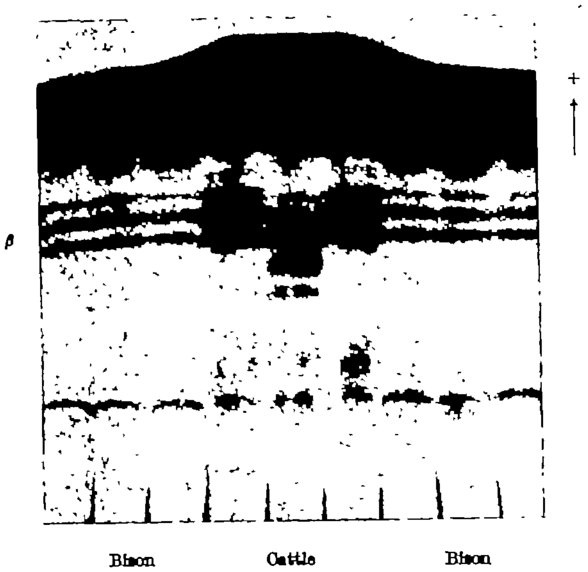

Fig. 2. Comparison between transferrin patterns in bison and in cattle

There are several explanations why we failed to detect polymorphism in bison transferrins and hæmoglobins. One is that the sample was too small and was not representative of all American buffalo. Another is that genetic variation in these traits was lost during the drastic reduction of the bison populations in the nineteenth century. For example, Owen *et al.*[8] proposed such an explanation in their discussion of the reasons for the small amount of variation in bison blood groups as detected in tests with cattle blood-typing reagents. But the possibility that bison evolved with little or no genetic variation in such traits cannot be excluded. Perhaps under natural selection mutants at the loci controlling blood groups, transferrins and hæmoglobins are not permitted to accumulate as rapidly as they do under artificial selection.

We thank Mr. Julian A. Howard, refuge manager of the Wichita Mountains Wildlife Refuge, Cache, Oklahoma, and Mr. C. J. Henry, refuge manager of the National Bison Range, Moise, Montana, for their co-operation in securing the blood samples.

Qualitative Differences in the Mechanism of Complement Fixation

THE sensitization of human red cells by complement-fixing antibodies can be demonstrated with specific anti-human complement serum. By immunizing rabbits with egg albumen/anti-egg albumen precipitate with bound human C', an anti-complement serum was obtained, which contains at least two antibodies against human complement components, that is, C'_{3a} and C'_4 (ref. 1).

When tested in immuno-electrophoresis this antiserum forms two precipitation lines with human serum, called β_1-C(C'_{3a}) and β_1-E (C'_4) (ref. 2).

Anti-complement serum reacts, for example, with sensitized Lewis cells, red cells sensitized with naturally occurring incomplete cold antibodies, and red cells obtained from patients with cold type hæmolytic anæmia. We performed cross-absorptions of the anti-complement serum with these different types of sensitized cells.

Table 1

	Anti-C'	Anti-C' × HA–c.a.*	Anti-C' × E–c.a.†	Anti-C' × E–L.a.‡
HA–c.a.*	+	–	–	–
E–c.a.†	+	+	–	–
E–L.a.‡	+	+	+	–

* *In vivo* sensitized red cells obtained from patients with cold-type hæmolytic anæmia.

† Erythrocytes sensitized with naturally occurring incomplete cold antibodies.

‡ Sensitized Lewis red cells, which behave as sensitized sheep cells (EA) with bound $C'_{1,4,2,3a}$.

The results of the cross-absorption procedures are given in Table 1.

Fig. 1 shows the immuno-electrophoretic pattern obtained by the reaction between human serum and the non-absorbed and absorbed anti-complement serum. Sensitized Lewis cells remove both anti-C'_{3a} and anti-C'_4 antibodies; after absorption with red cells sensitized with naturally occurring incomplete cold antibodies anti-C'_4 is exhausted only, whereas the sensitized HA-c.a. cells absorb neither anti-C'_4 nor anti-C'_{3a}. The results of the immuno-electrophoretic investigation perfectly correlate with those obtained in the serological cross-absorption experiments. One outstanding feature is that C'_{3a} appears not to be bound to those systems which usually do not show hæmolysis.

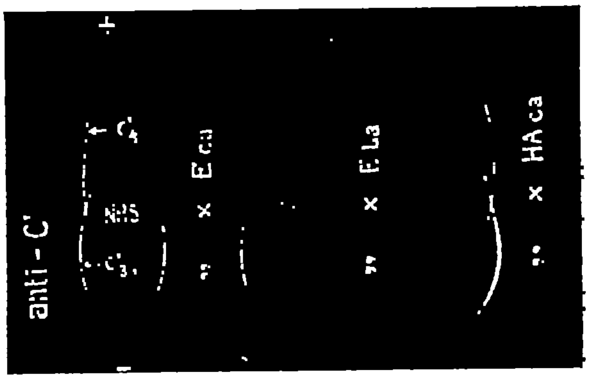

Fig. 1. Immuno-electrophoretic pattern obtained with non-absorbed and absorbed anti-C' serum

We have excluded the possibility that the agglutination of the HA-c.a. cells by the anti-C' serum was due to anti-β_2-M (19S γ-globulin) antibodies. However, several rabbit sera, even those of some non-immunized animals, possess the ability to agglutinate these HA-c.a. cells, sometimes in titres up to 32. This type of reaction, which is not caused by heterophile red cell antibodies, is under investigation.

Further experiments are needed to establish whether the reaction of anti-C' serum with HA-c.a. cells described here occurs on account of possibly present anti-C'_1, or is due to the as yet unexplained agglutinating-ability of certain rabbit sera.

Hæmagglutination Induced by Nucleic Acids

Precipitation of some protein particles, induced by nucleic acids due to the interaction phenomenon between these two components in certain conditions, has attracted the attention of numerous workers, especially of cellular biochemists. However, very little is known concerning the interaction between nucleic acids and biological corpuscles, such as blood cells and bacteria, except for the serological reports[1] of hæmagglutination of tanned erythrocytes coated with DNA by reacting with some antibody in sera of systemic lupus erythematodes. Experiments were therefore carried out to elucidate the general effects of nucleic acids—yeast RNA and sperm DNA, regardless of their species specificity—on erythrocytes.

The buffered salines (0·147 M sodium chloride containing 0·02 M citric acid–sodium citrate buffer solution in the range of 6·0–4·0) are used as the diluents of this experiment. The *p*H of each nucleic acid solution (0·1 per cent) is adjusted with 0·2 N sodium hydroxide and diluted with stock solution of buffered sodium chloride, so as to bring its final ionic concentrations the same as the diluents. To nucleic acid solutions with two-fold serial dilution, the same volume of 2·5 per cent human erythrocytes solution, washed and resuspended in diluent, is added in the test-tube and incubated for 15 min at 25° C. The results, that is, the degree of hæmagglutination reactions, are read macro- and micro-scopically, which are shown in Table 1. Erythrocytes, which are pretreated with trypsin, exhibit the conspicuous rise of nucleic acid-induced agglutination avidity, but not any change of agglutination titres of nucleic acids. The remarkable changes of agglutination titres of nucleic acid by applying different individual human erythrocytes are not found. Agglutination activity of nucleic acid solution can be absorbed with the erythrocytes. For example, 1 ml. of diluted RNA (dilution 1 : 8, that is, 25 γ/ml.) is completely absorbed with the same volume of 2·5 per cent erythrocytes solution (5×10^8/ml.), showing that RNA molecules over $1·8 \times 10^6$ can be fixed on the surface of one erythrocyte, assuming that the molecular weight of yeast RNA is 17×10^3 and Avogadro's number 6×10^{23}.

Table 1. Hæmagglutination Induced by Nucleic Acids

*p*H*		Over 5	4·8	4·6	4·4	4·2	4·0
Agglutination titre of nucleic acid solution	RNA†	> 1 : 1	1 : 4	1 : 512	1 : 512	1 : 512	1 : 512
	DNA†	> 1 : 1	1 : 4	1 : 128	1 : 128	1 : 128	1 : 128

* Microscopic examination reveals that this aggregation of erythrocytes is true agglutination, and not the rouleaux formation, which may be encountered in acid medium. There is no remarkable acid-induced hæmagglutination in *p*H 5 to 4 in these experimental conditions. Considerable degree of hæmolysis occurs at *p*H below 4.

† The original nucleic acid concentration (1 : 1) is 20 mg per cent. RNA and DNA are preparations from Nutritional Biochemical Corporation, U.S.A.

Addition of sera (*p*H 4·5) of human, rabbit, sheep and guinea pig inhibits this nucleic acid-induced hæmagglutination. As for the proteins, so far tested, human albumin shows this inhibitory action, while α-globulin, which is precipitated at *p*H 4·5, has no effect on this hæmagglutination. Erythrocytes of sheep, guinea pig and rabbit are agglutinated by nucleic acids also. (Both proteins were fractionated by Cohn's fractionation technique of human plasma proteins.)

From these results it is not so difficult to suppose that there are some receptors on the surface of erythrocytes, more generally on the protoplasmic membrane of erythrocytes, which can combine with nucleic acids to agglutinate them. The phenomenon that some proteins, such as ovo-[2,3] and human-albumin[4], can interact with nucleic acids in *p*H below isoelectric point of the former ones is attractive in the analysis of this reaction mode. It is reasonable to expect that certain proteins, which possess the isoelectric point at about *p*H 4·6, are determining receptors in this agglutination. In the same way, inhibition of this agglutination due to the presence of human blood albumin can be elucidated by the affinity of albumin for nucleic acids, so that it may deprive nucleic acid–erythrocytes complex of nucleic acid as a competitor. It is also possible that hæmagglutination induced by some viruses may be attributed to their main components, that is, their nucleic acids or nucleoproteins. Further studies on the nature of receptors of erythrocytes are now in progress.

PATHOLOGY

Pathology of the Effect of the Laser Beam on the Skin

The effect of the laser on the eye has been known since the work of Zaret[1,2]. The effect on the skin is not well known[3,4]. Previously, some physicists have reported subjectively no effects at all or only a slight pricking sensation of the skin[3].

The laser used for these preliminary experiments was a solid type with ruby crystal. The crystal has a diameter of ¼ in. and a length of 2 in. with a crystal optic axis of 90°. The emission is 6943 Å with a minimum energy input of 100 joules (2·0 kV). Reflectivity is 99+ to 90 per cent. Output at 400 joules input equals 0·84 joule. (Maser Optics, Inc., Boston, Massachusetts.) The laser head was mounted on an optical bench with an external lens system. Lenses used chiefly were a single convex lens with a focal length of 10·2 cm, a double convex with a focal length of 6·0 cm and a double convex with a focal length of 1·2 cm. A centring disk and also a special mount were used on the optical bench to hold the area to be exposed. A red light was attached to the head to aid in centring the beam. Protective glasses were used by operating personnel.

The skin specimens examined included white skin of rabbits and man, coloured skin of animals and man, pigmented baso-squamous papillomas (so-called seborrhœic keratoses), superficial hæmatomas in the skin of man, white skin of man covered with lamp black, indian ink, tars, and

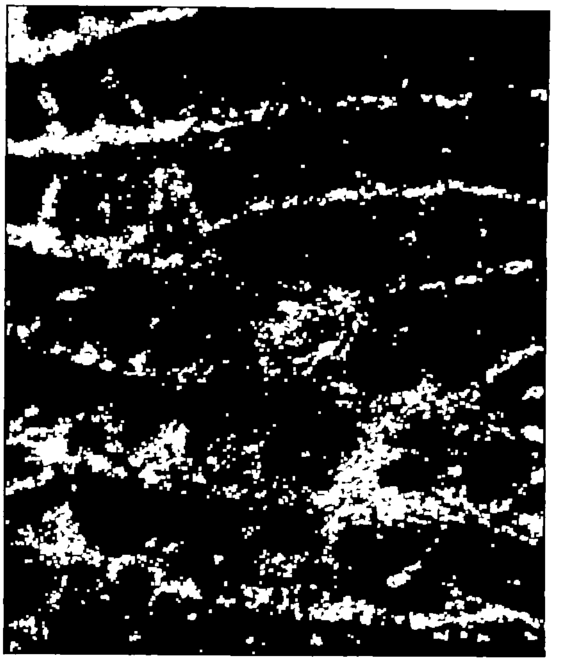

Fig. 1. Surface of skin of palm coloured by dihydroxyacetone and exposed to laser. Superficial crusted area is the area of impact (black-and-white picture from 'Kodachrome', × 50)

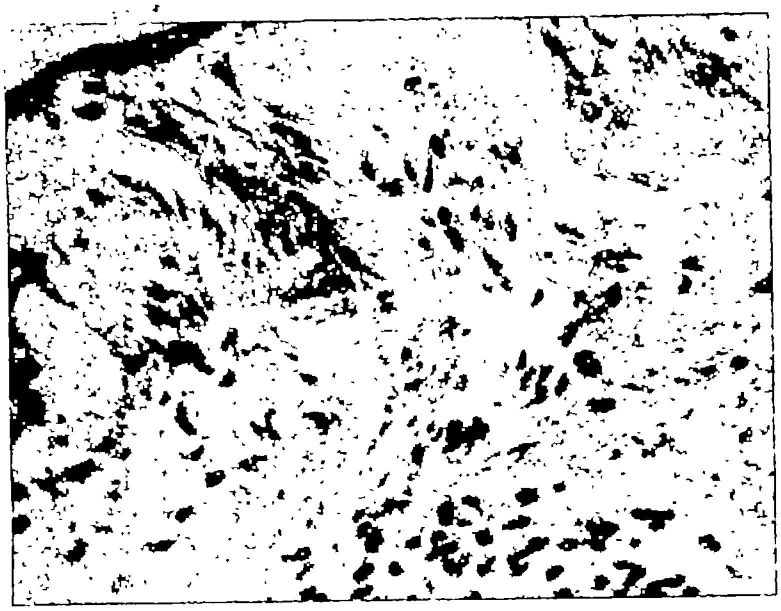

Fig. 2. Coloured skin after exposure to laser showing marked epidermal change (hæmatoxylin–eosin, × c. 300)

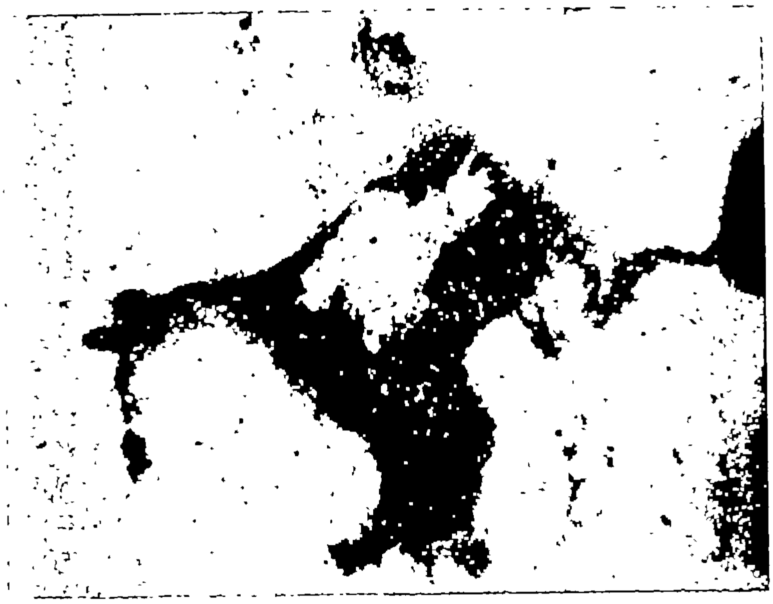

Fig. 3. Cytological preparation from pigmented basal cell carcinoma. Tissue fragments of red cells and tumour masses on slide exposed to laser, then stained with May–Grünwald Giemsa. White area represents area of impact (× c. 39)

coloured by dihydroxyacetone. Curretted material from a pigmented basal carcinoma and from calcinosis cutis were also used. Studies of tattoo marks are not included in this series.

In addition to the skin the following biological materials were also exposed to the laser beam: black widow spider, cockroaches, caterpillars, fresh human cytological preparations from buccal and vaginal mucosa, pigmented and non-pigmented basal cell carcinomas, melanomas, basosquamous acanthomas, molluscum contagiosum, wart, tissue cultures of HeLa cells, cultures of human chromosomes, cultures of bacteria and fungi. In this communication only skin pathology will be described.

The exposed area of skin was examined grossly and examined also with stereobinocular skin microscope at ×20 and × 40 and photographed in colour at × 1 and × 40. In a number of experiments the impact area was photographed in colour at the instant of impact of the beam.

Skin sections were fixed in formaldehyde, stained by hæmatoxylin–eosin and with sulphydryl stains. The interval time between exposure of the skin and the time of excision biopsy was recorded.

With the light-weight laser, the lesions in man were superficial even in heavily pigmented skin. As a rule, the deeper the pigmentation, the deeper the involvement of the epidermis. This is due to the absorption of energy of the laser beams in black substances. On white skin no pathology could be observed. Even application of lamp black or indian ink to the surface of white skin produced no evident lesions of keratin after exposure to the laser. The impact area of the laser was represented by a whitened zone, 1·0–1·5 mm in diameter, in the covering material. This, we believe, was caused by vaporization of the black covering. An effort was made to get black particles deeper into the epidermis by means of partial stripping of the skin with 'Scotch' tape. Then lamp black was rubbed in well and the surface cleaned off. Again, white area of impact of the laser beam was limited only to the dark particles. Later, with the formation of a blackish-brown crust, exposure to the laser beam produced a whitish area limited only to the crust and the laser beam was without any apparent effect on the smooth red skin under the dried crust.

In the coloured skin, the laser produced superficial lesions with fragmentation and splitting of the stratum corneum. Sulphydryl stains showed no changes of keratin adjacent to the impact area. In more severe lesions of coloured skin, cells of the upper spinous layer were eosinophilic and pycnotic; basal cells showed hydropic degeneration with cellular contraction, eosinophilia and pycnosis. In some areas the changes in basal cell varied in severity. Œdema was found in epithelial cells adjacent to the impact area. The dermis showed œdema and perivascular infiltrate. In some areas the perivascular infiltrate included eosinophils which had migrated also into the epidermis. This was observed in a biopsy taken 4 h after exposure. Finely granular, golden-brown pigmented areas were found in the dermis concentrated most heavily within the zones of perivascular infiltrate. The capillaries were dilated with the endothelial cells œdematous. In the lower dermis no changes were found in the eccrine glands. The intensity of the inflammatory infiltrate varied with the time-interval after biopsy.

On skin and hair of albino rabbits no lesions were evident. In the black pigmented skin of rabbit ear through and through tissue destruction was produced. Sections of the ear taken 1 h after exposure to the laser beam showed deep fissured area through epidermis, dermis and into cartilage. The dermis showed compression and increased density of collagen with a moderately thick border of neutrophilic infiltration about the areas. The adjacent dermis showed an œdema and a diffuse infiltration of lymphocytes and histiocytes. This biopsy was taken 1 h after exposure. The epidermis adjacent to the impact area showed œdema and loss of melanin pigment.

An urticating caterpillar, identified as a *Nygmia phaeorrhea*, had a black head, mostly black body with brown mid-zone and brownish-black setæ. Exposure to laser beam produced a deep reddish discoloured zone of the head area. After fixation in Davidson's formaldehyde fixative, hæmatoxylin–eosin stained sections were examined. These showed sharply demarcated areas of brown-coloured coagulation necrosis. Blackish-brown setæ exposed to the laser beam developed a golden-yellow colour.

An examination of lesions produced by higher powered lasers with the skin of man, with animals and with arthropods is still in progress.

Preliminary investigations, then, with a light-weight type solid laser with a ruby crystal showed that superficial destructive lesions may be produced in the skin of man. The more intense the colouring of the skin the deeper the reaction. Deep necrotic lesions were produced in pigmented areas of the rabbit ear.

RADIOBIOLOGY

Chemical Protection for the Incorporation of Phosphorus-32 into Nucleic Acids of Lymphatic Cells against γ-Irradiation

Honjo *et al.*[1] found that the lowered viability of Ehrlich ascites tumour cells due to continuous β-irradiation with yttrium-91 could be effectively protected by repeated additions of reduced glutathione during irradiation. This may be ascribed at least partly if not wholly to the protection for the synthesis of nucleic acids. Thus, we are interested in whether or not the incorporation of precursors into nucleic acids can be chemically protected against ionizing radiation. Henke *et al.*[2] observed the protective effect of cystein given intraperitoneally for the incorporation of phosphorus-32 into intestinal deoxyribonucleic acid of X-irradiated rats. In *in vivo* experiments, however, uncontrollable factors can scarcely be excluded; for example, migration of certain cells into, or out of, the organ concerned may occur after irradiation. Therefore, we carried out the *in vitro* experiment with the lymphatic cells, which are known to be more radiosensitive than Ehrlich ascites tumour cells in terms of nucleic acid synthesis[3,4].

Lymphatic cells, which had been obtained from appendices and Peyer's patches of rabbits and suspended in calcium-free Tyrode solution (*p*H 7·3), were irradiated with cobalt-60 γ-rays at room temperature either immediately before or 5–10 min after the addition of protectors in various concentrations and thereafter were shaken with phosphorus-32 at 37° C for 4 h. Deoxyribonucleic acid, ribonucleic acid and organic acid-soluble phosphate were isolated[3], and the specific activity of each fraction was determined as counts/min/μg phosphorus. Each value of specific activity is the mean from the duplicate samples. Chemical protectors used were cysteamine and *S*,2-aminoethylisothiuronium·Br·HBr (AET) (Nippon Shinyaku Co., Kyoto).

The inhibitions of incorporation referred to various γ-doses are shown in Fig. 1. If two curves representing the inhibitions for deoxyribonucleic acid and ribonucleic acid are extrapolated, both of them intersect the ordinate at 0 per cent of inhibition, corresponding to 10 r. on the abscissa. This may mean that the threshold for the response of the lymphatic cells to γ-radiation, measured by the incorporation of phosphorus-32 into nucleic acids, is about 10 r.

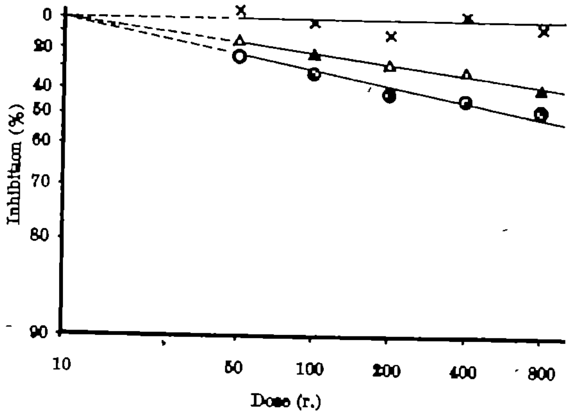

Fig. 1. Dose-effect relation in log–log plots. ○, Deoxyribonucleic acid (37·6); △, ribonucleic acid (146·0); ×, organic acid-soluble phosphate (1,258). Figures in parentheses indicate the specific activities of the unirradiated control. 3 × 10⁶ cells per tube were used. Cf. ref. 4 for the conditions of γ-irradiation and incubation in detail

The incorporations into nucleic acids were not significantly impaired by cysteamine alone, up to the concentration of 0·2 mg/ml., but they were severely affected with 2 mg/ml. (inhibition for deoxyribonucleic acid : 86·4 per cent). AET proved to be much more noxious to these cells. The incorporation into deoxyribonucleic acid was inhibited by about 50 per cent at 0·2 mg/ml., being equivalent to 0·055 mg/ml. of cysteamine on molar basis. Since AET is converted to 2-mercaptoethylguanidine·HBr at neutral *p*H (ref. 5), the inhibition may be owing to the latter agent. Of interest is the fact that the incorporation into organic acid-soluble phosphate was either thoroughly unaffected or somewhat enhanced by cysteamine, at least up to 2 mg/ml., while the incorporation was inhibited by more than 90 per cent by AET in this concentration.

The impairments for the incorporation were not remarkably effaced even if the chemical agents were removed by washing the cells before the incubation.

Some protective effect could be observed when the lymphatic cells were irradiated after addition of cysteamine (Table 1). The effect became much more distinct in higher concentrations, though the incorporation activity was affected remarkably by cysteamine alone as stated before. As shown in Table 1, cysteamine seems to be

Table 1. Effects of Cysteamine and AET on the γ-induced Inhibition of the Incorporation of Phosphorus-32 into Lymphatic Cells

Protector	Concentration of protector (mg/ml.)	Specific activity in percentage of the control which added with protectors but not irradiated			
		Deoxyribonucleic acid		Ribonucleic acid	
		Protectors added before irradiation	Protectors added after irradiation	Protectors added before irradiation	Protectors added after irradiation
Cysteamine	0·02	67		63	
	0·20	63		67	
	0·45	66	45	84	56
	1·00	83	42	112	49
	2·00	100		97	
AET	0·10	53	52	49	55
	0·20	58		54	

Concentrations of protectors indicated are those at the time of irradiation, they are reduced by half at the time of incubation, because of addition of phosphorus-32 solutions. γ-Ray dose applied is 400 r. throughout the experiment. Specific activities of the irradiated samples (without protectors) in percentage of the unirradiated control are 47–51 for deoxyribonucleic acid and 52–57 for ribonucleic acid.

effective, when present at the time of irradiation. On the contrary, AET failed in exertion of protective action in the concentration so far as examined, irrespective of whether it was added before or after the irradiation.

The discrepancy between our result and others reporting the effectiveness of AET *in vivo* has remained unsolved. It may be probable that cysteamine and AET do not necessarily play the same part in protection *in vivo*. In this connexion, the marked difference between cysteamine and AET in their noxious effect on the incorporation into organic acid-soluble phosphate is worthy of note.

Changes in the Excretion of Sodium by Saliva after Whole-body Irradiation in Rats

We have investigated the excretion of sodium in the saliva of irradiated rats by means of the radioisotope of sodium-22. The following method was used. White male rats of the laboratory strain weighing 150–200 g were divided into three groups: the first group containing 10 rats formed controls, the second and third groups consisted of 20 rats each. The animals were fed by a standard diet and accepted water *ad libitum*.

All the rats were administered intraperitoneally 25 μc. of sodium-22 in 1 cm^3 of physiological solution per kg of the live-weight. After 24 h, the second and third groups of rats were irradiated with a dose of 1,000 r. by an X-ray Macrophos apparatus at 200 kV., 15 m.amp, focus distance of 120 cm. The time exposure amounted to 105 min; 0·5 mm aluminium and 0·5 mm copper were used as filter. The dose was controlled by means of a Mecapion dosemeter. After the exposure 3 animals survived 2 days, and 6 animals 3 days. Ten animals in the last group were used as controls.

Samples of saliva were taken from the first and third groups 96 h after exposure and from the second group 72 h after exposure. Just before saliva was taken, the whole-body radioactivity was measured by means of a whole-body counter with 6 Geiger–Müller tubes which was designed in our Institute[1]. Saliva was taken for 20 min according to Benarde *et al.*[2] under thiopental anaesthesia after the administration of 'Pilocarpin'. Thiopental was applied at a dose of 45 mg/kg intraperitoneally, 'Pilocarpin' at a dose of 10 mg/kg of the live-weight, subcutaneously. The samples obtained were weighed and using a standard the radioactivity was determined by an end-window tube for measuring β-radioactivity.

As the rats excrete the administered radiosodium in urine and faeces at differing rates, it was necessary to correct the results of radiosodium concentration in saliva accordingly. If the initial activity administered to one rat amounted to A_0(μc.), the activity of the same rat, when saliva was taken, measured by the whole-body computer, was A(μc.), the concentration of radiosodium obtained in saliva c(μc./g), then the corrected value of concentration $c_{\text{corr.}}$ (μc./g) was computed from the following equation:

$$c_{\text{corr.}} = c\,\frac{A_0}{A}$$

The results are plotted in Fig. 1.

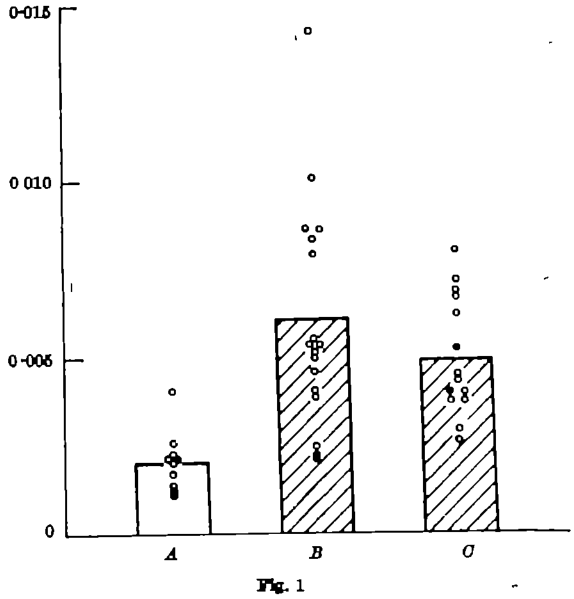

Fig. 1

The corrected concentration of radiosodium in μc./g of saliva is plotted on the abscissa. The height of column A represents the average value of the concentration in controls. The individual points describe the individual values of radiosodium concentrations in saliva. Similarly column B represents the average value and individual values of concentration in rats 72 h after exposure, and column C in rats 96 h after exposure.

There is a significant increase of radiosodium concentration in saliva of rats exposed to a dose of 1,000 r. after 72 and 96 h as compared with controls. The probability of the insignificance of differences of both experimental groups in comparison with controls is less than 0·5 per cent.

It has been shown[3] that the 24-h period between the administration of sodium-22 and the first action in the organism (exposure) is sufficient time to produce equilibrium between the administered radioisotope and the exchangeable sodium in bodies of rats. Therefore the observed relative changes of the radioisotope concentration may be evaluated similarly as changes in the total sodium concentration in saliva. According to the results in the literature, on about the 3rd and 4th day, changes of concentration of sodium in blood[4,5] are not so great as to cause the changes in saliva which we observed. It may lead to the conclusion that the values obtained are caused directly by a disturbed mechanism of saliva excretion.

We might find the explanation in a disturbance of the active sodium transport in the cells of chicks in the columnar epithelium of ducts.

BIOLOGY

Synthesis of Enzymes during the Germination of Fungus Spores

THE hypothesis that the development of an organism is mediated by alterations in its enzyme systems is generally accepted. Illustrative data, however, are scarce, though some changes in rat liver enzymes have been reported[1,2]. In the fungi, the development from the resting spore to an active growing mycelium is a very dramatic phenomenon. Usually, under proper conditions, the spore swells, produces a germ tube which elongates, branches, and forms a mature mycelium. If any marked changes in the enzyme content of the fungus occurs, one would expect such alterations at some period during germination, before the germ tube was fully formed. A change of this kind was thought to occur during the activation of ascospores of *Neurospora crassa* by heat[3], but this effect could not later be confirmed[4]. Indirect evidence that the enzymes of a spore can be different from those of mature mycelium can be deduced from the catabolism by *Tilletia caries* of glucose variously labelled with carbon-14. The spores utilized glucose through the Entner Douderoff pathway, while the mycelium catabolized the sugar through the Embden, Meyerhof, Parnas system and hexose monophosphate shunt[5]. Results presented here show that in one fungus, *Ustilago zeae*, specific qualitative and quantitative changes in enzymes content occur during the germination of a spore.

Smut spores were obtained from diseased field corn and sieved to a homogeneous mixture. They were germinated in 100 ml. of 5 per cent molasses in a 500-ml. Erlenmeyer flask on a reciprocal shaker for various periods. Samples were taken at intervals up to 12 h, when only about 25 per cent of the spores had formed incipient germ tubes about half the diameter of the spores. If germinated for longer periods, about 75 per cent of the spores produced germ tubes. Assays for all enzymes of the Embden, Meyerhof, Parnas system, the hexose monophosphate shunt, and citric acid cycle were made on spores that were washed three times with distilled water, then ground with sand and suspended in buffers. Standard assay procedures were followed[6]. The only enzyme assays on which no certainty could be placed were those for pyruvic dehydrogenase, and α-ketoglutarate dehydrogenase; these enzymes were very difficult to detect even in growing mycelia and therefore the results have not been included. Oxygen consumption was measured on whole spores in the presence of 50 μmoles glucose in Warburg respirometers. Protein synthesis was studied by determining the amount of incorporation of phenylalanine-1-^{14}C into the smut spores. The spores were incubated with the amino-acid in molasses medium, then treated with sulphuric acid to hydrolyse protein. Phenylalanine was separated by paper chromatography, eluted, and the c.p.m. measured.

Results in Table 1 show that in resting spores some enzymes which are needed for glucose metabolism are either absent, or are present in such minute amounts as to be undetected. Missing in the hexose monophosphate shunt are glucose-6-phosphate dehydrogenase, 6-phosphogluconic dehydrogenase, transketolase and transaldolase. Missing citric acid cycle enzymes are aconitase, succinic dehydrogenase, and fumarase. Even after 6 h incubation in the molasses medium, detectable quantities of these enzymes had not been synthesized. However, they were present after 12 h germination, the period when the germ tubes were first beginning to form. All enzymes of the Embden, Meyerhof, Parnas pathway for glucose catabolism were present even in the resting spores. During the germination process, not only were hitherto undetected enzymes synthesized but the specific activities of those enzymes originally present in resting spores were also increased. The examples in Table 1 show increases within 6 h, and further increases at 12 h.

Table 1. COMPARISON OF SPECIFIC ACTIVITIES OF ENZYMES IN TELIOSPORES OF *U. maydis* AT DIFFERENT PHASES OF GERMINATION

Enzyme	Specific activities units/mg protein		
	0 h	6 h	12 h
Triose phosphate dehydrogenase*	0·015	0·03	0·10

α-Glycerol-PO$_4$ dehydrogenase*	0	0	0·009
Glucose-6-PO$_4$ dehydrogenase*	0	0	0·006
6-Phosphogluconic dehydrogenase*	0·014	—	0·027
Transketolase‡	0	0	22·8
Transaldolase‡	0	0	6·6
Aconitase§	0	0	160·0
Fumarase§	0	0	240·0
Succinic dehydrogenase*	0	0	0·005

* One unit equals one μmole substrate transformed per min.

† A unit is that amount of enzyme which gives a change in optical density of 0·01/h at 540 mμ.

‡ A unit is that amount of enzyme which gives a change in optical density of 0·01/h at 405 mμ.

§ A unit is that amount of enzyme which gives an initial rate of increase in optical density of 0·001/min at 240 mμ.

Weak respiratory activity of resting spores, even in the presence of glucose, is shown by their low oxygen consumption: Q_{O_2} is 1. With increasing periods of incubation the spores consumed oxygen at a greater rate until just at germ tube formation the Q_{O_2} is 20 (Fig. 1). If one accepts the incorporation of phenylalanine-1-^{14}C into the spore as indicative of protein synthesis, then there is a concomitant increase in enzyme protein (Fig. 1).

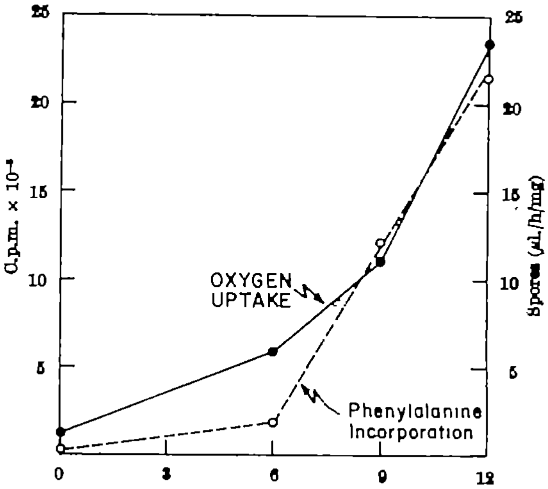

Fig. 1. Incorporation of phenylalanine-1-^{14}C into protein and oxygen consumption during the formation of *Ustilago maydis* teliospores

Comparing the three criteria on a time-scale reveals a strong coincidence among them. Before 6 h, the increase in protein and oxygen consumption is relatively small, and none of the missing enzymes had been synthesized. After that time, when enough of the missing enzymes have been made to allow the ready metabolism of glucose, the oxygen utilization rose sharply and continued at that rate at least until the appearance of the germ tubes at 12 h. Protein synthesis, as measured by phenylalanine incorporation, follows the increase in oxygen consumption very closely. Thus, in *U. zeae* the development of the organism can be linked with the formation of enzymes that are needed in carbohydrate metabolism.

The oxygen consumption by resting spores of *U. zeae* is very low, as might be expected in the absence of enzymes of the hexose monophosphate shunt and citric acid cycle; complete oxidation of carbohydrates or fats would not be possible. The presence of all components of the Embden, Meyerhof, Parnas pathway should have allowed the functioning of the glycolytic system, yet there was no evidence of carbon dioxide production under anaerobic conditions.

From these investigations it is also evident that spore germination cannot be conceived simply as germ tube formation. The morphological manifestation of development appears long after physiological mechanisms begin to operate. The synthesis of needed enzymes and the oxidation of carbon provide the energy and intermediates that are necessary for germ tube formation.

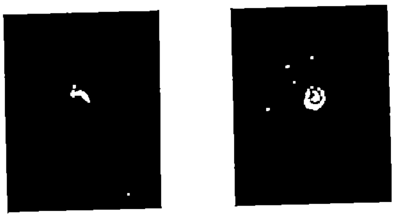
Effect of *Pseudomonas tabaci* on the Metabolism of Starch in Tobacco Leaves

IN the host tissues infected by various plant pathogens, including viruses, bacteria and fungi, as a rule starch accumulates around the infection area[1-3]. By contrast, the toxin-induced chlorotic halo formed in White Burley tobacco leaves infected by *Pseudomonas tabaci* (Wolf and Foster) Stevens fails to show any starch reaction (Fig. 1). The low starch content of the affected area was also shown by quantitative chemical determination[4] (Table 1). The assays were made 7 days after needle inoculation.



A B

Fig. 1. Parts of a tobacco leaf after needle-inoculation with *Pseudomonas tabaci*. *A*, Untreated; *B*, stained with iodine

The decrease in starch content could also be induced by the injection of bacteria-free culture filtrate (Table 1). Czapek–Dox nutrient medium incubated with *Ps. tabaci* for 48 h was used. Treatments were carried out on intact plants by injecting one half of the leaves with the culture filtrate and the other with Czapek–Dox nutrient as control. Measurements were made 3 days after injection.

Table 1. EFFECT OF *Pseudomonas tabaci* ON THE STARCH CONTENT AND PHOSPHORYLASE ACTIVITY OF TOBACCO LEAVES

Treatment of leaves	Starch content* (mg/g fresh weight)	Phosphorylase activity* Synthesized amylose (mg/g fresh weight/1 h)	Phosphorylase activity* PO_4^{3-} liberated (mg/g fresh weight/1 h)
Control†	2·6	4·5	1·8
Needle inoculated	1·5	1·2	0·6
Control‡	5·2	4·4	1·6
Injected with culture filtrate	2·3	2·3	0·9

* Values from representative experiments.
† Unaffected areas of the same leaf.
‡ Half-leaf injected with Czapek–Dox nutrient.

To elucidate the possible mechanism responsible for decrease in starch content the activity of the two major enzyme systems involved in starch metabolism was measured. A negligible and equal amylase activity was found in the extracts from control and culture filtrate treated leaves. The activity of phosphorylase, however, exhibited striking differences. The extent of amylose synthesis from glucose-1-phosphate was measured as follows: 500 mg tissue was extracted in the cold in 2·5 ml. acetate buffer *p*H 6·0. The reaction mixture contained 1 ml. crude extract (without centrifugation), 10^{-2} M sodium fluoride, 0·2 ml. 1 per cent dextrin as primer, and $1·7 \times 10^{-2}$ M glucose-1-phosphate in 2·3 ml. final volume. After incubation at 30° C for 30 min the reaction was stopped by adding equal amounts of 10 per cent trichloroacetic acid (controls were treated with trichloroacetic acid at zero time). The starch (amylose) content was determined colorimetrically in centrifuged samples by adding 0·2 ml. of an iodine solution containing 60 mg iodine/100 ml. A standard curve was prepared from soluble starch. Alternatively the orthophosphate set free during starch synthesis was measured[5].

As shown in Table 1 phosphorylase activity, as compared with the controls, was markedly less both in the halo areas of the infected leaves and in the tissues treated with culture filtrates.

The *Ps. tabaci* strain used in these experiments does not hydrolyse starch. The culture filtrate added to phosphorylase-containing plant extracts *in vitro* did not diminish the activity of phosphorylase. Therefore, it can be stated that the decrease in phosphorylase activity is due to an indirect effect of *Ps. tabaci* on the metabolism of the host. This effect is specific because the activity of some other enzymes, for example, glucose-6-phosphate dehydrogenase, increases in the tissues surrounding the infection area. The parallelism between the decrease in starch content and inhibition of phosphorylase activity suggests a causal relationship.

Optimum Leaf Area Index in the Potato Crop

IN his review of the effect of competition for light on crop growth Donald[1] notes the existence of but two published accounts presenting evidence to support the generally adopted conception of an 'optimum leaf area index' as the ratio of leaf area to ground covered at which the balance of photosynthesis over respiration is at a maximum value. For kale crops in southern England the figure lies between 3 and 5·4 (ref. 2). In Australia, subterranean clover was found to reach its highest net assimilation rate when the leaf area index lay between 4 and 5 (ref. 3). More recently, Stern and Donald[4] have shown that the optimum leaf area index for clover in Australia varies with the amount of light present, particularly the amount which penetrates to the lower leaves, rising from 3·5 at a radiation-level of 50 g cal/cm²/day to a nearly constant 5 above 150 g/cal/cm²/day. Donald[1] calls for more evidence for other crops and different regions.

In an experiment on the effect of applying four levels of a 12 per cent N : 12 per cent P_2O_5 : 18 per cent K_2O fertilizer to a crop of Majestic potatoes at Boghall, Midlothian, in 1961, measurements were made of leaf area and the dry matter of leaves, stems, roots and tubers at four dates each approximately three weeks apart. The plants which received 2·5 and 5 cwt. per acre rates of fertilizer (Fig. 1) show a steady rise in leaf area index to 4·4 and 5·3 respectively at the third sampling date, declining thereafter to 3·9 and 4·9. The plants given the 7·5 and 10 cwt. per acre treatments rose swiftly through the level of leaf area index 5 to reach maxima of 7·0 and 8·3, afterwards declining to 5·5.

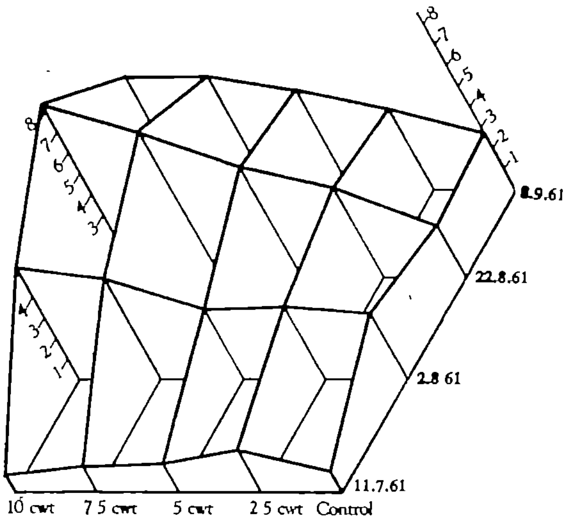

Fig. 1. Leaf area index at four dates of Majestic potatoes treated with four levels of fertilizer. Treatments: 10 cwt., 7·5 cwt., 5 cwt., 2·5 cwt. Control. Sampling dates: 11.7.61; 2.8.61; 22.8.61; 8.9.61

Table 1. Net Assimilation Rates in g/m²/week of Majestic Potatoes treated with Different Levels of Fertilizer

Sampling	Control	2·5 cwt.	5 cwt.	7·5 cwt.	10 cwt.
I–II	37·68	32·30	39·64	53 94	49·13
II–III	9 65	35·60	50·80	40 68	38·30
III–IV	17·98	11 79	10·46	0 72	−6·57

Table 2. Rate of Assimilation in g/m²/week of Material devoted to Tuber Production (Economic Assimilation Rate) in Potatoes treated with Varying Levels of Fertilizer

Sampling	Control	2·5 cwt.	5 cwt.	7·5 cwt.	10 cwt.
I–II	27·64	23·23	23·71	25·56	19·47
II–III	6 74	33·01	41·08	33·19	24·79
III–IV	18 67	12·91	11 98	4 78	2·31

The maximum net assimilation rate (Table 1) achieved by the high fertility-level plants occurs between samplings I and II when the leaf area index is below 5. On the low fertility-level plots maximum net assimilation rate occurs between samplings II and III at leaf area index values between 3·5 and 5·3. Between sampling dates III and IV the net assimilation rate of plants receiving the highest level, 10 cwt., decreased below zero because the loss of lower leaves, which had turned yellow, withered and dropped off, was greater than the increase in tubers. This process of leaf shedding was observed on all plots and is confirmed by the drop in leaf area index values (Fig. 1). The values found at this stage in crop development do not therefore give a true net assimilation rate and no way can be found to collect the lost leaf material in the field in order to make a correction. To overcome this difficulty it was decided to consider only that part of assimilation devoted to tuber formation by substituting dry weight of tuber per square metre of leaf area for total dry weight of plant material per square metre in the calculation. It is proposed to call this quantity the economic assimilation rate. In general, economic assimilation rate (Table 2) is, in the later stages of crop development, highest in the low fertility level plots and lowest in the high fertility level plots. Curves for economic assimilation rates against mean leaf area index between the sampling dates (Fig. 2) show that optimum leaf area index for tuber production lies around 2·6 in the early stages of development and around 4·3 later in the season. The drop in tuber yield on plots to which high levels of fertilizer have been applied[4] may be explained by the production of excess foliage which so shades the lower leaves that they cannot produce sufficient carbohydrate to meet their own requirements for respiration.

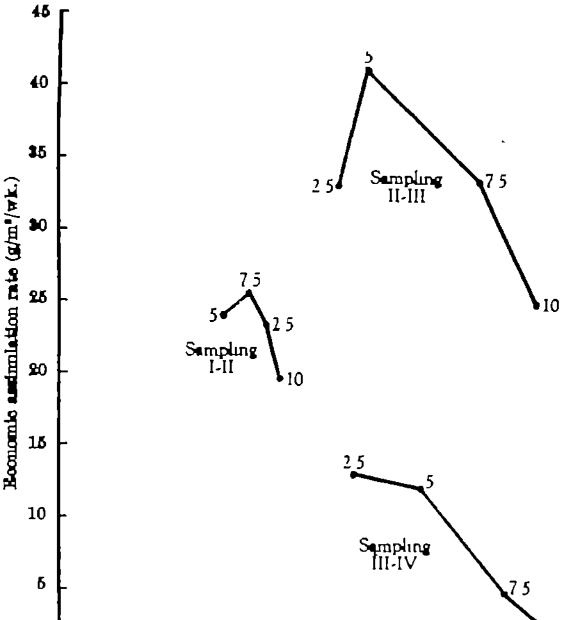

Fig. 2. Curve of economic assimilation rate on mean leaf area index between sampling dates

Prevalence and Importance of Viable Spores of *Septoria* spp. in Samples of Commercial Celery Seed

In a recent communication Mukhath and Wood[1] suggest that celery seedlings more frequently become infected by mycelium carried within the seed than by spores from pycnidia on the seed.

Viable spores have been found in an appreciable proportion of infected samples during recent surveys of celery seed received for testing for purity and germination at the Official Seed Testing Station.

Marshall (ref. 2 and unpublished work) successfully germinated spores from 6 of 30 samples examined during 1957–58 and from 7 of 53 samples examined during 1958–59. During 1960–61 pycnidia on three samples were observed to exude spores during the standard visual blotter test for their presence, and for two of these samples the presence of viable spores was demonstrated by several techniques, including a seedling inoculation test[3]. In 1961–62 the seedling inoculation test, being developed as a means of checking declarations of efficient hot-water treatment[4], confirmed the presence of viable spores in 9 of 19 samples tested from a total of 34 showing visual infection.

During storage there is a fairly rapid decline in the number of pycnidia which contain viable spores (even so several samples have given infective washings in the August following the presumed year of harvest). Some of the samples tested were of over-yeared seed, and therefore the results are an underestimate of the viable infection present in the seed of any one harvest year.

Diseased seedlings have been grown from infected seed placed on blotters[3], but were not produced from all the viable seeds with oozing pycnidia. Diseased seedlings are rarely obtained from infected seeds grown under glasshouse conditions; perhaps disease initiation by spores depends on the existence of very humid conditions, or even free water.

The low viable infections normally encountered make it difficult to test the efficiency of seed treatments and to obtain confirmation or otherwise of hypotheses concerning infection. But it is evident that viable spores are common enough to be an important potential source of disease outbreaks.

Heterothallism in *Ustilago cynodontis* (Pass.) Henn.

INFLORESCENCE smut, *Ustilago cynodontis* (Pass.) Henn., is a common parasite of perennial Bermuda grass, *Cynodon dactylon* (L.) Pers. The disease is manifested by the production of black, sooty, smut sori in the spikes of the host inflorescence (Fig. 1). One of the most interesting aspects of the life history of this smut, and one that has received no attention from biologists in the past, is that of heterothallism and sex. Mehta[1] demonstrated seedling infection of Bermuda grass originating from seed-borne teliospores of *U. cynodontis* and reported that the smut perennates in the host from year to year. However, he did not report any observations pertaining to sexuality in the fungus. A comprehensive survey of heterothallism in the Ustilaginales by Whitehouse[2] likewise made no mention of *U. cynodontis*, although more than 30 heterothallic smut species were discussed.

Teliospores of *U. cynodontis* were observed to germinate on 3 per cent potato–dextrose agar, producing four-celled promycelia (basidia) and lateral sporidia (basidiospores). Monosporidial cultures were obtained with the aid of a Chambers micro-manipulator by isolating individual sporidia from very young colonies arising from single germinated teliospores. Each monosporidial line thus originated from a separate teliospore. Eighteen monosporidial lines were isolated in this manner and afterwards were mated on potato-dextrose agar in all possible combinations with each other. The matings were examined after 24 h incubation at 25° C. Two types of compatibility reactions were noted: positive or + reactions denoting sporidial fusions and negative or − reactions indicating incompatibility.

Compatibility relations between pairs of monosporidial lines of *U. cynodontis* were determined by use of the Bauch test. Bauch[3] found that, in *Ustilago violaceae* (Pers.) Roussel, mating types could be determined from the general appearance of the paired cultures. When the mating types were different, considerable white aerial mycelium (Süchfaden) developed, whereas only sporidial or non-aerial hyphae (Wirrfaden) were evident when the cultures were of the same mating type. In studying *U. cynodontis*, the authors found the Bauch test to be a rapid and reliable method of determining compatibility among monosporidial lines of this fungus. As shown in Fig. 2, compatible matings (*A*, *B*, *D*, *E*) produced a white mycelial mat of aerial hyphae, whereas non-compatible matings (*C* and *F*) remained as sporidial mixtures. Lack of anastomosis among non-compatible sporidial matings was confirmed by microscopic examination. The compatible matings were demonstrated to be pathogenic by inoculating seed of Bermuda grass and afterwards observing the emergence of smutted inflorescences.

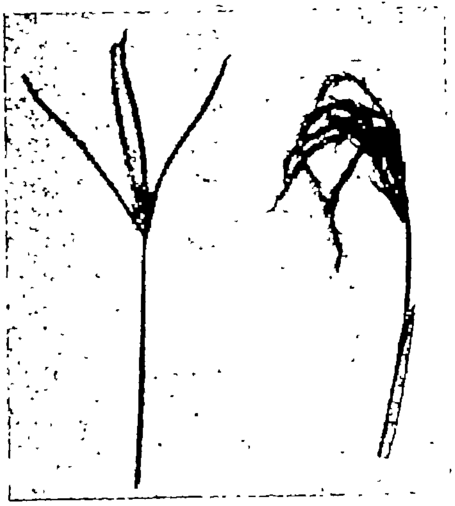

Fig. 1. A healthy inflorescence of Bermuda grass (left), and an inflorescence showing smut sori (*Ustilago cynodontis*) in the spikes (right)

The results of a diallel cross of 18 monosporidial lines (162 matings) of *U. cynodontis* are shown in Table 1. Based on the premise that sporidia of the same compatibility type do not anastomose, the results clearly indicate two intra-sterile, cross-fertile compatibility groups. Thus monosporidial lines 2, 4, 6, 7, 9, 10, 12 and 16 are placed in group I, whereas lines 1, 3, 5, 8, 11, 13, 14, 15, 17 and 18 are placed in group II. The presence of these two compatibility or mating groups is evidence of the existence of heterothallism in *U. cynodontis*. When only two mating types are observed among pedigreed sporidia of smut fungi, the heterothallism is described as bipolar.

The evidence presented here is based on four identical experiments each confirming simple bipolar sexuality in *U. cynodontis*. However, when monosporidial lines from widely separated geographic areas were mated, the

	18	+	+	+	+	+	+	+	+	−	−	−	−	−	−	−	−	−	−

Positive compatible matings as evidenced by sporidial fusions and the production of aerial hyphae are indicated as + reactions; incompatible matings as − reactions.

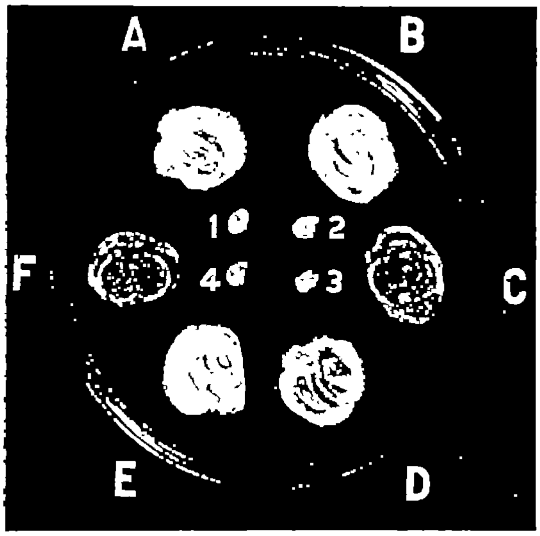

Fig. 2. Compatibility relationships among monosporidial lines of *Ustilago cynodontis* as indicated by the Bauch test reactions. The plate shows four monosporidial lines (small centre colonies) mated in all possible combinations (six larger outer colonies). Colonies *A* (1 × 2), *B* (1 × 4), *D* (3 × 2), and *E* (3 × 4) are covered by white mycelial growth denoting compatibility, whereas colonies *C* (2 × 4) and *F* (1 × 3) have remained as sporidial mixtures indicating incompatibility

evidence suggested more than two compatibility groups in this fungus. According to Whitehouse[2,4], the expression of multiple compatibility groups in smuts is predicated on the existence of 'sterility factors'. Therefore, what may appear to be multipolar sexuality in *U. cynodontis* could be relegated to simple bipolar sexuality on the basis of the effect of these factors.

Inhibition of Flowering in Poinsettia by Gibberellic Acid

The formation of flowers and decorative bracts in poinsettia (*Euphorbia pulcherrima* Willd.) is induced by short photoperiods[1], the plants remaining vegetative in long day-lengths. Among short-day plants the perennial *Fragaria* spp.[2] and *Kalanchoe blossfeldiana*[3] are inhibited from flowering by gibberellin. This is in contrast to the short-day annuals typified by *Perilla nankinensis*[4,5], *Xanthium pennsylvanicum*[4], *Chenopodium amaranticolor*[4] and *Nicotiana* spp.[6], where flower induction seems usually to be unaffected by this chemical[7]. The strawberry also differs from the short-day annuals in that flower induction seems to be promoted by lowering the temperature during induction[8,9]. As poinsettia exhibits the same negative temperature response[10], it seemed interesting to test the effect of gibberellic acid on flower induction in this species.

In the preliminary experiment poinsettia plants were transferred on January 1, from long day-lengths to short day-lengths for flower induction. Gibberellic acid was then sprayed in aqueous solutions at either 20, 10 or 5 p.p.m. twice weekly. After five applications the concentrations were reduced to half in each case. Control plants were unsprayed. After a further eight applications, treatment was stopped and all plants were returned to long day-lengths to check further photoperiodic induction. Coloured bracts were forming in control plants (unsprayed) by this time, and the plants were in full flower by early April. Flowering was much delayed in the plants which had been sprayed with gibberellic acid. Those which had received sprays of 20 (later 10 p.p.m.) did not flower until late summer and then only produced a few cyathia and poor coloration of bracts. With lower rates an intermediate response was obtained. All rates of application increased stem length.

In the second experiment plants were sprayed weekly with gibberellic acid in aqueous solution at 40, 20, 10, 5 or 2·5 p.p.m. during an induction period of 6 weeks' duration, commencing on October 25. Two sets of control plants, one subjected to short-day induction and the other retained in long day-lengths, were unsprayed. On November 23 the experimental plants were returned to long day-lengths as before. By this time differences between plants treated with gibberellic acid and the induced control plants were already obvious.

The plants were retained in the glasshouse over winter and inspected for flowering from time to time. Again, as in the first experiment, flower induction was not completely inhibited but all rates of application of gibberellic acid delayed flowering, reduced the number of cyathia which developed and reduced the density of coloration of bracts as well as promoting stem elongation. By the end of February the induced control plants and those sprayed with 10 p.p.m. or less were in flower, but not those sprayed with 20 or 40 p.p.m. Counts made at this time showed that the numbers of developing cyathia were reduced from

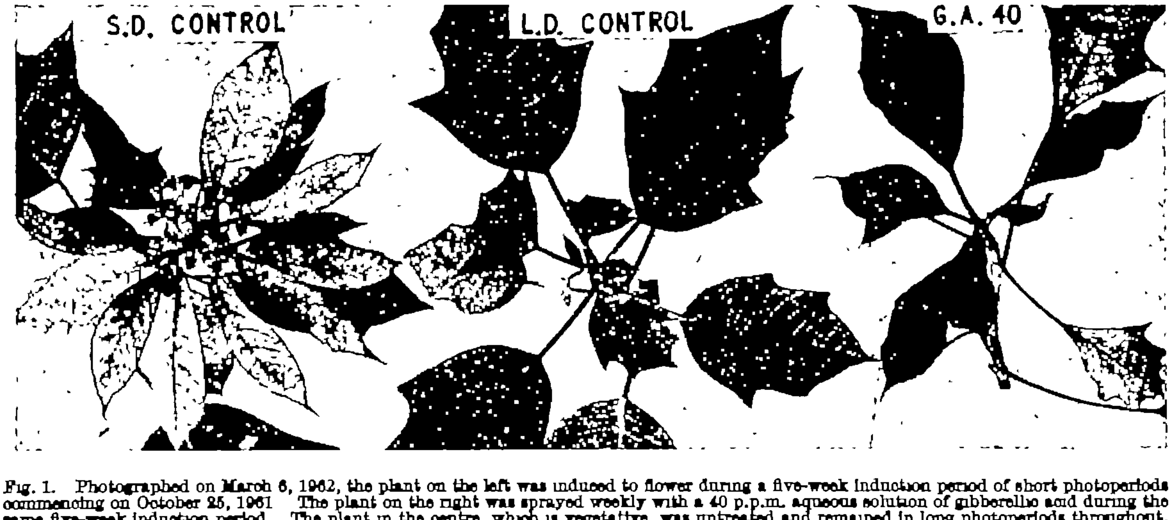

Fig. 1. Photographed on March 6, 1962, the plant on the left was induced to flower during a five-week induction period of short photoperiods commencing on October 25, 1961 The plant on the right was sprayed weekly with a 40 p.p.m. aqueous solution of gibberellic acid during the same five-week induction period The plant in the centre, which is vegetative, was untreated and remained in long photoperiods throughout. Only the upper portion of each plant is shown

a mean of 18·5 in control plants to 5·3, and these greatly retarded, in plants treated with 40 p.p.m. solution. By mid-May a proportion of the plants treated with 40 p.p.m. were still not in flower and it was obvious that the stimulus to flowering in these plants was extremely small. The second set of control plants, which had been retained in long day-lengths throughout the experiment, remained vegetative (Fig. 1).

A slow development of cyathia can also be obtained by partial induction, that is, subjecting the plants to inductive day-lengths for only one or two weeks. The side effects of gibberellic acid on tissue elongation, however, tend to mask superficial resemblances between partially induced plants and plants retarded by gibberellic acid.

It is possible that complete inhibition rather than retardation could be obtained by building up the level of gibberellic acid in the plant before exposure to short day-lengths.

Fragaria spp., *Kalanchoe blossfeldiana* and *Euphorbia pulcherrima* thus seem to differ from the aforementioned short-day annuals in their flowering response to gibberellic acid, and by inference, differ in some way in the biochemical processes by which photoperiodic perception is transformed into flowering responses.

The gibberellic acid used in these experiments (*YF* 4961 formulation) was kindly supplied by Plant Protection, Ltd.

Neuraminidase in Mammalian Brain

CONTAMINATION of serum with neuraminidase-producing bacterial cells promptly produces changes in the electrophoretic pattern. The mobility (surface charge) of the α_1-globulins (orosomucoid and α_1-antitrypsin), of some α_2-globulins (for example, haptoglobin) and of the β_1-globulin, transferrin, decreases on release of sialic acid from the molecular surface[1]. Vulpé[2] has published electrophoretic protein patterns of rabbit sera before and during development of experimental encephalomyelitis induced by injections of a brain suspension in combination with Freund's adjuvant. The changes in serum presented are similar to those produced by neuraminidase. Furthermore, the transferrin of human cerebrospinal fluid is electrophoretically heterogeneous[3], indicating that part of it has lower sialic acid content than the most common transferrin type of Caucasians. These two observations prompted the present investigation of mammalian brain for neuraminidase. This enzyme is common among micro-organisms, and has been found in chick-embryo chorio-allantois but not in mammalian tissue[4].

Freshly obtained guinea pig, bovine and human brains were freed from their meninges. Weighed samples of the cerebral hemispheres were then homogenized with twice their weight of physiological saline. It was presumed that the sialic acid-rich mucolipids of the brain suspension would serve as substrate for the postulated brain enzyme. To detect the presence of neuraminidase, samples of homogenized brain were incubated at 37° C for variable time-periods; but usually 1 h, with three times their volume of 0·1 M buffer of varying *p*H.

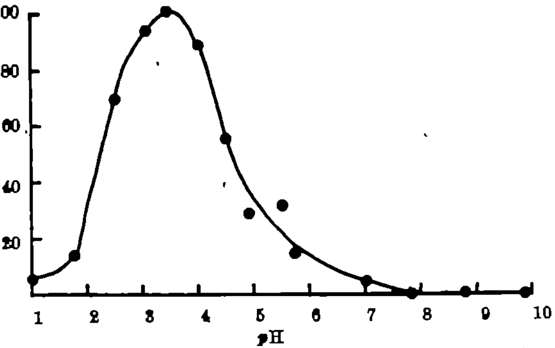

Fig. 1. Neuraminidase activity of brain suspensions in relation to *p*H

The samples were afterwards centrifuged for 3 min and sialic acid measured in the supernatant solution by the thiobarbituric acid method of Warren[5], appropriate correction being made for the presence of 2-deoxyribose in the solutions. This method measures free, but not bound, sialic acid. For each test a blank sample, treated in the same way as the test but centrifuged without previous incubation, was also assayed for sialic acid. The total sialic acid content of the brain homogenates was determined by heating the homogenates with 0·1 N sulphuric acid for 1 h at 80° C, centrifuging and measuring sialic acid in the supernatant by Warren's method.

The release of sialic acid depended markedly on the *p*H of the incubating solution (Fig. 1). In the three species the optimal *p*H was 3·5–4·0. Little or no sialic acid was released when the *p*H was below 2·0 or above 5·5. When the brain homogenates were incubated at *p*H 4·0 for varying time-periods progressive release of sialic acid occurred. This release was almost linear during the first 2 h, by which time, in bovine brain, 15 per cent of the total sialic acid present had been released, but after 2 h the rate of release decreased and after 24 and 48 h 35 and 47 per cent, respectively, had been released.

Heating the brain homogenates from the three species in a boiling water bath for 3 min completely prevented the release of sialic acid during subsequent incubation at *p*H 4·0 and 37° C. After such heating, however, partially purified pneumococcal neuraminidase released sialic acid just as quickly from the brain as from unheated brain homogenate.

In order to check that the material released during incubation and being measured by the thiobarbituric acid assay procedure really was sialic acid, bovine brain homogenate was incubated at 37° C with acetate buffer, *p*H 4·0, for 48 h. Penicillin and streptomycin had been added to prevent bacterial growth. The time-concentration curve for sialic release followed the same principal course as in the short period experiments. The homogenate was then dialysed against several batches of distilled water. The dialysates were concentrated and purified by the method of Svennerholm[6]. The final product after crystallization three times from ethanol, ether, and petroleum ether was found to give the colour reactions typical of sialic acid with thiobarbituric acid, orcinal, Ehrlich's reagent and diphenylamine, and on paper chromatography in 4 solvent systems and high-voltage electrophoresis to have the same R_F value and electrophoretic mobility as authentic *N*-acetyl-neuraminic acid (NANA). In addition the infra-red spectrum was identical with that of NANA[7,8].

These results show that NANA is released from guinea pig, bovine and human brain when they are homogenized and incubated at 37° C. The fact that the release occurs much more quickly at *p*H 3·5–4·0 than at more acid or alkaline *p*H and that it is prevented by prior heating of the brain to 100° C is strong evidence that the release of NANA is enzymatically catalysed. Whether this enzyme is a 'neuraminidase' as defined by Gottschalk[9], in that it catalyses "the hydrolytic cleavage of the glycosidic bond joining the keto group of neuraminic acid to D-galactose of D-galactosamine and possibly to other sugars", is not known. The pH optimum, 3·5–4·0, is different from that found for bacterial neuraminidase (pH 5–6) and from that found by Warren and Spearing[10] for the enzyme present in plasma glycoprotein preparations (pH 5·5), which resembled the bacterial enzyme in this respect. The pH optimum was, however, closer to that of the enzyme present in chick embryo chorioallantois[4] (pH 4·5).

We thank Dr. R. Larsson, Institute of Chemistry, University of Lund, for performing the infra-red spectroscopic examination.

Growth of Juvenile Red-eared Turtles as influenced by Gravitational Field Intensity

PREVIOUS investigations have shown that, although sufficiently high gravity as simulated by continuous centrifugation can retard growth of certain organisms, a moderate increase in the gravitational field intensity can sometimes slightly enhance growth[1–3]. A similar pattern is reported here for juvenile red-eared turtles (*Pseudemys scripta elegans*). However, a more dramatic growth enhancement was obtained during moderate centrifugation than had been obtained with other forms.

Accelerated growth of other forms under the influence of continual centrifugation has been noted. Gray and Edwards[1] found that growth of wheat (*Triticum vulgare*) coleoptiles during the first 24 h of exposure to 10*g* was accelerated. Wunder[2] noted accelerated growth of fruit-fly (*Drosophila melanogaster*) larvæ at 500*g*. The femur bones of white mice display accelerated growth and rounder cross-sections at 4*g*, despite the fact that their total body-mass decreases[3]. Preliminary results in this laboratory indicate that accelerated growth of mice may occur at 1·5*g*. These findings would lend credence to the hypothesis that for any given organism there may be a specific gravitational field intensity most conducive to growth. The fastest growth would occur at the field in which the growth-stimulating effects of gravity are greatest in comparison with the other gravitational effects which normally retard growth.

Turtles were chosen for these investigations because they have a unique structure and because they are aquatic. The shell of the turtle would tend to serve as a natural 'anti-*g* suit'. An aquatic environment would offer buoyant support which would partially counteract the influence of high gravity.

These turtles, which at the beginning of an experiment measured approximately 34 mm in length and 9 g in weight, were exposed to centrifugal fields ranging from 5 to 28*g* for periods of 5–9 weeks. Throughout the experiment, continual 24 h a day lighting and temperatures of approximately 27° C were maintained. Turtles were removed each day for a 20-min period for feeding and cleaning of cages. They were removed for a 6-h period each week for growth measurements. In this way, it was possible to keep the animals active throughout the winter, a time when hibernation normally occurs. Turtles were kept in plastic refrigerator boxes (7·75 in. × 5·5 in. × 4 in.) containing approximately 500 ml. of water. As many as 6 turtles were kept in the same container. The diet consisted of lean chopped beef containing enough beef-bone dust to constitute 10 per cent of the total mass of food. The criterion for growth reported here was change in carapace-length; however, preliminary analysis of results indicates that changes in body-mass were comparable with changes in body-length.

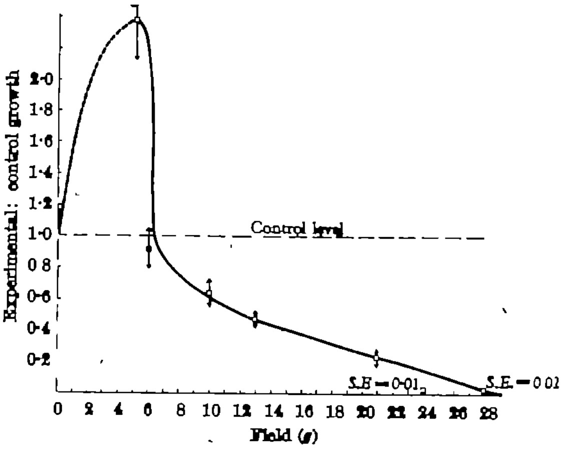

Fig. 1. Average rate of linear growth relative to the paired control turtle ± *S.E.* Over a five-week period, length for both experimental and control turtles is nearly a linear function of time. Control rates are of the order of 1 mm per week. However, this varies markedly with both the season of the year and the exact age of the turtles

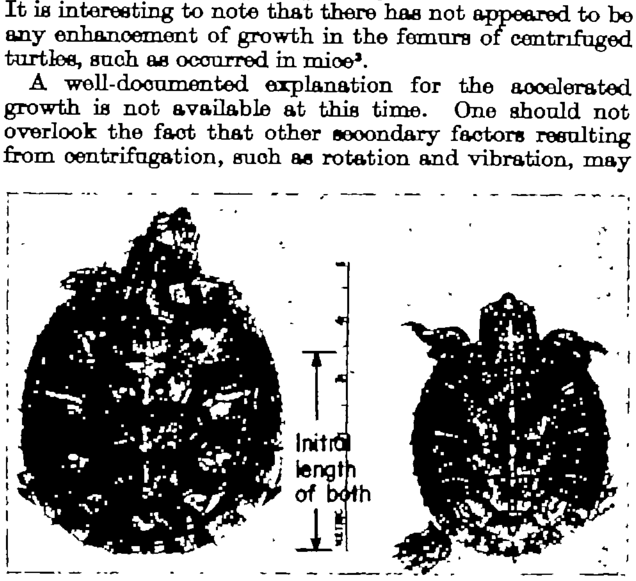
As can be seen in Fig. 1, experimental animals exposed to 5*g* grew approximately twice as fast in length as their controls during five weeks of exposure. Growth at 6*g* did not differ significantly from that of the controls. With further increases in field, there occurred a progressive growth decrement of the type reported with other forms.

With some experimental animals, there was both an absolutely and a relatively greater shell mass in turtles exposed to 5*g* as compared with the 1*g* controls. Such an accelerated growth in shell mass would be expected according to Wolff's Law[4], which proposes that mechanical force acting on a skeletal structure will enhance growth of the stressed portion. In the case of turtles, the shell constitutes the primary, functional skeleton. It is interesting to note that there has not appeared to be any enhancement of growth in the femurs of centrifuged turtles, such as occurred in mice[3].

A well-documented explanation for the accelerated growth is not available at this time. One should not overlook the fact that other secondary factors resulting from centrifugation, such as rotation and vibration, may



5*g* for 9 weeks   Control

Fig. 2. Experimental and control turtles after nine weeks of exposure to 5*g*. Note the larger size of the experimental animal and its wider growth lines

be of significance in the accelerated growth of turtles. These turtles withstand maintained centrifugation much better than do mice of comparable size. Perhaps such factors as buoyancy, shell, and lower body temperature protect the turtle from the deleterious results which have been demonstrated for mice and certain other warm-blooded animals. If this were so, the net developmental acceleration would accordingly be more pronounced.

Long-Distance Migration of Salmon

IT was reported recently[1] that a salmon tagged as a smolt in the estuary of the River Usk in Monmouthshire was caught some eighteen months later near Sukkertoppen on the west coast of Greenland.

Information has now been received that in October, 1962, another English salmon was caught in the same area. This fish was tagged as a smolt in the River Wye at Brockhampton, near Hereford, on April 5, 1961.

ENTOMOLOGY

Insects attacking *Striga* in Kenya

WILLIAMS and Caswell[1] have reported *Smicronyx* sp. (Curculionidae; Coleoptera) attacking *Striga* sp. in Nigeria. Murthy[2] has given an account of the attack of *Smicronyx albovariegatus* Faust. on *Striga* in India and has listed other insect pests of *Striga* in that country.

Striga hermonthica Benth. (Scrophulariaceae) is an important root parasite of sorghum, the principal cereal crop of the low-lying areas near Lake Victoria in Nyanza Province, Kenya. Maize and wild grasses are also attacked. In 1960 and 1962 *Striga* plants were examined for insect damage. In both years the commonest pest was found to be a small agromyzid fly, which has been identified as a new species, *Ophiomyia strigalis* Spencer[3]. Attack commences when *Striga* begins to flower in late June; and by the beginning of August more than 90 per cent of plants have been attacked. The eggs are inserted singly into the soft epidermis in the axils of leaves 1–1·5 in. above soil-level. The larva makes a narrow mine, stained purplish-black, just underneath the epidermis. The mine goes almost straight downwards to below soil-level, where it then pursues a more tortuous course under the epidermis of the root to a depth of 3–4 in. The mature larva returns up the mine and pupates at soil-level where the site of the puparium can be detected as a small blister of the epidermis. Up to 10 puparia have been found in a single plant; the mean number found in August 1962 was 2 puparia per plant. The maximum interval which has been observed between the caging of infested *Striga* material and the emergence of adult flies is 25 days. Attack causes the root epidermis to rot and peel off, and reduces the number of lateral roots, but no debilitation of the aerial parts of the plant, or reduction of numbers of flowers or fruits has been observed.

O. strigalis is attacked by a number of hymenopterous parasites. In 1960 a collection of infested *Striga* material yielded 22 *O. strigalis*, 26 *Eucoilidea* sp. (Cynipoidea), 2 *Opius liogaster* Szepl. (Braconidae) and 2 *Herberia* sp. (Pteromalidae). In 1962 the incidence of these parasites was lower. Some *O. strigalis* eggs have been found to contain Hymenopterous pupæ.

In 1960 about 10 per cent of *Striga* plants at Kibos were found to bear one to three stem galls, usually on the main stem about 3 in. above soil-level. The primary gall-former appeared to be a *Eurytoma* sp. (Eurytomidae; Hymenoptera). Other insects obtained from the galls were a cecidomyid (Cecidomyidae; Diptera) the larvæ of which appeared to feed on fungus in the cavities of the galls a *Bracon* sp. (Braconidae; Hymenoptera) and a *Ceraphron* sp. (Ceraphronidae; Hymenoptera).

Gall-bearing plants had fewer mature fruit than non-infested plants, but it could not be determined whether this was an effect of attack or whether only late-maturing plants were attacked. Only one galled plant has been found in 1962.

Le Pelley[4] records *Platyptilia taprobanes* Fldr. and *Stenoptilia zophodactyla* Dup. (Pterophoridae; Lepidoptera) from *Striga* in Tanganyika. No *Smicronyx* sp. have been found on *Striga* in Kenya.

I thank the Director, Commonwealth Institute of Entomology, for identifying the insect species concerned, and the Director of Agriculture, Kenya, for permission to publish this communication.

Effect of Synthetic 'Queen Substance' (9-oxodec-*trans*-2-enoic acid) on Ovary Development of the House-fly, *Musca domestica* L.

RECENT investigations[1] have shown that when 'queen substance' (9-oxodec-*trans*-2-enoic acid) is distributed throughout the colony of honey bees, it partially inhibits the development of ovaries in workers and influences their behaviour by inhibiting queen-cell construction. Similar effects of crude extracts of queen honey bees have been demonstrated on other groups of social insects, for example, *Formica fusca* L.[2] and *Kalotermes flavicollis* F.[3] This non-specificity for orders of social insects suggests that 'queen substance' might have similar inhibitory effects on ovary development even of non-social insects. This hypothesis was tested by examining the effect of synthetic 'queen substance' on ovary development in the house-fly, *Musca domestica* L.

In the house-fly the ovaries of newly emerged virgin females are undeveloped (Table 1) and female flies require a protein diet such as milk for egg development. When newly emerged female flies were 6–8 h old, samples of twenty flies each were injected in the thorax with 5 μl. per fly of a 2 mg/ml. of dilute ethanolic solution of synthetic 'queen substance' with a 50 μl. Hamilton micro-syringe, and injections were repeated at the time-intervals shown in Table 1. Higher concentrations of synthetic 'queen substance' were found to be toxic and lower concentrations did not show any appreciable effect on the inhibition of ovary development in the house-fly. The treated and control flies were allowed to feed on a 1 : 1 (v/v) mixture of condensed milk and water, replenished daily, for a total period of 96 h. Then the flies were dissected and their ovaries measured.

Table 1. EFFECT ON OVARY DEVELOPMENT AND MORTALITY OF THE HOUSE-FLY, *Musca domestica* L., OF INJECTIONS OF SYNTHETIC 'QUEEN SUBSTANCE' (9-OXODEC-*trans*-2-ENOIC ACID)

	Treatment of female flies (20 flies per test) Material injected*	Times of injection (h)	Mean dimensions of ovaries (mm)† Length	Width	Percentage of mortality after 96 h
1	None	—	0·7	0·4	100
2	'Queen substance'	0	1·7	1·1	5
3	Distilled water	0	3·1	2·0	0
4	'Queen substance'	0, 24	1·4	0·9	5
5	Distilled water	0, 24	3·1	2·1	5
6	'Queen substance'	0, 48	1·2	0·8	10
7	Distilled water	0, 48	3·1	2·0	10
8	'Queen substance'	0, 24, 48	1·0	0·7	10
9	Distilled water	0, 24, 48	3·1	2·1	0

* 5 μl./fly of a solution of 2 mg/ml. of synthetic 'queen substance' (9-oxodec-*trans*-2-enoic acid) dissolved in 5 per cent ethanolic solution was injected in flies in tests 2, 4, 6 and 8. Equivalent volume of distilled water was injected in tests 3, 5, 7 and 9. All flies except in test 1 were fed on a mixture of milk and water (1 : 1, v/v) for a total period of 96 h.

† Means are based on measurements of ten flies randomly selected from each of five replicated tests involving twenty flies.

The effect of synthetic 'queen substance' on the ovary development of the house-fly is shown in Table 1. Similar results were obtained with an equivalent dosage of the sodium salt solution of synthetic 'queen substance'.

These results show that the continuous presence of a certain amount of synthetic 'queen substance' in the insect body is necessary for complete inhibition of ovary development in the house-fly. Synthetic 'queen substance' appears to be metabolized or excreted by the house-fly rather rapidly, and thus it must be supplied at regular intervals or its inhibitory effect on ovary development wears off. This effect of synthetic 'queen substance' appears to be similar to that on honey bees where worker bees must receive a continuous supply of 'queen substance' from the queen honey bee, to inhibit their ovary development. Failure to demonstrate any inhibitory effect of 'queen substance' on ovary development in the house-fly in the work of Mitlin and Baroody[4] can also be explained from these observations. They washed 'queen substance' from the bodies of honey bee queens and injected the material obtained into house-flies or fed it to them in milk. It seems likely that the concentrations of 'queen substance' present in their preparations were too low to show any appreciable inhibitory effect on ovary development of the house-fly.

Further investigations on the effects of synthetic 'queen substance', by both feeding and by injections, on the sexual processes in the house-fly, the German cockroach, *Blattella germanica* L., and other insects, are being conducted.

These results and some unpublished data suggest the possibility of investigating the potentiality of synthetic 'queen substance' (9-oxodec-*trans*-2-enoic acid) as a 'female insect chemosterilant'.

I thank Dr. R. K. Callow, National Institute for Medical Research, London, for a gift of synthetic 'queen substance' (9-oxodec-*trans*-2-enoic acid) (synthesized by Glaxo Laboratories, Ltd., for experimental use only) and Prof. A. J. Thorsteinson and Dr. S. C. Jay of the Department of Entomology, University of Manitoba, for many helpful suggestions. This work was done during my tenure of a National Research Council of Canada post-doctoral fellowship.

CYTOLOGY

Aneuploids in Oat Varietal Populations

THE cultivated oat *Avena sativa* ($2n = 42$) normally forms 21 bivalents at meiosis, but on rare occasions a bivalent fails due either to asynapsis or desynapsis. The irregular transmission of the resulting univalents may lead to the formation of gametes deficient for a chromosome, or with an extra chromosome. If such aneuploid gametes are fertilized by euploid gametes, monosomic or trisomic offspring will arise.

As *Avena sativa* is a hexaploid, there is considerable duplication of genetic material and, in consequence, relatively high levels of aneuploidy are tolerated. Monosomics and nullisomics have been reported to be viable and, to some extent, fertile[1]. Thus once an aneuploid has arisen in a population, its progeny will add to the proportion of aneuploids in succeeding generations. However, a proportion of the progenies of monosomics and trisomics will also revert to euploid. The balancing of these two effects, together with the origin of aneuploids from euploids, will lead to the maintenance in a population of a low, but constant, level of aneuploidy.

The objects of the present investigation were to confirm the report of Riley and Kimber[2] that aneuploids could be extracted from populations within a variety, and to assemble a collection of monosomics in an attempt to obtain a complete series deficient in turn for each chromosome of the haploid complement. Seed of the variety Sun II was obtained from the National Institute of Agricultural Botany, Cambridge (N.I.A.B.), from the Swedish Seed Association, Svalöf (S.S.A.), where the variety was bred, and from a commercial seed merchant. The three stocks were screened for aneuploids by checking the somatic chromosome numbers of young seedlings. Chromosome counts were made on temporary squashes of root-tips stained by the Feulgen technique. Plants giving aneuploid counts were grown to maturity, and their chromosome constitutions were confirmed either at meiosis or by checking the chromosome numbers of samples of their progenies.

The percentage of aneuploids obtained varied from 1·2–1·9 in the samples of the three populations studied (Table 1). Monosomics occurred with a greater frequency than other classes of aneuploid, but nullisomics, trisomics and plants with one or two telocentric chromosomes were also recorded. A supposed 44-chromosome plant failed to survive to maturity, and consequently could not be confirmed as an aneuploid.

Table 1. ANEUPLOID FREQUENCY IN THREE POPULATIONS OF *Avena sativa* VAR. SUN II

Stock	Chromosome constitutions 42	40	41	41 + telo	40 + 2 telos	43	Per cent aneuploid
N.I.A.B.	1,842	4	17	1	1	3	1·4
S.S.A.	1,095	2	17	–	1	1	1·9
Seed merchant	516	–	6	–	–	–	1·2
Total	3,453	6	40	1	2	4	1·5

It is apparent that a proportion of the variety is in fact aneuploid. In addition it should be emphasized that the recorded percentage is minimal, since inevitably, in a study of this kind, some aneuploids would have been discarded after being mistakenly identified as euploids. Also morphologically abnormal types had been rogued out of the populations in the immediately preceding generations. Consequently the frequencies of aneuploids recorded are not necessarily those to be expected in stabilized populations.

The observed frequency of aneuploids may be of importance for two reasons. First, it demonstrates that the occurrence of a proportion of genetically aberrant forms is probably a feature of oat varietal populations, due to the origin and maintenance of cytological abnormalities.

The significance of this in relation to the morphological and physiological purity demanded of oat varieties depends on the phenotypic expression of aneuploid conditions. The limited evidence so far obtained suggests that the euploid phenotype may be considerably modified by aneuploidy. If this is so it is not reasonable to expect the frequency of off types to be less than the aneuploid frequency of the variety.

Secondly, the frequency of monosomics in Sun II suggests there is a possibility that a complete series of monosomics can be assembled by screening varietal populations. At present there is no reason for supposing that certain monosomics occur at a greater frequency than do others. The usefulness of the mass screening technique for isolating a complete monosomic series in oats can only be assessed when the inter-relationships of those monosomics already assembled have been determined.

We thank Dr. G. D. H. Bell for his interest in this work, also the Association of Universities of the British Commonwealth for the grant of a scholarship to one of us (J. B. H.).

VIROLOGY

Increase of Plant Virus Infection by Magnesium in the Presence of Phosphate

THE increase of tobacco mosaic virus (TMV) infection induced by 0·1 M solutions of ammonium, potassium or sodium mono-hydrogen orthophosphate salts already has been discussed[1,2]. This phenomenon was defined as the 'phosphate effect' and has been interpreted as an effect on the host[3]. The action of the 'phosphate effect' is here considered to be both an effect on the virus and on the host[4].

The enhancing action of magnesium on infection has been observed with poliovirus[5] and with the yield of *r*II mutants of bacteriophage *T*4 (ref. 6). Magnesium in combination with glycine has been reported to stabilize potato yellow-dwarf virus[7], but not barley stripe mosaic virus[8]. Magnesium has also been shown to stabilize the helical regions of the ribonucleic acid of TMV[9]. Phosphate buffer (0·01 M) without magnesium was found to cause dissociation of yeast ribonucleoprotein into two components whereas no such dissociation occurred in the presence of magnesium[10].

Investigations were made to determine whether magnesium could increase infection of several plant viruses. The principal viruses used were the following: a strain of alfalfa mosaic virus (AMV) maintained in *Nicotiana tabacum* L. var. *xanthi*, n.c.; a strain of cucumber mosaic virus (CMV) maintained in young cucumber cotyledons as local lesions (used at 6 days after inoculation) (*Cucumis sativus* L. var. National Pickling); a strain of tobacco necrosis virus (TNV) maintained as local lesions on the primary leaves of blackeye cowpea (*Vigna sinensis* (Torner) Savi); and a strain of tobacco rattle virus (TRV) maintained in *N. tabacum* var. *xanthi*.

The primary leaves of blackeye cowpea were used principally for local lesion assay of the foregoing viruses. Primary leaves of pinto beans (*Phaseolus vulgaris* L.) were used to a lesser extent for assay of purified TMV. Inoculations were made by rubbing the upper surface of 'Carborundum'-dusted leaves of the assay host with a poster brush dipped in inoculum. The inoculum in most cases (except for TMV) consisted of crude virus suspension in water, magnesium, phosphate or phosphate containing magnesium. Although water was reported to inhibit infection[11], all leaves were quickly washed under tap water after inoculation in order to protect the inoculated leaves from salt injury.

Equivalent samples (usually 1 ml.) of freshly ground and appropriately diluted (with distilled water) infected-tissue suspensions were added to equal volumes of water, 0·01 M $MgCl_2$, 0·1 M KH_2PO_4–K_2HPO_4 buffer (*p*H 8·0), and to a 0·1 M magnesium chloride–phosphate buffer solution (*p*H 8·0). For the latter solution, 1 ml. of magnesium chloride was added to 9 ml. of 0·1 M phosphate buffer containing virus rather than in the reverse order to prevent precipitation. The *p*H remained constant for both buffer suspensions. Each preparation was inoculated to at least 24 cowpea leaves. The lesions were counted 3–4 days after inoculation.

Table 1. INCREASED INFECTION BY MAGNESIUM CHLORIDE IN THE PRESENCE OF PHOSPHATE

Virus	Supplement to inoculum* Control (water)	Magnesium chloride (0·01 M)	Phosphate (0·1 M, *p*H 8·0)	Phosphate + magnesium chloride (0·1 M, *p*H 8·0)
AMV	8·0	3·7	30·5	53·3
CMV	18·3	10·4	161·4	279·7
TRV	10·6	10·9	79·8	102·7
TMV	3·3	13·5	120·1	123·8
TNV	9·2	5·2	106·0	107·0

* Numbers represent average number of lesions from cowpea leaves from four separate experiments except for TMV and TNV which were assayed on pinto bean.

Table 2. EFFECT OF CALCIUM CHLORIDE ON THE PHOSPHATE EFFECT

Inoculum	Molar concentration (mM)	Average number of CMV lesions
H_2O	—	5·7
$CaCl_2$	10·0	3·0
Phosphate	100·0	129·1
Phosphate + $CaCl_2$	0·1*	108·9
,,	1·0	72·8
,,	10·0	20·7
,,	100·0	9·7

* Concentration of calcium chloride. The concentration of phosphate remained 100 mM throughout.

The results (Table 1) indicate that there is a decrease in infection from inoculum containing only 0·01 M magnesium chloride. It was noted, however, that the 'phosphate effect' was found to be enhanced in the presence of magnesium chloride. The average increase of the 'phosphate effect' by magnesium chloride for AMV, CMV, and TRV was about 53 per cent. In one experiment using CMV, magnesium increased the 'phosphate effect' to about 140 per cent. A lesser effect of the magnesium–phosphate complex was observed when relatively stable viruses such as TMV and TNV were used.

The effect of other cations was tested in the presence of HPO_4^{-2} by using 0·05 M *tris*(hydroxymethyl)aminomethane adjusted with 0·05 M phosphoric acid to *p*H 8·0. Monovalent cations such as potassium and sodium in the presence of this buffer tended to decrease TMV lesion numbers whereas magnesium chloride gave an increase. Divalent cations such as calcium could not be substituted in place of magnesium without the formation of calcium phosphate precipitates at such concentrations. With increasing concentrations of calcium chloride in phosphate buffer (calcium chloride to buffer, v/v, 1 : 10), the concentration of CMV in the supernatant decreased and there was no increase of the 'phosphate effect' (Table 2). Since it has been reported that sour cherry necrotic ringspot virus and barley stripe mosaic virus are adsorbed on the calcium phosphate precipitate only at low phosphate buffer concentrations[8,12], it is believed that in our case the CMV is trapped in the intermicelles during the *in situ* formation of the calcium phosphate precipitate at these higher concentrations.

It is likely that the action of magnesium is on the virus since greater increase of the 'phosphate effect' is observed with less-stable viruses than with more stable ones. In several trials using identical assay hosts, CMV showed greater infection by the magnesium–phosphate complex than did TNV. Other preliminary evidence indicates that AMV in the presence of the complex is found to remain active longer than virus in phosphate. Therefore, magnesium may act by stabilizing the virus.

The purified preparation of TMV obtained from R. Reichle is gratefully acknowledged. This work was supported by grant G9820 from the U.S. National Science Foundation.

Loss of the Hæmagglutinating Capacity of Fowl-plague Virus after Culture on HeLa Cells

CERTAIN viruses undergo changes in their hæmagglutinating capacity, when propagated in certain cultures. Green *et al.*[1] and Mogabgab *et al.*[2] discovered, by examining strains of influenza virus, that the hæmagglutinating capacity is modified when passing from one cellular system to another.

Recently, Moscovici *et al.*[3,4] described the fact that some strains of ECHO virus lose their hæmagglutinating capacity when cultivated on HeLa cells, whereas they retain such capacity if cultivated on monkey kidney cells. Moreover, the virus which has lost its hæmagglutinating capacity does not regain it when cultivated again on cells of monkey kidney.

More recently, Johnson *et al.*[5] showed that loss of hæmagglutinating capacity occurs when Coxsackie *A*-21 virus is cultivated on cells of cancerous origin (HeLa and *KB* strains), whereas the capacity is maintained when cultivating the virus on primary human embryonic epithelial cells and semi-continuous diploid human embryonic fibroblastic cells.

It has been also demonstrated by Cassel *et al.*[6] that on serial passage in the Ehrlich ascites tumour loss of hæmagglutinating power occurs in three vaccinia virus strains. Tumorous ascitic fluid was removed from mice, and a cell-free tumour fluid with hæmagglutinin-inhibition power obtained.

We have observed the loss of the hæmagglutinating capacity of fowl-plague virus cultivated on HeLa cells, whereas it retains its capacity when cultivated on chick embryo cells.

The maintenance medium used is the same for both types of cells. It consists of: Hanks's balanced salt solution, 85 per cent; lactalbumin hydrolysate (5 per cent), 10 per cent; calf serum, 3 per cent; penicillin, 100 U/ml.; streptomycin, 100 mg/ml.; nystatin, 20 U/ml.; phenol red (0·2 per cent), 1 per cent; $pH = 7{\cdot}2$. The cells are cultivated in hexagonal flasks of 'Pyrex' glass with a total capacity of 225 ml., containing 10 ml. of culture medium.

Starting from virus cultivated on chick embryo, 20 passages were performed with fowl-plague virus through chick embryo cells; the hæmagglutinating titre and egg lethal dose 50 per cent of each passage were determined.

It is possible to observe a rapid adaptation of the virus to the cellular culture, with stabilization of the evolution period of the infection, and appearance of cytopathic effects 24–48 h after inoculation of the virus.

The hæmagglutinating titre decreases from the first passage to the fourth, increasing afterwards up to a considerable value which is stable with small oscillations. The 50 per cent egg lethal dose undergoes a slight variation during the experiment, with an evolution apparently similar.

At the same time, 14 passages were made of fowl-plague virus on HeLa cells. For each one, samples were taken from the culture medium during the time of the passage; the hæmagglutinating titre and egg lethal dose 50 per cent were fixed. The adaptation of the virus is slower than in the preceding case; it becomes stable, but the evolution period of the infection is longer and the cytopathological effects appear later. The hæmagglutinating titre decreases rapidly, disappearing at about the third passage. However, the cytopathological effects continue to appear during all the following passages.

The existence of virus in the culture medium of infected HeLa cells was detected by electron microscopy; its morphological aspect is similar to that of the virus cultivated on chick embryo cells. Moreover, tests of complement fixation with antigen obtained from virus propagated on HeLa cells and with sera obtained from the same virus present a positive reaction reciprocally and in the presence of antigens obtained from virus propagated on chick embryo and chick embryo cells.

It has been shown that virus cultivated on chick embryo cells hæmagglutinates to a different extent from human type O, sheep and chicken erythrocytes, whereas virus cultivated on HeLa cells hæmagglutinates none of them.

Moscovici and La Placa[4] conclude that this phenomenon is due to an unknown virus-modifying factor, present in the human tumour cell and released at the time of infection, which causes a permanent modification of the surface of the virus. Johnson suggests the possibility that perhaps this is not an uncommon phenomenon among human enteroviruses, and that the loss of hæmagglutinating capacity is due to two types of infectious virus particles: positive and negative hæmagglutinating. When cultivated on malignant cells, they undergo a selection which favours the propagation of negative hæmagglutinating particles, whereas on non-malignant cells the selection is on the contrary.

Our experiments were performed in order to determine the possible existence of a hæmagglutination-inhibitory agent inside HeLa cells. Having dismissed the possibility of influence by the serum constituent of the culture medium (3 per cent calf serum)—since this is the same medium used for both types of HeLa and chick embryo cells—we now believe that we have discovered a new factor and are trying to determine its characteristics. This factor, obtained from free culture medium cell extracts, might possibly act inside the cells on the synthesis of virus hæmagglutinins, preventing their formation or otherwise neutralizing them afterwards.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, March 4

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. A. Morgan Jones: "The Coronary Collateral Circulation".*

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. Peter Haggett: "Coastal Deforestation in Brazil".

Institution of Electrical Engineers, Electronics Division P.G.E3 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Evaluation of Technologies for Fabricating H.F. Transistors" opened by Dr. J. R. Tillman, Mr. P. Beale, Mr. P. Charman and Dr. R. W. A. Scarr.

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. H. G. Conway and Mr. M. Hartland Thomas: "Engineering Problems of the Decimal and Metric Systems".

University of London (at the School of Pharmacy, 29–39 Brunswick Square, London, W.C.1), at 5.30 p.m.—Dr. P. W. Brian: "Two Biologically Active Fungal Metabolic Products. 1: Griseofulvin".*

Institution of Mechanical Engineers, Railway Engineering Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "New Materials which Could Play an Important Part in Railway Engineering".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Dr. B. K. Blount: "Science in Latin America". (Last of three Cantor Lectures on "Latin America—World of Tomorrow".)

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. J. Pickthall: "About Perfumery"; Dr. B. Dudley Sully: "Perfumery Chemicals from Pinene".

Tuesday, March 5

Institution of Electrical Engineers, Science and General Division (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. V. R. Sastry and Dr. J. W. Lynn: "Analogue Investigation of the Stability of a Graphite Power Reactor".

University of London (at the School of Pharmacy, 29–39 Brunswick Square, London, W.C.1), at 5.30 p.m.—Dr. P. W. Brian: "Two Biologically Active Fungal Metabolic Products. 2: Gibberellic Acid".*

University of London (in the Large Geology Lecture Theatre, Imperial College of Science and Technology, Royal School of Mines, Prince Consort Road, London, S.W.7), at 5.30 p.m.—Dr. D'Arnaud Gerkens: "Seismic Noise and Resolving Power".*

Institution of Mechanical Engineers, Process Engineering, Refrigeration, Ventilation and Vacuum Plant Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Mechanical Aspects of Mixing of Solids".

Institute of Plastics (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. T. C. Moorshead: "Static Electricity".

Wednesday, March 6

University of London (at the Institute of Diseases of the Chest, Brompton Hospital, London, S.W.7), at 5 p.m.—Dr. R. W. Riddell: "The Bacteriological Investigation of Hospital-acquired Infections".*

Institute of Petroleum (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. A. W. Crook: "Developments in Elasto-Hydrodynamic Lubrication".

Institution of Electrical Engineers, Power Division P.G.P8 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. L. Roullier: "Testing of Mechanical Joints in Insulated Aluminium Conductors".

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5.30 p.m.—Prof. R. S. Scorer· "Convection".

British Institution of Radio Engineers, Electric Acoustics Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. S. C. Brown: "Travelling Wave Crystal Amplifiers".

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (at the College of Technology, Chesterfield), at 6.30 p.m.—Mr. H. W. B. Gardiner, Mr. E. A. Heywood and Mr. W. J. Worsdell: "Design of Machines for Electric Lamp Manufacture".

Royal Institute of Chemistry, London Section—(joint meeting with the Chelsea College of Science and Technology Chemical Society, at the Chelsea College of Science and Technology, Manresa Road, London, S.W.3), at 7 p.m.—Mr. R. A. Saunders: "Recent Advances in the Mass Spectrometry of Organic Compounds".

Royal Microscopical Society (at the Edward Lumley Hall, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2), at 7 p.m.—Soiree and Exhibition of Modern Microscopes and Ancillary Equipment.

Thursday, March 7

Zoological Society of London (in the Meeting Room, Regent's Park London, N.W.1), at 10 a.m.—Symposium on "The Mammalian Epidermis and Its Derivatives".

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. W. K. Taylor: "Cortico-Thalamic Organization and Memory"; Mr. D. E. Broadbent and Miss Margaret Gregory: "Evidence Concerning a Recent View of the Mechanism of Human Attention".

Institute of Refrigeration (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 5.30 p.m.—Prof. G. F. Lorentzen: "The Freezer Chain—Problems and Possibilities".

Institution of Electrical Engineers (joint meeting with the Institutions of Civil and of Mechanical Engineers, at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. R. S. Edwards: "Objectives and Management in Nationalized Industry" (Ninth Graham Clark Lecture).

University of London (in the Beveridge Hall, Senate House, London, W.C.1), at 6 p.m.—Sir Frederick Brundett: "The Neglected Sea" (Haldane Memorial Lecture).*

Institute of Metals (at 17 Belgrave Square, London, S.W.1), at 7 p.m.—Mr. T. Williams: "Practical Aspects of Explosive Forming".

Friday, March 8

Institute of Fuel (in collaboration with the City and Guilds of London Institute, at the Borough Polytechnic, Borough Road, London, S.E.1), at 10 a.m.—Conference on "Education and Training in Fuel Technology in Relation to National Needs".

Society for Analytical Chemistry (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 2.15 p.m.—Annual General Meeting. 2.45 p.m.—Dr. A. J. Amos: "The Society Yesterday, Today and Tomorrow".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. E. W. Arndt: "Automation in the Laboratory".

Saturday, March 9

London County Council (at the Horniman Museum, London Road Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Malcolm Lyall-Watson: "Animal Behaviour in Zoos".*

Monday, March 11

Institution of Mechanical Engineers, Industrial Administration and Engineering Production Group (at 1 Birdcage Walk, Westminster, London, S.W.1)—All-day Discussion on "Metallurgical and Engineering Problems in the Machining of Materials".

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 4 p.m.—Symposium on "Noise in Weaving Machinery".

University of London (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Dr. B. Ackner: "Emotional Reactions to Physical Illness".*

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. D. W. Sciama: "The Unity of the Universe".

Institution of Electrical Engineers, Electronics Division P.G.E8 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. L. Lewin: "Microwave Theory or Microwave Green Fingers ?"

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Reinhold Baer (Frankfurt am Main): "The Reduced Rank of a Group".*

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"Lords of the Forest" (Colour film).

Women's Engineering Society (at "Hope House", 45 Great Peter Street, London, S.W.1), at 7.30 p.m.—Dr. A. R. Flint· "The Channel Bridge Project".

Monday March 11—Tuesday, March 12

Society of Chemical Industry, Chemical Engineering Group; the Institution of Chemical Engineers, South-Eastern Branch; and the Institute of Petroleum (at the Royal Commonwealth Society's Assembly Hall, Craven Street, London, W.C.2)—Symposium on "Fluidization".

Monday, March 11—Thursday, March 14

Oil and Colour Chemists' Association (at the Royal Horticultural Society's Old and New Halls, London, S.W.1)—Fifteenth Technical Exhibition.*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (with a good honours degree) in Applied Mathematics—The Registrar, King's College (University of London), Strand, London, W.C.2 (March 9).

Lecturer or Assistant Lecturer (graduate in civil engineering or physics) in Soil Mechanics—The Registrar, The University, Manchester (March 9).

Assistant Lecturer (with an honours degree in biochemistry or equivalent) in Agricultural Biochemistry—The Secretary, The University, Aberdeen (March 15).

Lecturer in the Computing Laboratory—The Secretary of University Court, The University, Glasgow (March 16).

Research Biochemist (medical or science graduate, preferably with experience in the field of steroid chemistry) in the Department of Medicine, to undertake biochemical investigations as a member of a team engaged in clinical research—The Registrar, The University, Sheffield (March 16).

Professor (with considerable experience in research and university lecturing in either physics, chemistry, zoology or botany and preferably some administrative experience, including handling of staff and students) to head the Department of Science, University College of Cape Coast, Ghana—The Assistant Registrar (Overseas), University College of Ghana, 15 Gordon Square, London, W.C.1 (March 18).

Research Student (with a good honours degree or diploma in technology in mechanical engineering or in an applied science) in the Department of Mechanical Engineering, to undertake basic research into the thermal strains which occur in machine tool frames in practice—The Secretary, Royal College of Advanced Technology, Salford 5, Lancs, quoting Ref. MB/34 (March 22).

Lecturer (with special interests and qualifications in mineralogy and petrology) in Geology in the Faculty of Science—The Registrar, The University, Manchester 13 (March 23).

Librarian—The Registrar, University of Kent at Canterbury, c/o The Education Department, Springfield, Maidstone, Kent (March 23).

Assistant Lecturer or Lecturer (with a special interest in inorganic chemistry) in Chemistry at the University of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (March 30).

Assistant Lecturer in Animal Production—The Secretary, Wye College (University of London), near Ashford, Kent (March 31).

LECTURER (permanent or temporary) IN THE DEPARTMENT OF PHYSICS at the University of the Witwatersrand, Johannesburg—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, March 31).

SENIOR LECTURER or LECTURER (medically qualified with appropriate training and experience) IN CHEMICAL PATHOLOGY at the University of Ibadan—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (March 31).

LECTURER IN PHYSICAL OR INORGANIC CHEMISTRY; and a LECTURER IN THEORETICAL CHEMISTRY—The Secretary, The University, Edinburgh (April 1).

LECTURER (with an honours degree, preferably in chemical engineering with research and/or industrial experience) IN CHEMICAL ENGINEERING at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 15).

LECTURERS or ASSISTANT LECTURERS (3) IN PHYSICS at the University of Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 15).

READER IN MEDICAL MICROBIOLOGY at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, April 15).

SENIOR LECTURER (preferably with interests in the field of terrestrial or freshwater ecology) IN ZOOLOGY at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, April 15).

AGRICULTURAL CHEMIST (male, between 22 and 45, with an honours degree in agricultural chemistry or chemistry, with two years postgraduate experience in agricultural chemistry) in the Ministry of Agriculture, Kenya, to take charge of research projects into soil and plant nutrition problems of coffee—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. T/RD.213/80/03.

ASSISTANT LECTURER (with a good honours degree) IN BIOCHEMISTRY—The Secretary, The Royal College of Science and Technology, George Street, Glasgow, C.1.

MASTER TO TEACH MATHEMATICS throughout the school, including Sixth Form; and a MASTER TO TEACH CHEMISTRY, largely in the Sixth Form—The Headmaster, Bolton School, Bolton, Lancs.

POSTDOCTORAL FELLOW IN PHYSICAL CHEMISTRY, for work concerned with the application of radioactive tracer methods to the study of the solid state under the direction of Dr. J. N. Sherwood—Prof. P. L. Pauson, The Royal College of Science and Technology, George Street, Glasgow, C.1.

A new addition!

A RECORDING SPECTROPHOTOMETER at a price you can afford

★ *Compact and Transistorised* ★ *Grating Monochromator* ★ *New Automatic Facilities*

The Model 'R' double-beam recording grating spectrophotometer is a new addition to the Optica range of instruments for the ultra-violet, visible and near infra-red regions. The Standard Model 'R' incorporates the well-known Optica Grating Monochromator and has a working range of 186–760 mμ Built-in reflectance spheres make this instrument particularly useful for measurements on both turbid and opaque samples. The flat-bed recorder, operated by push-buttons, has four scanning speeds and allows any spectral region of 50, 100 or 200 mμ to be selected. The instrument is completely mains operated and the circuitry is partially transistorised; consequently the electronic units are very compact and neatly housed at the rear of the monochromator.

In addition to the standard instrument, a model with automatic controls is available. This revolutionary model will scan four samples automatically and will also record automatically either at a fixed wavelength or over a preselected range and, if required, at pre-set time intervals.

Full details of the Model 'R' and other Optica Spectrophotometers are available upon request.

Price £1,650 for Standard Model 'R'.

OXLEY

SOLDERLESS WRAPPED JOINTS

CHARACTERISTICS

Chassis thickness, 16–18 SWG—048/064"—1.2/1.6 mm.
Capacity, 1.5 pF
Operating temperature, 55°C ± 200°C

The Oxley "Barb" solderless wrapped connector is a speedily assembled lead-through of outstanding electrical and mechanical characteristics.

The spill is nickel flashed and solder dipped and spun to British P.O. Specification No. M38. Insert the bush in a .156 dia. plain hole in the chassis, and press the barbed spill firmly but slowly through the bush; the latter expands, particularly on the far side of the chassis, and results in the insulator becoming an integral part of it. In addition to its excellent qualities, a considerable saving of time is effected in assembly. Supplied in sealed packets of 100 and 1000.

ACTUAL SIZE

APPOINTMENTS VACANT

UNIVERSITY COLLEGE OF WALES
ABERYSTWYTH
DEPARTMENT OF BOTANY

Applications are invited for the following posts:

(1) Lecturer or Assistant Lecturer from October, 1963. Applicants should have special interests either (a) in experimental approaches to algology, or (b) in some aspect of the fine structure of plant cells. Initial salary according to qualifications and experience

(2) Demonstrator from October, 1963. Salary within the range £725 to £825, plus F.S.S.U.

Further particulars and forms of application regarding these posts may be obtained from the Registrar, to whom applications (including the names of two referees), should be sent by March 23, 1963

UNIVERSITY OF EDINBURGH
DEPARTMENT OF CHEMISTRY
LECTURESHIPS

Applications are invited for the following posts in the Department of Chemistry: Lecturer in Physical or Inorganic Chemistry. Lecturer in Theoretical Chemistry. The salary scale (under review) is £1,150 by £50 to £1,350; bar: £1,400 by £50 to £1,500 by £75 to £1,950 per annum, with placement according to qualifications and experience, and with superannuation benefit and family allowance where applicable. The successful candidates will be expected to take up duty on October 1, 1963.

Further particulars may be obtained from the undersigned, with whom applications (six copies), giving the names of two referees, should be lodged not later than April 1, 1963.

CHARLES H. STEWART,
Secretary to the University

UNIVERSITY OF OXFORD
READERSHIP IN THEORETICAL PHYSICS

Applications are invited for the appointment of a Reader in Theoretical Physics. The stipend will be on the scale £1,975 by £75 to £2,425 (commencing according to age and qualifications) with children's allowances and F.S.S.U. The reader will be required to engage in advanced study or research, to lecture and give instruction in Theoretical Physics under the direction of the General Board of the Faculties, and to take part in the supervision of research in the Department of Theoretical Physics. He may not undertake more than six hours a week of private tuition without the leave of the General Board of the Faculties.

Applications (six copies), including statement of age, academic career, experience and published work, with the names of two referees, should reach the Secretary of Faculties, University Registry, Oxford, by April 15, 1963. The reader will be expected to take up office on October 1, 1963, or as soon as possible thereafter.

RHEOLOGY OF MORTAR AND PLASTER

Physicist or Physical Chemist required for investigations on the rheology and other physical properties of mortars and plastering materials. Applicants should have at least second-class honours degree and research experience; previous knowledge of these materials or of a related field an advantage, but not essential. The appointment will be made in the Scientific or Senior Scientific Officer grade, at a salary appropriate to qualifications and experience. Superannuation under F.S.S.U. Pleasant environment in a growing organization.

Apply, with full particulars, to Director of Research, The Chalk Lime and Allied Industries Research Association, Church Street, Welwyn, Herts.

HAWKER SIDDELEY AVIATION

WHITWORTH GLOSTER AIRCRAFT LIMITED
ARMAMENTS DIVISION

The Research Department of Whitworth Gloster Aircraft Limited invite applications for the following positions for work on the guided missile Seaslug and other advanced projects.

RESEARCH OFFICER ON ASSESSMENT AND PERFORMANCE
RESEARCH OFFICER ON SYSTEM STUDY WORK
RESEARCH OFFICER ON AERONAUTICAL ENGINEERING
RESEARCH OFFICER ON AEROELASTIC INVESTIGATIONS

The Department is responsible for the assessment and appraisal of complete guided missile systems and has extensive computing facilities, both analogue and digital. The essential qualification is a good Degree in either Mathematics, Physics, Aeronautical, Electrical, or Mechanical Engineering and a desire to learn how to integrate complex engineering systems

Previous experience is not essential but would be a distinct advantage and will be reflected in the salary offered

Replies should be addressed to:

Staff Personnel Officer, WHITWORTH GLOSTER AIRCRAFT LIMITED, Baginton, Coventry, quoting reference ARM/AL/MCT.

WHITWORTH GLOSTER AIRCRAFT LIMITED

VICTORIA GENERAL HOSPITAL
Halifax, Nova Scotia, Canada

Requires the Services of

ISOTOPE TECHNICIAN

QUALIFICATIONS: Technician required for Clinical Isotope Department of large referring hospital. Equipment modern and wide range of investigative procedures carried out routinely. Applicants should be qualified in Medical Technology and should have experience in handling radioactive materials and will be expected to assist in the students training programme. Good working conditions.

SALARY: $3,000–$4,650 commensurate with qualifications and experience.
Full Civil Service benefits.

Application Forms may be obtained from the Nova Scotia Civil Service Commission, P.O. Box 943, Provincial Administration Building, Hollis Street, Halifax, Nova Scotia.

7678

NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING
(UNIVERSITY OF READING)

Applications are invited for a post in the Statistics Section of the Institute. Candidates should have an honours degree in mathematics, with preferably an interest in biology. Duties include consultation and research on design and analysis of experiments, and co-operation with the research staff of the Institute in the statistical aspects of the work. Appointment in Scientific Officer (£768 to £1,271) or Senior Scientific Officer (£1,396 to £1,720) grade, according to age and experience.

Applications, naming two referees, to Secretary, N.I.R.D., Shinfield, Reading. Quote ref 63/6.

SCOTTISH MARINE BIOLOGICAL ASSOCIATION
OCEANOGRAPHIC LABORATORY
EDINBURGH

Scientific Officer or Senior Scientific Officer for research on marine plankton, hydrography and fisheries. Opportunities to develop statistical techniques in ecology. Fifteen years data and computer facilities available. Salary, depending on age and experience, in range £768 to £1,271 (Scientific Officer) or £1,396 to £1,720 (Senior Scientific Officer) but special consideration might be given to more senior candidates. F.S.S.U.

Further particulars and application forms from the Officer-in-Charge, Oceanographic Laboratory, Craighall Road, Edinburgh, 6.

AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

DIVISION OF RADIOPHYSICS

EXPERIMENTAL OFFICER–DATA ANALYST

Applications are invited for appointment to a position of Data Analyst with the Organization's Division of Radiophysics located in the grounds of the University of Sydney, N.S.W.

The duties will involve the analysis of and assistance in the interpretation of the results of cloud seeding and similar experiments and participation in the statistical design and physical assessment of the experiments

Applicants should possess either a degree or a diploma in Physics and Mathematics and have some interest in statistics, or similar qualifications in Statistics and have some interest in Physics.

SALARY : Dependent upon qualifications and experience within the ranges :

£A1,376 per annum to £A2,231 or £A2,331 to £A2,631 per annum.

Fares paid for the appointee and his dependent family. Further particulars of conditions, etc., supplied on application to :

Mr. P. F. Butler, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2,

to whom applications (quoting Appointment No. 780/295), should be addressed by March 30, 1963.

THE INTERNATIONAL NICKEL COMPANY (MOND) LIMITED

requires

SENIOR ASSISTANT

in the

TECHNICAL INFORMATION SECTION

DEVELOPMENT AND RESEARCH DEPARTMENT, LONDON

Duties will include abstracting, indexing, translation and literature searches. Candidates, who should preferably not be older than 35, must offer a degree (or equivalent) in metallurgy, the physical sciences or engineering and have a sound knowledge of French. Some Spanish or Italian would also be useful.

Pension and assurance schemes are in operation and, in appropriate cases, assistance can be given with housing.

Apply giving full particulars of qualifications, experience, age, salary required etc., to :

The Technical Information Officer,
Development and Research Department,
The International Nickel Company (Mond) Limited,
Thames House, Millbank, London S.W.1.

Mark envelope " Confidential M. 13."

MARQUETTE UNIVERSITY SCHOOL OF MEDICINE

MILWAUKEE 3, WISCONSIN

DEPARTMENT OF MICROBIOLOGY AND IMMUNOLOGY

Invites application of Lecturer in Medical Microbiology and Immunology. The lecturer is to participate in teaching medical students during one semester of the academic year in co-operation with the staff of the Department. The remaining time of the year can be devoted to research. Modern, adequate research facilities. Annual salary £3,200, or higher, depending on rank and experience.

RESEARCH. VACANCY EXISTS FOR Qualified Assistant to work in the field of Powder Metallurgy, including Hot Pressing. Some experience in carbide would be an advantage. Candidates should possess a degree or equivalent qualification, and preferably some industrial research experience. Conditions of employment are good and include pension and bonus schemes. Salary will be commensurate with qualifications and experience.—Applications, giving full particulars to Personnel Officer, The Carborundum Company Ltd., Trafford Park, Manchester 17, quoting reference R D.2.

McGILL UNIVERSITY

MONTREAL

A permanent teaching and research appointment is available in the Department of Civil Engineering and Applied Mechanics for a man with interests in the broad field of engineering hydrology. Required qualifications are Ph.D. or equivalent research experience. Extensive soils and fluids laboratories are available for independent research. Teaching load is moderate. Initial appointment as Assistant Professor, salary range $7,000 to $9,000 plus benefits, to be made September 1.

Inquiries to Professor J. O. McCutcheon, Chairman, Department of Civil Engineering and Applied Mechanics

---

PHYSICIST TO LEAD RESEARCH GROUP in the field of thermo-electricity required by an expanding organization specializing in the production of the rare metals and semi-conductor materials. Minimum qualifications Ph.D. or equivalent and preferably at least two years' experience in industrial research. The post presents great opportunity to a scientist of the right character. Good working conditions in the country but close to London.—Apply Box No. 688, T. G. Scott and Sons, Ltd., 1 Clement's Inn, London, W.C.2.

QUEEN'S UNIVERSITY

KINGSTON, ONTARIO, CANADA

EXPERIMENTAL PHYSICIST

Applications are invited for an appointment in Experimental Physics from September 1, 1963. Fields of Research in which candidates will be considered are Radio Astronomy, Nuclear Physics, and Solid State Physics Salary and rank will depend upon qualifications and experience. The minima of the salary scales are as follows: Professor, $12,000 ; Associate Professor, $9,000 ; Assistant Professor, $7,000 per annum. The new three-million-dollar physics building with a research wing is on schedule for completion in 1963. One purpose of the appointment is to strengthen postgraduate work. This is an excellent opportunity for a research physicist with a good publication record to find satisfaction in the combination of teaching and research.

Applications and inquiries should be addressed to the Head of the Department of Physics.

UNIVERSITY COLLEGE OF CAPE COAST, GHANA

DEPARTMENT OF SCIENCE

Applications are invited for

LECTURESHIPS
and
ASSISTANT LECTURESHIPS

in the following subjects: 1. Chemistry. 2. Zoology. 3. Botany. 4. Physics. 5. Mathematics. Applicants must have good science degrees with, preferably, experience in teaching. Teaching experience up to Sixth Form or " A " Level may be considered. It would be an advantage for candidates to have the following special interests, for Zoology: Marine Zoology or Physiology or both or Vertebrate Zoology; for Botany: Morphology or Mycology or Taxonomy (field work). Research facilities will be available in due course. Unusual opportunities exist for Biologists. Salaries: Lecturer, £G.1,050 by £G.50 to £G.1,400 by £G.75 to £G.1,850; £G.1.900 per annum. Assistant Lecturer, £G.900, £G.950 per annum. Twenty per cent addition for non-Ghanaians. Entry at appropriate point. Appointment normally five years in the first instance. Outfit allowance £G.60 (where applicable). Car maintenance allowance £G.150 per annum. Family allowance for non-Ghanaian £G.50 per annum for each child in West Africa or, if under 21 years of age and being educated outside West Africa £G.100 per annum (maximum five children). Accommodation with basic furniture. Rent not exceeding 7.5 per cent of salary. F.S.S.U. policies maintained if already held or superannuation on similar basis. Passages for appointee and family on appointment and normal termination payable. Annual leave with three return passages in every four years for non-Ghanaians and one in every three years for Ghanaians.

Applications (six copies), giving details of qualifications, etc., and naming three referees, should be sent before March 18, 1963, to the Assistant Registrar (Overseas), University of Ghana, 15 Gordon Square, London, W.C.1, from whom further information may be obtained.

ROYAL COLLEGE OF SCIENCE AND TECHNOLOGY

GLASGOW

POST-DOCTORAL FELLOWSHIP IN PHYSICAL CHEMISTRY

Applications are invited for the above post. The work will be concerned with the application of radioactive tracer methods to the study of the solid state and will be under the direction of Dr. J. N. Sherwood. The appointment will be for a period of two years from October 1, 1963. The salary will be £1,000 per annum plus F.S.S.U. benefits

Applications, including the names of two referees, should be sent to: P. L. Pauson, Professor of Chemistry, George Street, C.1, as soon as possible.

UNIVERSITY OF IBADAN

Applications are invited for (a) Senior Lectureship or (b) Lectureship in Chemical Pathology, from medical., qualified candidates with appropriate training and experience. Salary scales: (a) £2,650 by £100 to £2,950 per annum. (b) £2,200 by £100 to £2,600 per annum, both carrying honorary consultantships to University College Hospital. Passages paid for appointee, wife and up to five children under 11 years, on appointment, approved overseas leave and termination where applicable. Children's and car allowances. F.S.S.U. Part-furnished accommodation at rent not exceeding 7 per cent of salary.

Detailed applications (ten copies), naming three referees, by March 31, 1963, to Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1, from whom further particulars may be obtained.

BACK ROOM BOYS NEED NOT APPLY—

for we have no back room in which to accommodate you.

Our Research Laboratory in the Home Counties is an integral part of our business in the food industry and has contributed very substantially to our successful record of growth. The work of our Research Scientists brings them into contact with all Departments connected with the development and marketing of our well-known range of products—production, sales, market research and raw materials buying.

Although the Research Scientist operates from the Laboratory (which is amongst the best equipped in the industry) his influence on the Company's progress goes far beyond the ability to conduct successful research : he is a member of our management organisation and his success is measured as much by his effectiveness in contributing to the overall development of a project as by his capacity as a Research Scientist.

As evidence of this, we could quote a number of examples of men who have joined our organisation as Research Scientists and have subsequently been promoted into other Divisions of the Company, e.g. brand management. You could well develop along similar lines, although, of course, there is nothing to preclude you from developing your career within the Research Laboratory if your interest lies more in this direction

Our expansion has created the vacancy for an additional Research Scientist and if you would like to learn more about us, we should be pleased to hear from you. You should have a good honours degree in pure science and a higher degree is desirable We would prefer you to have had experience of research work, preferably in industry and you should be in the age range 25–33.
The initial salary will be in the range

£2,000—£2,300 p.a.

and we operate a non-contributory pension, sick pay and life assurance scheme In the event of a move of house being necessary, the Company will assist in defraying the cost of the removal and will help in obtaining a mortgage

Please address your application in confidence to Personnel Manager, Box 693, T. G. Scott and Son, Ltd , 1 Clement's Inn, London, W.C.2

AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

DIVISION OF ANIMAL HEALTH

RESEARCH BIOCHEMIST

Applications are invited for appointment to a position of Research Biochemist with the Organization's McMaster Animal Health Laboratory, situated in the grounds of the University of Sydney, with which a close association is maintained

The appointee will be required to undertake research on some aspects of chemical pathology particularly in relation to the effects of parasitism.

Applicants should possess an Honours degree in science or a degree in Veterinary Science, with postgraduate training and research experience in Mammalian Biochemistry

SALARY : Dependent upon qualifications and experience within the range :

£A1,541 to £A2,296 per annum.

Salary for a woman will be £A188 per annum less than corresponding rates for men.

Promotion within C.S.I.R O. is by merit and may ultimately go beyond the upper limit of the scale within which the original appointment is made

Fares paid for the appointee and his dependent family Further particulars supplied on application to :

Mr. P. F Butler, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, to whom applications (quoting Appointment No : 202/214), should be addressed by March 30, 1963.

Gas Chromatographers

SWISS subsidiary of the leading U.S. Gas Chromatography company is seeking a qualified Technical Representative as manager for its Sales and Service office in the U.K. The applicant should have a background in Organic Chemistry, two or more years of practical gas chromatographic experience and some basic knowledge of instrumentation. A pleasant personality and interest in meeting people is necessary. Actual sales or management experience is desirable but not essential.

The initial salary, which will be commensurate with qualifications, will be in the region of £2,000

Detailed application indicating present salary to Box 692, T G Scott and Son, Ltd , 1 Clements' Inn, London, W C 2

UNIVERSITY COLLEGE OF NORTH WALES

BANGOR

Applications are invited for the recently instituted Chair of Physical Oceanography. The Chair is intended to provide opportunities for a new approach in the application of the physical sciences to oceanography. It will offer scope for the development, in association with the existing department of Marine Biology, of an integrated programme of teaching and research at undergraduate and postgraduate levels. Applicants should have a wide basic knowledge of physical oceanography, or some field of applied mathematics, physics, geology, or chemistry, which is related to oceanography. The appointment will date from October 1, 1963, or from some other date to be agreed. The salary will not be less than £2,900 per annum, and in addition there will be F S.S U. benefits and family allowances.

Further particulars may be obtained from the Secretary and Registrar, The University College of North Wales, Bangor, to whom twelve copies of the application should be sent not later than March 25, 1963.

ROYAL MILITARY COLLEGE OF SCIENCE

Requires Senior Lecturers or Lecturers in Mechanical Engineering and Mathematics. Duties: Teaching at University level. The successful candidate will lecture to degree courses and specialized courses and, for the post in Mechanical Engineering, assist with laboratory classes. There are extensive well-equipped laboratories. Research is encouraged and work will be suitable for publication and submission for higher degree. Qualifications· First- or second-class honours degree or equivalent. For the Mechanical Engineering post at least two years' experience in teaching, industry, or in research establishments is also required and special experience in the field of theory of mechanics or machines would be an advantage. Salary: Senior Lecturer, £1,396 to £1,720 ; Lecturer, £768 to £1,271. Starting pay may be above the minimum in both cases ; credit for postgraduate experience and National Service. Superannuation under F.S.S U Prospects of permanency. Residential accommodation for single man, prospects of house for married man.

Further particulars and forms from the Registrar, Royal Military College of Science, Shrivenham, Swindon, Wiltshire. (5)

UNIVERSITY OF ESSEX

WIVENHOE PARK, COLCHESTER

CHAIR OF CHEMISTRY

Applications are invited for the First Chair of Chemistry. Salary not less than £2,900 per annum (new scale) with family allowances

Applications should be received not later than March 11, by the Registrar (University of Essex, Wivenhoe Park, Colchester), from whom further particulars may be obtained.

DEVELOPMENT AND EXPLOITATION OF SCIENCE IN THE PUBLIC INTEREST

IN view of the attention which has been given in Parliament and elsewhere in the past year or so to the use of the development contract, it is scarcely surprising that the latest annual report of the National Research Development Corporation* should give some space to discussing the Corporation's activities generally and the extent to which the Corporation is achieving its purposes. Quite apart from the emphasis placed on the work of the Corporation in recent reports from the Council for Scientific and Industrial Research and the co-operation now established between the Corporation and that Department, the Minister for Science has on several occasions recognized the value of the Corporation's work and indicated a readiness to reconsider whether the Corporation is appropriately placed under the Board of Trade. This is being examined by the Trend Committee; but in the meantime the functions of the Corporation received some comment in the report, *Science in Industry*, published last November by the Conservative Political Centre (see *Nature*, 197, 629; 1963).

The Corporation, which was set up in 1949 under the Development of Inventions Act, 1948, was broadly intended, first, to provide a single public body to exploit commercially those patent rights derived from inventions made in the research establishments of Government Departments and the Research Councils. Secondly, it was held that the liaison between centres of research such as the universities and the colleges of technology, on one hand, and industry, on the other, should be strengthened by a public body which could assume the responsibility for undertaking the work of patenting and exploiting inventions. Thirdly, it was believed that a public body should be formed to ensure the full exploitation of the inventive talent of the nation, which, it was sometimes alleged, was frequently frustrated by lack of support for the individual inventor without industrial connexions.

The original Act gave the Corporation the permissive function of securing "where the public interest so requires" the development and exploitation of inventions from publicly supported research and also of inventions from other sources which lack a sponsor. These functions were extended under the 1954 Act, which empowered the Corporation to sponsor research likely to lead to inventions of practical importance. This exploitation activity has been carried out on a considerable scale, and more than 1,000 licence agreements have already been made with industry, of which more than 900 were with United Kingdom firms. The resulting revenue totals about £1·5 million, and payments to individual inventors from these receipts total nearly £300,000; but the Corporation has found no trustworthy evidence to support the belief that inventions are being suppressed because of their effect on the position of established products. The latest report is particularly encouraged by the increase in the number of approaches made by university inventors, and although it is disappointed at a decrease in these coming from Government Departments and Research Councils, one important consequence of the formation of the Corporation is that the medical profession's tradition of refraining from patenting medical discoveries has been reversed and the Corporation is now developing and exploiting in the public interest a number of discoveries in the medical field.

While for financing much technological development the United Kingdom relies, and must continue to rely, on industry, the Corporation has helped industry with a number of projects which appeared worth while from a national point of view. Invariably, such projects required a long development period or resources beyond those available to the firm concerned, or the invention was applicable to no existing industry or seemed unlikely to offer sufficient return to the developer. In these activities the Corporation has gained a unique experience in making the specialized arrangements required with industry and inventors and has evolved its own methods of handling individual projects based on a commercial approach. It is believed that the experience gained will be of much value in handling future projects, but fundamentally the Corporation's obligation to try to pay its way is not readily reconcilable with the obligation to act in the public interest.

The main difficulty is the prolonged period usually required before returns come in on any substantial scale. As much as fifteen or twenty years may elapse between the financing of a project and any substantial return, and in addition the risks are greater than normal. At the end of June 1962, the Corporation's indebtedness to the Board of Trade was almost £6 million, of which just more than £5 million was represented by advances and £920,000 by accrued interest. Its borrowing powers from the Board of Trade at Treasury rates of interest is limited to £10 million and the power to make advances up to this ceiling expires in June 1969.

The report recapitulates five commercial disabilities under which the Corporation at present operates. Overall, the sponsorship of inventions is notoriously speculative, and especially when the Corporation is concerned with inventions which industry itself is not prepared to sponsor on its own account. While, however, the development of an invention is essentially a risk-taking activity, the Corporation is not provided with risk capital. It operates on loans which cannot be written off and on which interest accumulates, notwithstanding that the money may become locked up in long-term development projects, which if successful will produce no income until industry has taken over, or if unsuccessful will be irrecoverable. Thirdly, while industry normally pays for development out of the trading profits it earns, the Corporation is not permitted, except in special circumstances, to enter into trading. It has thus no bread-and-butter business or trading profits to use for financing new projects, establishing reserves, or paying for unsuccessful ventures.

Fourthly, much work and money are involved in assessing the 1,000 inventions submitted every year. Costs are heavy in terms of overheads, staff salaries, payment for independent experts' reports, experimental work, etc., but although a high proportion of each year's submissions is discarded, the assessment activity is very important if inventors are to have a fair deal and no invention of importance to the community is to remain neglected. Finally, in the nature of the business heavy costs are incurred in patenting inventions at home and overseas, to protect the export trade of United Kingdom manufacturers. The statutory requirement to accept and exploit all inventions offered to the Corporation by Government Departments calls for large outlays on patent costs, and while much of this expenditure bears fruit, a considerable part proves to be abortive.

---

* National Research Development Corporation. Report and Statement of Accounts for the year 1st July, 1961, to 30th June, 1962. Pp. ii+34. (London: H.M.S.O., 1963.) 2s. 3d. net. See also p. 960 of this issue of *Nature*.

The Corporation is particularly disturbed that most of its present income is derived from a small number of the inventions in its portfolio. Although it might happen in the future that a single invention would yield a revenue sufficient to transform the whole of the Corporation's financing, in the absence of any such windfall the prospects of the Corporation being able to balance its accounts on the basis of interest-bearing capital with no power to write off are remote. Since the Corporation operates solely on interest-bearing loans without any risk or equity capital in the notoriously hazardous field of invention, its members are forced to conclude that, with its existing capital structure, the prospects of the Corporation achieving its statutory objective of paying its way must be remote.

Nevertheless, the members of the Corporation are in no doubt that the continued existence of the Corporation is justified. Bearing in mind the vast Government expenditure on research and development in other spheres of activity, they consider the public receives exceptional value for money from the activities of the Corporation. It has played a major part in establishing industries of great potential importance, and in introducing important products or processes in others, for relatively small outlay by the community. Much of this outlay of £6 million, including interest charges, will prove to be recoverable. Moreover, and this is of special importance, the Corporation's methods of operation encourage the establishment of industries and processes capable of standing on their own feet rather than relying on continuing Government subsidies.

Specifically, the Corporation obtains substantial revenue, much of it from abroad, from inventions arising in the United Kingdom; it provides unique facilities for inventors who seem, by and large, to consider that they are fairly treated; it bridges the gap between research carried on in public research establishments, the universities, etc., and the practical application of the results of such research; it works in increasingly close co-operation with industry's own research establishments and seems to be gaining steadily the confidence of industry itself; it has taken the initiative in providing co-ordinating machinery for investigating and sponsoring projects of common interest to more than one field of industry or to different firms within the same field, frequently projects which otherwise would never have been started. It has also helped to develop inventions in the surgical and pharmaceutical field primarily for their humanitarian rather than profit-earning value; it fosters projects calculated basically to be of value to the nation where the prospects of return to the Corporation are slender or non-existent; and it has acted in a catalytic role in introducing research results to industry again with no resulting financial reward.

These judgments are substantiated from the present report and from earlier annual reports, and the conclusion that, with its strict control of expenditure and its small, loyal and now uniquely experienced staff, the Corporation has a part of increasing practical value to play in the nation's affairs that cannot be dismissed or discounted as *ex parte*. It is fully supported by comments in reports from the Advisory Council on Scientific Policy, the Council for Scientific and Industrial Research and by the observations in the report *Science and Industry* from the Carr Committee of the Conservative Party, which on political grounds at least might be expected to be critical of an institution created by a Labour Government. That Committee, however, fully recognized the value of the Corporation's work and that its main difficulty has been to meet its statutory obligation to pay its way. While it considers that the commercial slant should be retained, both for its value in maintaining the morale of the Corporation's staff and in ensuring that the projects are assessed and reviewed, it suggests that extra support should be given, possibly by some form of direct grant, to those projects to which a special degree of risk is attached.

This proposal could well involve difficulties in view of the exceptionally long time that is likely to elapse before any substantial returns are received on advances for projects of this character; reconsideration of the place of the Corporation in the Government organization for civil research and development as well as of the basis of its finance may be advisable. The latter could well fall outside the terms of reference of the Trend Committee, but the Carr report also recommends further consideration of a recommendation of the Radcliffe Committee on the Working of the Monetary System. This was for an Industrial Guarantee Corporation which would "guarantee for a commission, an agreed proportion of loans made by existing financial institutions to borrowers wishing to finance novel processes or the manufacture of new types of product". Implementation of this proposal might enable the National Research Development Corporation to obtain the extra support needed by insuring its more risky projects with this body.

The Carr Committee urges that this recommendation of the Radcliffe Committee should be adopted. However, although it considers that the National Research Development Corporation has not so large a part to play in financing certain kinds of invention as was thought when it was first established, it does not discuss the question how far the Corporation could be used for other purposes, such as placing of development contracts. It was in this context that the Minister for Science indicated that he had asked the Trend Committee to look specifically at the functions of the Corporation and its position under the Board of Trade. Both the Carr report and the Corporation's own annual report demonstrate that the Corporation has a real part to play in financing invention and they should stimulate further thought as to the most appropriate means by which the necessary finance should be provided. Such consideration should now be proceeding as it is unlikely that the Trend Committee will feel free to make recommendations on that aspect of the Corporation's work.

What might equally receive attention, however, is the more positive function opened up for the Corporation under the 1954 Act, through which it is continually surveying the needs of industry for new techniques and products, for improving existing ones, and for developing new knowledge resulting from present-day research. The report sites its investigations in the cryogenics field which have led to the sponsorship of the cryogenic engineering project and its efforts to encourage in the United Kingdom the establishment of adequate industrial facilities in this field. Its investigations in relation to the mechanical properties of solids are also noted. A conference sponsored at the University of Cambridge in July 1961 to formulate proposals for research and development in this relatively new field aroused considerable interest. The tempo of work generally was increased and programmes have been expanded to take note of the recommendations of this conference, and steps are being taken to co-ordinate the work being carried out in the public research establishments.

It may be for consideration how far the National Research Development Corporation should function in this way and whether it is not here entering on activities which the Council for Scientific and Industrial Research should be fostering. If the Corporation through its experience has a vital contribution to make, activities of this kind provide one strong reason for placing it in closer relation to the Department of Scientific and Industrial Research and within the survey and responsibility of the Minister for Science rather than the Board of Trade. Some clear thinking on these and related issues is imperative when the whole structure of Government organization for civil research and development comes under review.

RADIOBIOLOGY'S EXPANDING FUNDAMENTALS

Fundamentals of Radiobiology

By Z. M. Bacq and Peter Alexander. Complete revised second edition. (International Series of Monographs on Pure and Applied Biology. Division: Modern Trends in Physiological Sciences, Vol. 5.) Pp. xii + 555. (London and New York: Pergamon Press, 1961.) 70*s*. net.

In the preface of the first edition of this book, the authors remarked on the diversity of disciplines involved in radiobiological work, and radiobiologists do indeed need to have an acquaintance, at least, with a wide variety of subjects. The difficulties for beginners in this field can easily be imagined, and a brief but adequate survey of the basic facts and present working hypotheses is very necessary for them. The 350 pages of the first edition proved to be a very useful text for this purpose, but the second edition runs to more than 500 larger pages and the tiro's task has thus increased. Much new material has been incorporated and the increase in size is in many ways an indication of the enormous number of radiobiological publications during the six years between the editions. An increase in the amount of data available, however, should not necessarily mean an increase in the 'fundamentals' of a subject. As the authors have resisted the temptation to change their title when they changed publishers, it is hoped that they will resist the temptation of turning their volume into a large text-book. Perhaps this second edition is merely suffering from the adiposity of adolescence, in which case we can look forward to the third and fourth editions regaining the slimness of the youthful *Fundamentals*.

The book is, however, still unique in its general usefulness and no other covers the scientific aspects of the subject so well. Although primarily intended for beginners, more experienced workers will, no doubt, refer to it for guidance in those aspects of the subjects outside their own field. These latter users will find a good deal of extra information and some shifts of emphasis in the new edition. The nature of the initial chemical lesion is stressed, the chapter on radiation effects on macromolecules has almost doubled in size and the section on "alteration of permeability in cells" is replaced by one on "the enzyme-release hypothesis". The chapters on the processes of restoration and the physiopathology of radiation sickness are greatly expanded and there are new chapters on delayed effects and the interaction between cells and tissues following irradiation. As one would expect from these authors the chapter on chemical protection is particularly useful. Genetic effects of radiation are only very briefly described.

This is not an impersonal book, and it is pleasant to note how the authors are ready to become expansive when they reach their own interests and how, after marshalling a number of theories, they are ready to offer summaries and conclusions. There is sometimes a lack of clarity in the writing and in some parts peculiar phraseology is used; for example, "profound trouble in cholesterol synthesis" (p. 399). Misprints, even when acknowledging illustrations (for example, Figs. 20–2 and 20–3), and errors such as "polynucleated" instead of "polymorphonucleated" and "picnotic" instead of "pyknotic" are not uncommon. Numerous references follow each chapter, but occasionally they are not mentioned in the text, and in one instance experiments are attributed to an author which he did not do and a conclusion which he did not draw.

CLASSICAL PROBLEMS IN PHYSICS

Cavendish Problems in Classical Physics

Edited by Prof. A. B. Pippard. Compiled by the Staff of the Cavendish Laboratory, Cambridge. Pp. x + 51. (Cambridge: At the University Press, 1962.) 5*s*. 6*d*. net; 1 dollar.

In the preface to this excellent collection of problems, Prof. Pippard mentions the situation that faces university teachers of physics. It is necessary to move with the times, and to spare no efforts to make physics, and a career in physics, attractive to students. 'No amount of exciting new presentations of the basic ideas is going to make it easy for the student to acquire professional competence If he cannot make a good showing at these classical problems all his expertise in the realm of ideas is so much vanity; for they are examples of what will continually confront him in the practice of his art." What he is really saying was said long ago, that there is no royal road; and as improved teaching takes the drudgery out of learning, the discipline must still remain. The observations in the preface are wise, and relevant to physics teaching at all levels nowadays; though one feels that Prof. Pippard is inconsistent in saying that the conversion of electrical units is responsible for more error than anything else in physics, and also chiding as folly the views of those who settle for avoiding conversions.

The problems are varied and challenging. Some are straightforward calculations, a few are standard theorems, many involve the two- or three-stage application of elementary principles and would be within the scope of a scholarship candidate; others, not too difficult in principle, require a mature mathematical approach. They find the chinks in the armour, too ; of two equally innocent-looking examples, I did one in my head and spent a fruitless hour on the other. In general, the forty or so questions on thermodynamics seem to be more exacting than the rest—perhaps because they offer the inquisitor more scope, or it may be that one meets this type of question less regularly and is less able to judge.

A selection of classical problems naturally includes examples gross as Earth; and besides satellites and rockets there is one about the building of the Great Pyramid.

one on the interantipodeal tunnel, and one about the Eiffel Tower. It also covers the classical physics of the microscopic world—free electrons, α-particles, protons and electrons in atoms. The correspondence principle, the Schrodinger equation, and Planck's constant appear; these are properly classical too. (There ought to be alternative answers to the problem about engraving the Lord's Prayer on a pin-head, since it comes in two lengths, differing by about 8 per cent.)

Many of the problems originated as questions in Part 1 of the Natural Sciences Tripos. Behind them lies an inventive genius that can design examples to exercise specific techniques, and build in both standard difficulties and unusual subtleties; with an occasional sparkle of wit. I have not sampled all the problems myself; but I am sure that they will develop the competence of students at this level, while maintaining their interest and enthusiasm.

G. R. Noakes

TECHNOLOGY AND SCIENCE OF CERAMICS

Progress in Ceramic Science

Vol. 2. By Dr. J. E. Burke. Pp. vii+245. (London and New York: Pergamon Press, 1962.) 80*s*. net.

Science of Ceramics

Vol. 1: Proceedings of a Conference held at Oxford, 26–30 June 1961, under the auspices of the British Ceramic Society and the Nederlandse Keramische Vereñiging. Edited by G. H. Steward. Pp. 334. (New York and London: Academic Press for the British Ceramic Society, 1962.) 65*s*.

TEN years ago anyone wanting a book on either the technology or science of ceramics would have had a rather limited field from which to choose, but so rapid has been the development of interest in non-metallic inorganic materials in the past few years that the supply of substantial literature can barely meet the demand. Technological pressure in the field of materials research has opened up new horizons both for the applied scientist and for the fundamentalist in solid state physics, and the two books reviewed here illustrate both aspects of this.

The book *Progress in Ceramic Science* is the second of a series put out by the publishers to provide a continuing review under the general editorship of Dr. J. E. Burke of the General Electric Co. Research Laboratory, Schenectady, and contains just four major contributions from American authors. The first, on dislocation etch-pits in non-metallic crystals, provides a useful survey of theory and techniques which should offer some encouragement to workers who are apt to complain that their materials are so full of holes anyway that crystal defects can scarcely matter! The second article deals with the catalysed crystallization of glass, and comes from the laboratory (Corning) in which the 200-year-old observation of Réaumur has been turned into a brilliant practical reality. The theory of crystallization in glasses is outlined, and nucleation by the use of oxide and metal catalysts and by the action of ultra-violet light or X-rays on photosensitive glasses is discussed. Next comes a chapter on radiation damage, an important question in view of the increasing interest in the use of oxides and carbides, rather than elemental metals, in nuclear engineering. The last chapter is an examination of the problem of thermal conductivity in ceramic dielectrics and provides a wealth of new experimental information on a wide range of oxide materials and glasses.

The book *Science of Ceramics* is quite different in character and is in effect a supplementary volume to the *Transactions of the British Ceramic Society*. It is the outcome of a joint effort between the British and Netherlands Ceramic Societies to co-operate in providing a European forum for the exchange of papers on the 'basic' science of ceramics, and it is a record of the proceedings of a conference held in Oxford in the summer of 1961—the first, one understands, of a series of such conferences. Apart from the very useful and authoritative review of sintering by Prof. J. White with which the book opens, the other twenty-two papers are accounts of various researches in progress, ranging from studies on clays themselves to the properties and performance of end-products as diverse as building ceramics, high-permittivity dielectrics and fluoride-based ceramics.

Both books are very well produced and contain some fascinating optical and electron micrographs. With such a rapidly expanding subject, it would be pointless to comment on the probable permanent value of either volume, but there is no doubt of their timeliness and immediate value.

N. F. Astbury

ORGANIC SEMICONDUCTORS

Organic Semiconductors

Proceedings of an Inter-Industry Conference. Editors: James J. Brophy and John W. Buttrey. Pp. xi+243. (New York and London: The Macmillan Company, a Division of the Crowell-Collier Publishing Company, 1962.) 68*s*., 9.00 dollars.

THE recognition that conjugated organic substances can behave as intrinsic semiconductors by virtue of thermally excited π-electrons only dates from 1948. Over the ensuing years a few papers appeared every year, until around 1958 contributions started to appear in various scattered conferences. By this time the main types of compound, phthalocyanines, polyaromatics, charge-transfer complexes, etc., had been recognized, and in 1959 there appeared reports of semiconductivity in polyacrylonitrile. This activity had developed in such widely scattered countries as England, the U.S.S.R. and Japan, and around 1959 several large American industrial firms decided to proceed on from literature surveys to active experimental work. The result has been an ever-increasing volume of papers which have given considerable stimulus to the subject. The present volume is entirely concerned with these American contributions. The first three papers, by R. G. Kepler, O. H. LeBlanc, jun., and M. Silver, are concerned with the experimental and theoretical aspects of determination of charge carrier mobility in highly purified single crystals of anthracene. The pulse techniques advocated by these authors may be expected to be widely adopted by workers in the field and form a contribution of great importance.

Further papers deal with charge-transfer complexes in single crystal form, and there are a variety of papers dealing with d.c. measurements on compressed powders, of which the two papers by H. A. Pohl on semiconduction in polymers are worth special mention. There is a very substantial contribution by C. A. Klein on the electrical properties of pyrolytic graphites, and the volume concludes with a not too illuminating "management appraisal". Those academic scientists interested in the purely scientific aspects of organic semiconductors will be able to find a good deal of the present work available in fairly accessible journals. But industrial scientists requiring a fairly up-to-date collection of papers prepared with industrial research in mind will find this volume very useful. I myself have long held the opinion that industrial developments in this field have been held up by the need to secure collaboration between electrical and chemical industries. Conferences such as the present one should help to break down the dividing barriers, and deserve every encouragement.

D. D. Eley

FINGER-PRINTS, PALMS AND CHROMOSOMES*

By Prof. L. S. PENROSE, F.R.S.
Galton Laboratory, University College, London

Historical Notes

THE analysis of finger-prints from the point of view of personal identification is well known. Early examples can be taken from Chinese documents. In modern times the method is used by police and immigration officials. The principle involved is that the ridges formed by the raised apertures of sweat glands have unique detailed formations which have arisen almost by pure chance. The large-scale pattern of ridges, however, is much less fortuitous in origin. There are anatomical regularities[1]. There are also normal variations, which represent hereditary differences between members of separate populations, members of the same population or members of the same family.

The contrast between general pattern and detail is made fairly clear by the study of identical twins. The general configurations of ridges agree, as hereditary traits should, on the hands of such pairs, and there are usually only slight differences in arrangement; but the details do not agree and are individually specific.

All configurations are laid down permanently at a very early period of development, during the third month of fœtal life. Best known are those on the finger-tips.

Description of Triradii, Main Lines and Creases

The systematic classification of ridge patterns, which can be used as a preliminary in personal identification, was first proposed by Galton[2]. It depended on the recognition of 'deltas', now known as 'triradii'. These are natural centres, and the radiant ridges form the main lines of the patterns or configurations.

A triradius can be defined as the meeting point of three spokes which demarcate three regions, each containing a system of almost parallel ridges. One triradius on a finger-tip always accompanies a loop pattern (Fig. 1) and two produce a whorl. In the absence of any triradius, the pattern is known as an open field, arc or arch.

On the palm there are normally four triradii, one at the base of each finger, called *a*, *b*, *c* and *d*, and another, known as *t*, near the base of the fourth metacarpal bone or at some point on its axis.

By starting at the triradii, the configurations of the main lines of the dermal ridges can be marked out (Fig. 2). The patterns produced on different hands fall into natural groups and the most prominent lines are named, for example, *A* and *D*.

At this point it may be well to emphasize that the dermal ridge main lines are of an entirely different character from the flexion creases which have such an attraction for fortune-tellers. The flexion lines on the palm, traditionally named after the head, the heart and life, and the creases on fingers certainly show interesting variations, but the ancient interpretations have to be revised.

Physiological Variations

These large-scale patterns of lines and creases are all strongly, but not exclusively, influenced by heredity. On the corresponding hands of identical twins, dissimilarities can be attributed to environmental modifications; they differ about as much from one another as do normally the left and right hands of a single person.

Just as the sexes differ in stature and other physical traits, so also are there characteristic peculiarities of dermal ridges to be found in males and females by careful analysis. All these variations can be considered to be physiological, like the fact that female stature is less than male stature; their presence sometimes obscures pathological changes in pattern.

Tests of Inheritance of Dermatoglyphic Traits

Analytical investigations of hereditary influence can best be made by quantitative methods which involve counting ridges between specified points or measuring angles. One well-established result is that obtained by measuring the size or 'intensity' of the finger-tip patterns. The measurement is made by counting the ridges crossed

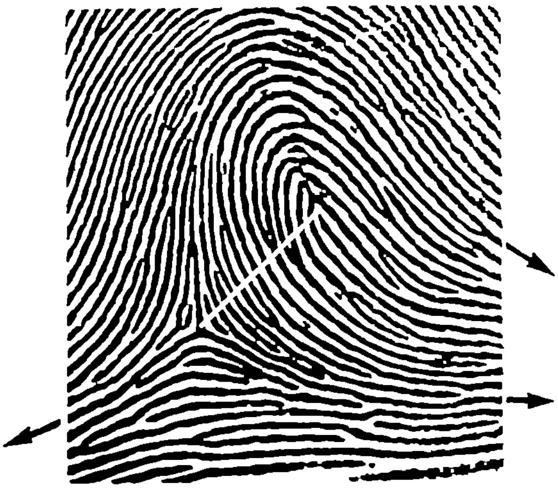

Fig. 1. Loop pattern on a finger: the arrows mark continuations of the three ridge lines which radiate from the delta or triradius. The white line joining the delta to the pattern core crosses 18 ridges

Fig. 4. Stereotype pattern found in mongolism

by a straight line drawn from the triradius to the core of the pattern[3]. An arch scores zero and a loop 12, on the average: usually whorls score still higher, about 19 (only the larger of the two numbers obtained in a whorl is recorded). The total score for all ten fingers averages about 145 in males and 127 in females. It is a trait which, like stature, is determined by many genes with a combined additive action. This is demonstrated by analysis of families, in the traditional manner, using correlation coefficients to measure hereditary likeness. The characteristic value, in a random population, for parents and their children and for sib pairs is 0·5; and this is very closely approached by observations on the total finger-ridge count[4]. Equality of inheritance from father and mother to sons and daughters excludes sex-chromosomal influence.

Other traits, such as the position of *D*-line exit, the third interdigital pattern[5], the number of ridges between *a* and *b*, the presence or absence of thenar[6] patterns and the maximal *atd* angle[7], can all be shown to have strong genetical determination; but these features are more capricious than the total finger pattern quantity and more influenced by early fœtal environment. Some of them, like angular measurements, can alter with age.

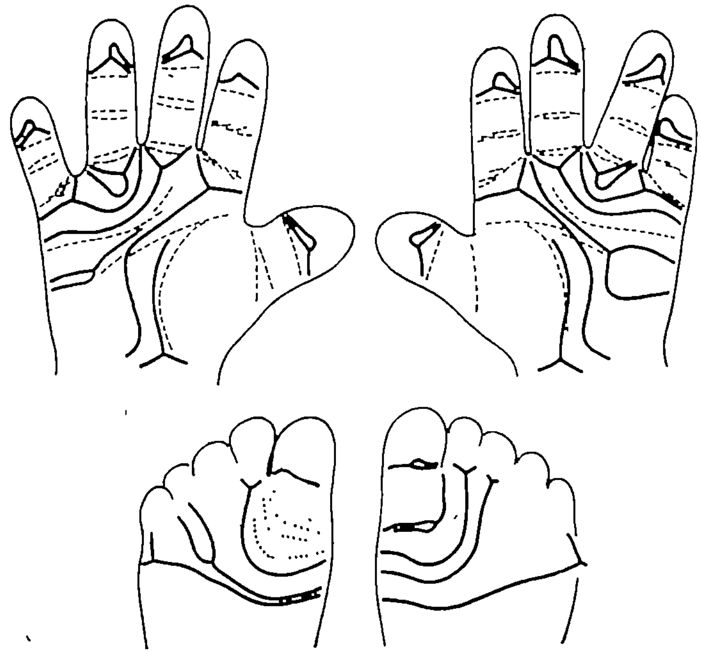

Fig. 5. Main lines on prints of palms and soles from a mosaic mongol female child whose cells are about 1/3 trisomic and 2/3 normal. Note the open field on left hallucal area (scale for hands and feet doubled)

Distortions caused by Growth Abnormalities

Any early disturbance of growth which affects the hands r the feet is liable to cause distortions of the natural lermatoglyphic patterns. The classical example is olydactyly, in which an extra digit is often associated vith an extra triradius. Conversely, ectrodactyly[8], or oss of digits, and also syndactyly, fusion of digits, leads o loss of triradii or alterations of arrangements which nay be very extensive (Fig. 3). These distortions can be orrectly said to be caused by abnormal genes, but they re secondary effects; the underlying developmental listurbances are the more direct results of abnormal gene ction. Some distortions are quite obscure in origin, uch as the very rare vertical alignment found in some alms and usually connected with digital deformity.

Distortions caused by Chromosomal Aberrations

Many curious and unexpected distortions of pattern on alms and soles occur in connexion with chromosomal berrations. The common types indeed present highly haracteristic peculiarities. I will describe them in turn.

(1) *Mongolism.* This condition, in which there is a nultiplicity of anomalies, was first recognized nearly a hundred years ago by Down. It has, of course, nothing to do with Mongolian peoples specifically. Recently its origin in chromosomal aberration has been proved. The hands were first examined dermatoglyphically by Cummins[9] in 1936. Before this the flexion creases had interested clinicians, and the transverse palmar crease, or simian line, played an important part in diagnosis. According to the students of cheiromancy, this crease is equivalent to the fusions of the lines of the head and the heart; it is a sign of concentrative mental power. Other alterations in flexion lines of mongols include a marked crease between first and second toes and occasional absence of the distal creases on the fifth fingers[10]: these have passed unnoticed by cheiromancers.

On the hands, one noticeable feature of the mongol stereotype is the strong tendency for every finger to possess a loop pattern rather than a whorl or an arch (Fig. 4). Moreover, the distribution of radial loops on digits IV and V in mongolism is unusual as compared with normal hands. The total finger-ridge count is less variable than among normal people[11]. Very characteristic is the central position, on the palm, of the triradius *t* which sub-tends an angle of about 80° with the points *a* and *d* (and in this position it is called *t*″) instead of the normal 45°. Hypothenar patterns are common and thenar patterns rare. A distal loop is nearly always present between *b* and *c* (the third interdigital region). The ridges themselves are often poorly formed.

On the hallucal area of the sole, patterns are infrequent and an open field is typical[12].

One of the recent important discoveries in human cytology is that more than one genetical cell type can take part in the formation of the same individual. A person in whom this occurs is called a mosaic. A person can be a partial mongol in that only a proportion of his cells are abnormal. These abnormal cells are usually distributed fairly evenly over the whole body and thoroughly intermingled. It has, for many years, been observed that some people exist who have a few characteristics of mongolism but that they are otherwise perfectly normal. There are also mentally sub-normal patients who are incomplete mongols. Some of these people are in fact mongol-normal mosaics in varying degrees. Their dermatoglyphs are interesting in that they show some of the features of the mongol stereotype (Fig. 5)[13]. The degree

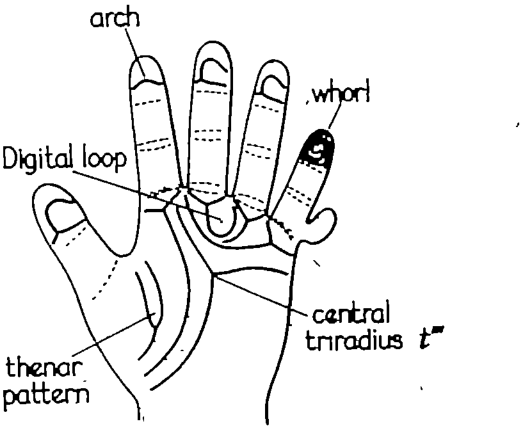

Fig. 6. Palmar pattern stereotype found in trisomy 18

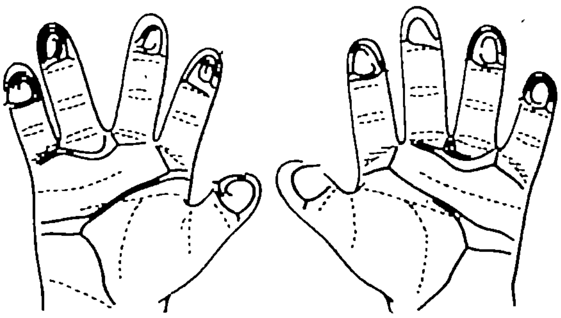

Fig. 9. Typical dermatoglyphics in Turner's syndrome

of distortion is not closely related to the proportion of abnormal cells, as demonstrated in cultures, nor to the level of mental development attained.

(2) *Trisomy* 13. An entirely different group of peculiarities characterizes other trisomic conditions. Those connected with trisomy of chromosome No. 13 (it may be No. 14 or No. 15—we are not quite sure) are striking. Deformities of the eyes, lips, palate and ears are part of the clinical picture. Polydactyly may be present and this itself is likely to upset the dermatoglyphic pattern. The stereotype includes a very distal axial triradius, the position of which, as measured by the angle *atd*, is distorted more than it is in mongolism and could sometimes be called t''' (Fig. 6). The extra patterns, however, tend to be in the thenar, not the hypothenar, region. Unlike the mongols, their fingers show both arches and whorls as well as loops (Fig. 7). On the soles of the feet there are few triradii and peculiar loops or open fields are the rule[14]. These observations are obtained with considerable difficulty since most of these cases fail to survive more than a few weeks and the hand-printing even of normal new-born infants is far from easy.

(3) *Trisomy 17 or 18*. The third kind of well-established autosomal aberration concerns trisomy of either chromosome No. 17 or No. 18, it is uncertain which. The head is long, ears are 'low set' and the chin is small. Again there is a stereotyped distortion of dermal ridge patterns along with a group of physical peculiarities (Fig. 8). The hands are specially difficult to examine because the fingers are held permanently flexed but with the distal joint extended. There is absence of the distal flexion creases on most fingers and the tips only rarely have any triradii on them and nearly all the patterns are arches[14]. In contrast to the mongols and trisomics No. 13. the palms show no obvious abnormality. The hallucal areas of the soles, however, have somewhat unusual configurations with fairly wide open fields and there are arches on the toes.

(4) *Turner and Klinefelter types*. When we come to sex chromosomes there is a wealth of material for study, and some surprising results have been derived. First of all, Turner's syndrome, in which there are only 45 chromosomes in each cell nucleus because there is one X and no Y present, shows various peculiarities. The patients are females with short stature and are liable to have webbing of the neck and slight limb deformities. There is no very stereotyped dermatoglyphic pattern but a general tendency to certain types of arrangement (Fig. 9). The pattern intensity on the finger-tips is high, large whorls are common and the total ridge number is, on the average, greater than normal. On the palms, the axial triradius is found nearer the centre than is usual in controls: on the average it is in the position t' (Fig. 10). Thenar patterns are not uncommon. The upper region of the palm is

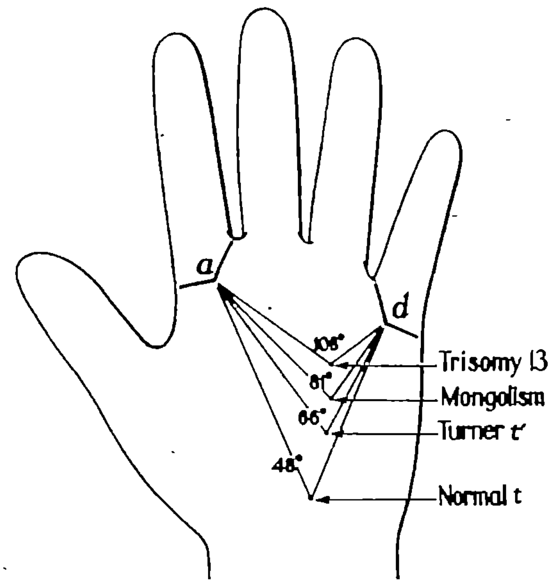

Fig. 10. Mean position of most distal triradius t in children up to 4 years of age

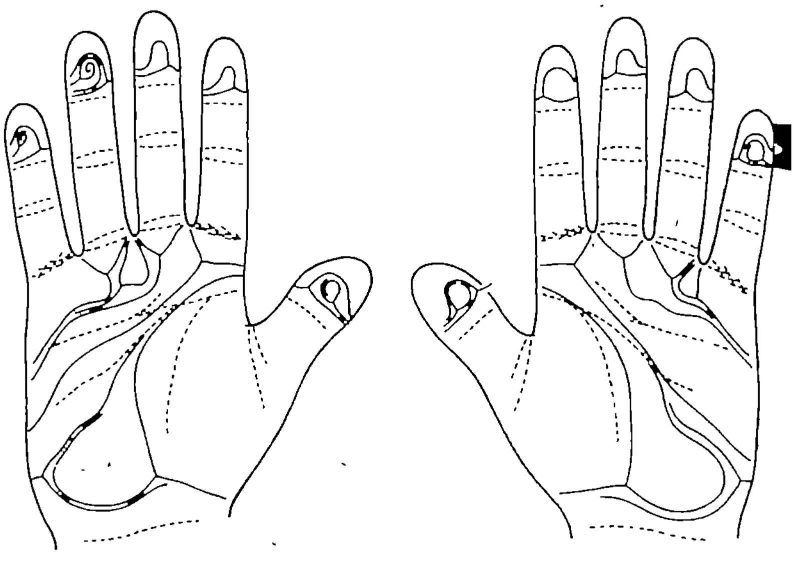

Fig. 11. Example of dermatoglyphics in a male with $XXXXY$ sex chromosomes

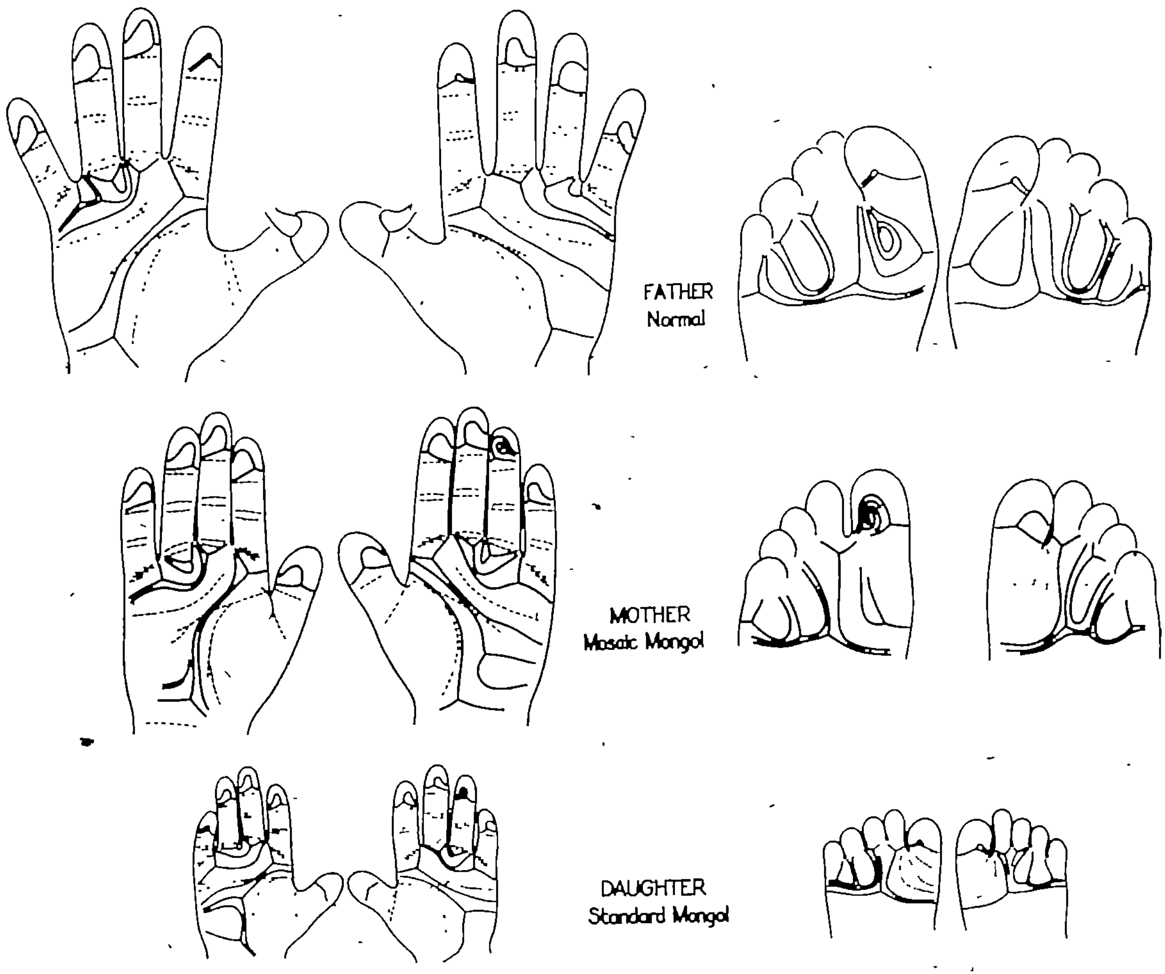

Fig. 12. Palms and soles in a family with mosaic mongol mother and standard mongol daughters

often peculiar in that triradius *b* tends to move towards the ulnar side of the hand. Correspondingly, the distance between *a* and *b* and the mean number of ridges between them is increased.

Mosaics composed of Turner and normal cells show the same features as in Turner's syndrome and, also, other conditions, where one of the *X* chromosomes in a female is grossly aberrant morphologically as, for example, when it forms a ring and has suffered deletion.

One might suppose that a person who has too many *X* chromosomes, instead of two few, would show the opposite characteristics of the Turner's syndrome. The triple-*X* females, however, show very little deviation from the normal dermatoglyphs. The tendency for high ridge scores to occur on finger-tips in a Turner is replaced by a normal, and perhaps a slightly lowered, count. Males, with additional *X* chromosomes giving rise to the syndrome of Klinefelter, are tall rather than dwarfed and they have, in association, rather long hands and feet. Finger-prints show a slight general tendency towards patterns with low counts and arches are quite frequently observed. The axial triradius, on the average, is low down in the palm, probably a little lower than in normal hands, especially when there are more than two *X* chromosomes[15], as occasionally happens (Fig. 11); there is, however, no obvious stereotype connected with the possession of too many *X* chromosomes. There is insufficient information to say what effect is produced by having too many *Y* chromosomes.

(5) *Miscellaneous anomalies.* Many miscellaneous examples are known where chromosomal aberrations have been found and where enthusiasts have printed the hands and feet in the hope of finding characteristic variations. Sometimes observers are lucky and sometimes not. The key factor seems to be to what extent the chromosomal change induces a disorder of limb growth for, as we have seen, any such change is likely to distort the normal patterns. Since many of the aberrations observed are unique, the evaluation of the findings is difficult. Usually the most useful information obtained is that the patient's dermal ridge patterns do, or do not, resemble a known stereotype associated with known trisomics. The observation may then be used to aid the cytologist in sorting out which chromosome is involved in a particular aberration. For example, if the hands of a patient trisomic for a small chromosome do not show any traits of mongolism, there is a strong likelihood that the chromosome concerned is not the usual one, for example, No. 22, not No. 21.

Genetical Studies on Distortions

Somewhat more definite results can be obtained when groups of close relatives are studied. The correspondence between a chromosomal aberration and a dermatoglyphic pattern can be followed through more than one generation. Here are some examples.

(1) *Mongolism with mosaicism.* It was possible, over a period of years, to examine the inheritance of the position of the axial triradius in relation to mongolism before anything could be known about its chromosomal origin. It became clear that mothers of mongols, especially if they had more than one affected child, were more

likely than control females to have centrally placed axial triradii[7]. No explanation then seemed satisfactory. However, if the mother should, as is now known to happen, suffer from an aberration involving chromosome No. 21, this could both tend to cause mongolism in her children and produce some features of the mongol stereotype on her own hands and feet (Fig. 12). The best example of this occurs when the mother is herself a mongol or a mosaic mongol[16].

(2) *Mongolism with translocation.* Another type of situation occurs when the mother transmits what is called a translocated chromosome, caused by breakage followed by the rejoining of the wrong ends. In one section of a certain family, every individual who carried an abnormal chromosome after it had arisen by translocation also had a central axial triradius like the two mongols who occurred among its members[17].

(3) *Other unbalanced-autosomal complements.* Equally striking are some cases of abnormal children with aberrations of unusual kinds affecting the larger chromosomes and whose hands showed remarkable dermatoglyphic patterns which included strong thenar configurations[18]. Unbalanced in chromosomal complement they showed, as in mongolism, evidence of growth disturbances and mental retardation. In two families the father, though physically and mentally normal, carried the same translocation as the abnormal children in a compensated form; in each case, his palms exhibited less marked but similar peculiarities to those of his offspring.

Conclusion: Information about Location of Genes from Dermatoglyphs

It would be natural to infer, from observations like those on the families just described, that the gene for this or that dermatoglyphic pattern was located on the aberrant chromosome concerned. One must, however, be wary of all such inferences unless supported by family investigation. Some people have rashly supposed that, because Turner patients are short and Klinefelters are tall, the genes for stature must occupy loci on the X chromosome. Previous observations on the inheritance of stature, however, have shown it to be autosomal, not sex-linked. Exactly the same reasoning precludes us from attributing the observed changes in finger-ridge and a–b ridge counts in Turner's syndrome to the X chromosome genes. Similarly, the stereotypic peculiarities in trisomics, like triple-21 (mongolism) and triple-13, must not be attributed perfunctorily to genes located on No. 21 or No. 13, respectively. The problem of gene location involves extensive long-term investigations. In the meantime let us take pleasure in the fact that even the obscure study of dermatoglyphic patterns is, in spite of its inherent difficulties, at last beginning to play a significant part in the ever-widening field of human genetics.

I thank a great number of colleagues who have helped me to obtain material for dermatoglyphic studies. In particular I thank Prof. P. E. Polani, Dr. J. Lindsten and Dr. M. Fraccaro for many hand-prints from cases of Turner's syndrome, Dr. J. H. Edwards, Dr. C. E. Blank, Dr. W. J. Mellman, Dr. O. J. Miller and Dr. A. Shapiro for obtaining prints from patients with other chromosomal aberrations, Dr. Sarah B. Holt for making available to me the results of her measurements, and Mr. A. J. Lee for his drawings.

AUTOMATIC COMPARISON OF FINGER-RIDGE PATTERNS

By MITCHELL TRAURING

Hughes Research Laboratories, Hughes Aircraft Co., Malibu, California

THE usefulness of finger-ridge patterns in personal identification was established by the investigations of Galton[1–3], after earlier work by Herschel[4] and Faulds[5]. Among many other results, Galton demonstrated that individual finger-ridge patterns are permanently and uniquely characterized by the occurrence and arrangement within them of certain common local details or 'minutiæ' (Fig. 1). This result led to world-wide adoption of the practice of comparing identified and unidentified finger-ridge patterns with regard to the types, orientation and locations of their minutiæ, as an ultimate test of personal identity. The difficulties of automating such comparisons are apparent in the demands they now make on human abilities, not only in detecting and typing the minutiæ in varied ridge-line backgrounds, but also in comparing their locations, for the latter are considered in relation to overall ridge-line topology in order that their comparison be valid as between a finger-ridge pattern recorded at one time and the same pattern, scaled and distorted by physiological and environmental changes, observed at a later time.

It is the purpose of this article to present, together with some evidence of its feasibility, a method by which decentralized automatic identity verification, such as might be desired for credit, banking or security purposes, can be accomplished through automatic comparison of the minutiæ in finger-ridge patterns. The novelties in the method are its use of: (1) photosensitive minutia detectors, which act automatically; (2) 'relative' co-ordinates of minutia location, which are unaffected by affine pattern transformations, supplanting much topological complexity; (3) a tolerance on the agreement required of minutia locations, which allows for detector inaccuracies and for slight departures of actual pattern transformations from strict affineness. For concreteness, the method will be presented in the form of an operational description of an identity verification system. Throughout, patterns will be assumed plane, as when pressed against a flat surface, and the only minutia types utilized will be the ridge end and valley end.

The prospective user of the identity verification system must initially undergo a non-automatic registration

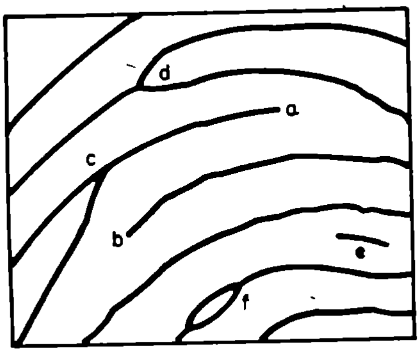

Fig. 1. Portion of fingerprint pattern (diagrammatic, enlarged) after Galton, showing minutiæ. *a* and *b* are ridge ends, *c* and *d* are ridge branchings or valley ends, *e* is an island, and *f* is an enclosure. The ridge end and valley end are the principal minutia types, accounting for almost all minutia occurrences

process wherein data on certain of his minutiæ are taken and stored against the times when claims shall be made on his identity. In this registration process, a set of three non-collinear minutiæ, W, X and Y, designated as 'reference minutiæ', and a number of others, P_i, designated as 'test minutiæ', are selected in one of the registrant's patterns. The registrant places his finger in position in a simple mechanical guide, where the co-ordinates and orientations of W, X, Y and the P_i are measured relative to rectangular co-ordinate axes the origin of which is denoted by O, fixed in the guide. The data stored by the system for each of the three reference minutiæ, W, X and Y, are: its type, its rectangular co-ordinates, its orientation, and its situation relative to one or two immediately neighbouring minutiæ. The data stored for each of the test minutiæ P_i are: its type, its orientation and, not its rectangular co-ordinates, but its 'relative' co-ordinates ξ_i, η_i in a system based on the reference minutiæ, which are computed from its rectangular co-ordinates and those of the reference minutiæ by means of the pair of simultaneous equations $\overrightarrow{OP_i} = \overrightarrow{OW} + \xi_i \overrightarrow{WX} + \eta_i \overrightarrow{WY}$.

When, at a later time and possibly a distant place, a claimant appears and requests that his identity be verified as that of a certain registrant, the system automatically retrieves its above-described stored data on that registrant, for comparison with data to be obtained by automatic observation of the claimant's minutiæ. The claimant places his finger in a guide identical to that used in registration, and having identically fixed rectangular co-ordinate axes the origin of which is denoted by O', whereupon automatic minutia detectors such as that of Fig. 2 scan his pattern, detect his minutiæ and observe their types, their rectangular co-ordinates and their orientations.

As a ridge end detector, each ray and the central disk can distinguish between fully light and not-fully light states. The rays and the disk are connected to circuitry which signals the occurrence of a target illumination state wherein, simultaneously, (*a*) the central disk is fully light, (*b*) there are exactly two unbroken sequences of fully light inner rays, and (*c*) there is exactly one unbroken sequence of fully light whole rays. This corresponds to the presence of the image of a ridge end approximately as shown in Fig. 2*B*. The point marked with an *X*, circumferentially midway in one sequence of fully light inner rays and radially midway in an outer ray, is taken to be the observed location of the detected ridge end. The greatly enlarged image of the whole finger ridge pattern is systematically scanned over the target to detect all its ridge ends. Operation as a valley end detector is entirely analogous.

Now, if the claimant is *bona fide*, the automatically observed rectangular co-ordinates of his reference minutiæ and orientations of his reference and test minutiæ will roughly approximate the corresponding retrieved registrant's data, owing to the guide-imposed similar placement of patterns in the rectangular co-ordinate systems of the registration and verification processes, to the moderateness of ordinary intervening pattern changes, and to the high expected detector accuracies. Though this approximation may be a crude one, inadequate to the full task of identity verification, it can be depended on to preserve the approximate orientations of all the minutiæ (a feature used further on) and, of interest here, enable the system to identify correctly the three reference minutiæ, which were at W, X and Y in the registrant's pattern, in their transformed observed locations W', X' and Y' in the claimant's pattern.

Having identified the reference minutiæ in their transformed observed locations W', X' and Y' in the claimant's pattern (correctly for a *bona fide* claimant or falsely by coincidence for an occasional impostor) the system proceeds to compute, for each of the registrant's test minutiæ P_i on which 'relative' co-ordinates ξ_i, η_i have been retrieved, the rectangular co-ordinates of its predicted transformed location Q_i' in the claimant's pattern, using the pair of simultaneous equations $\overrightarrow{O'Q_i'} = \overrightarrow{O'W'} + \xi_i \overrightarrow{W'X'} + \eta_i \overrightarrow{W'Y'}$, the retrieved ξ_i, η_i and the observed rectangular co-ordinates of the reference minutiæ.

It can be shown that if the claimant is *bona fide*, if the transformation his pattern has undergone since registration is perfectly affine (that is, is a translation plus a linear transformation, which latter includes differential scalings

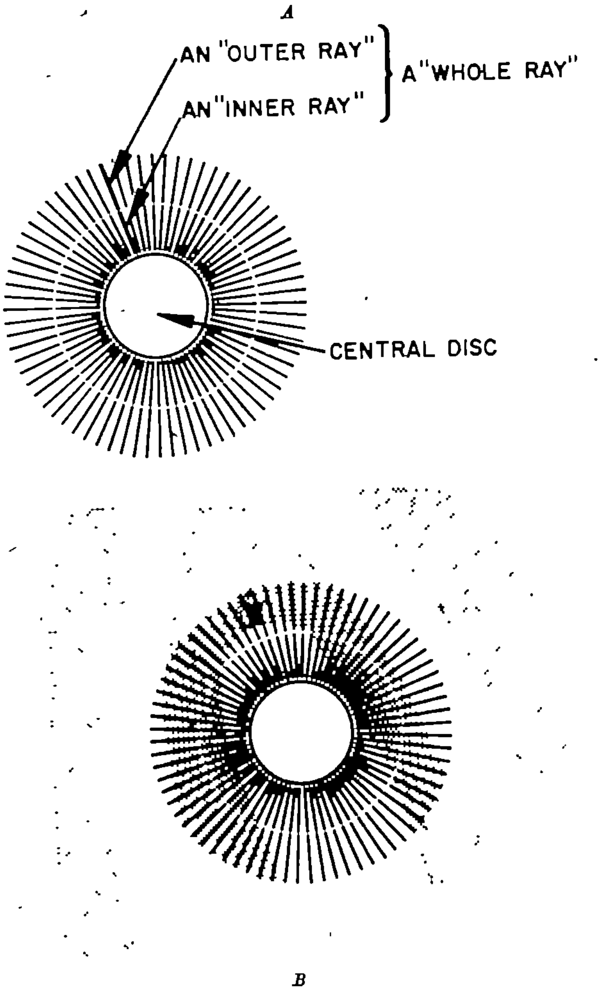

Fig. 2. Minutia detector. *A*, Minutia detector target, an array of photosensitive rays and a photosensitive disk; *B*, target with greatly enlarged image of pattern fragment superimposed

along different directions), and if the claimant's minutiæ are located by the detectors with perfect precision, the locations Q_i' in the claimant's pattern predicted as described will be perfectly correct, and the system will, in fact, observe the transformed test minutiæ to be at the computed rectangular co-ordinates, and observe their types and approximate orientations to agree with retrieved test minutia data.

The situation is only slightly altered in the more practical case of a near-affine pattern transformation and fairly precise minutiæ detection. It can be shown that if the claimant is *bona fide*, if his pattern transformation nowhere deviates by more than a from perfect affineness, if the detectors' errors in locating minutiæ are no greater than ϵ, and if all the registrant's test minutiæ have been chosen within the triangle WXY of reference minutiæ, the system will observe the transformed test minutiæ in the claimant's pattern at locations within a distance $2\epsilon + a$ of those predicted as here for them and, as before, the observed minutia types and approximate orientations will agree with retrieved test minutia data. This result provides the desired practical grounds for comparison of the registrant's and claimant's patterns. On these grounds, the system verifies a claim as genuine if, and only if, for each of the registrant's test minutiæ P_i on which data are stored, it detects a minutia in the claimant's pattern the observed location of which matches, to within $2\epsilon + a$, the transformed location Q_i' predicted for P_i, and whose observed type and approximate orientation match those retrieved for P_i.

Such a system will not reject *bona fide* claimants, as demonstrated. Only by rare chance will an impostor's pattern agree so well with that stored for the claimed identity that his claim will be falsely verified. To estimate this chance, the reasonable-appearing assumptions are made that: (a) approximately, the locations of minutiæ in a pattern are random, the two minutia types are equally likely, the two utilized approximate minutia orientations ('clockwise' and 'counterclockwise') are equally likely, and the location, type and approximate orientation of a minutia are independent of one another and of other minutiæ; (b) the 'wave-length' (width of one ridge plus adjacent valley) varies by at most 2:1 over any individual pattern; (c) the local ratio of ridge-to-valley width is never outside the range 1:3–3:1; (d) normal pattern variations are so nearly affine that a of the foregoing discussion is never greater than half the average pattern wave-length; (e) detectors such as those described are feasible, for which the errors ϵ of the foregoing discussion are no greater than half the local ridge or valley width. On these assumptions, it can be shown that, for registrant's patterns wherein N test minutiæ have been chosen for data storage and comparison purposes, and false claimants whose pattern areas display s minutiæ per square mean pattern wave-length and who are free to use the 'best' of their ten patterns, the probability of false identity verification is about $10r(9\pi s/16)^N$, where r is the probability that satisfactory reference minutiæ appear in the false claimant's pattern.

To obtain numerical values for s and N in the foregoing expression, observations were made on a series of twenty finger-ridge patterns, all adult male, mid-finger right hand, ulnar loop. First, considering these as false claimant's patterns, the area of minimal minutia density was deleted from each. The largest observed value for s in a remaining area was found to be 0·11 minutiæ per square average wave-length. Next, considering them as registrant's patterns, a quadrilateral was drawn in each pattern with vertices at prospective reference minutiæ (this presumes the separate use of two three-reference-minutiæ 'relative' co-ordinate systems). The least number of test minutiæ found in such a quadrilateral was 16; this, reduced to allow for the small sample of patterns and for possible malformed minutiæ, suggests that N may conservatively be taken as 12. The final constant, r, can at present only be guessed at; the value 1/100 is felt to be conservative. On substitution of the cited values for s, N and r, the expression given here yields, as a rough estimate of the false verification probability for a combination of 'weak' registrant and 'strong' impostor, 4×10^{-10}, or 1 chance in 2,500,000,000. In a simpler mode of operation in which it makes use only of valley ends, and hence has no need for auxiliary means of eliminating the false ridge end pairs occasionally created by breaks and creases in the pattern, the system's false verification probability, similarly estimated, becomes no greater than 10^{-7}, or 1 chance in 10,000,000.

There have also been examined the demands that a system of the kind herein described will make on its users and on its internal data storage, computation and communication facilities, with results which indicate its technical feasibility, speed (a few seconds per claim), and convenience of use.

MODIFICATION OF THE DESIGN OF THE PROPOSED BENELUX RADIO TELESCOPE

By DR. W. N. CHRISTIANSEN*, DR. W. C. ERICKSON and DR. J. A. HÖGBOM
Sterrewacht, Leyden, The Netherlands

RECENTLY, the design of the Benelux radio telescope which was described by Christiansen and Högbom in *Nature*[1] has undergone drastic revision. The previous design involved several cylindrical parabolic reflectors with apertures of 5 km. It appeared to be entirely feasible technically, but several considerations have led us to adopt an even more ambitious proposal. The first of these was on the basis of operating frequency. The previous design was for a 400-Mc/s instrument. We have not yet obtained satisfactory protection of this frequency from terrestrial interference. Since the 1,400–1,425 Mc/s is now well protected, it appeared wise to utilize this higher frequency, if possible. The available funds appeared sufficient to consider seriously an instrument satisfying the original goal of 1-min resolution in spite of the closer tolerances and higher cost per unit receiving area necessitated by the higher frequency.

The growing recognition of the importance of polarization and spectral studies has equally influenced our plans. The stretched-wire reflectors of the previous design would have been intrinsically polarized, and any change of polarization would be impossible. A change of operating frequency for spectral studies would have required modification of approximately 20 km of line feed. This would have been practically impossible, and we have been led to adopt a design involving parabolic dish-type reflectors with point feeds. Although approximately

---

* Present address: School of Electrical Engineering, University of Sydney.

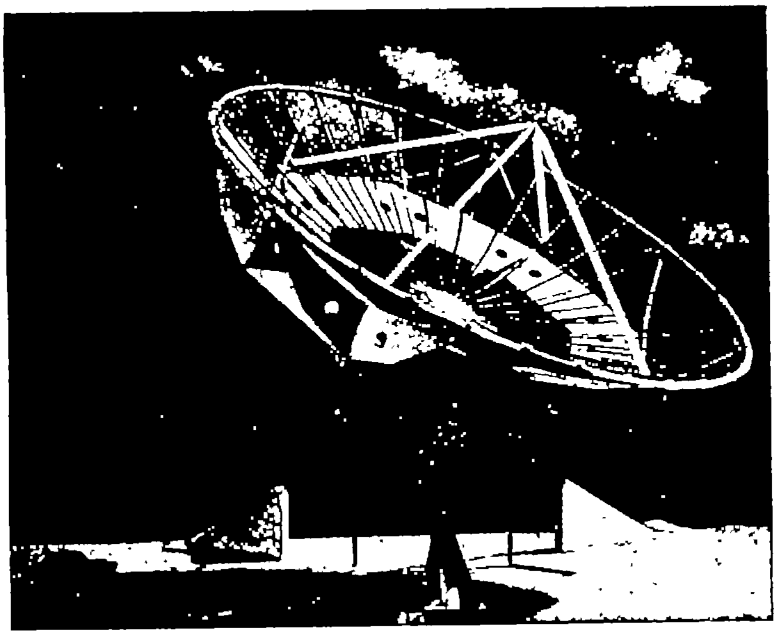

Fig. 1. A model of one of the 30-m reflectors

100 reflectors will be required, modification of their feed systems might be accomplished in a matter of weeks. Therefore, polarization and spectral studies become feasible.

In addition, the examination of the 21-cm line has been stressed in the Netherlands during the past decade. The 1,420 Mc/s operating frequency will allow these studies to continue with unequalled resolving power.

Previous studies were limited to Mills cross-type configurations utilizing receiving elements of various types. The foregoing considerations have now dictated the use of parabolic dish-type elements, but various configurations other than the Mills cross design have been considered. However, it appeared that a cross-type design would be the most suitable system also at the new design frequency of 1,420 Mc/s. A full report concerning the present plans is to be published[2].

The new proposal involves approximately 100 equatorially mounted reflectors, each of 30 m diameter. A model of one of the reflectors is shown in Fig. 1. Sky coverage will be from the north celestial pole to +5° declination. The total collecting area will be much less than that of the previous design, but the telescope will be able to follow an object for about 4 h in right ascension, and this longer integration time gives the instrument a sufficiently high sensitivity. The Benelux Cross will therefore not be basically a survey instrument; it will be used mainly for high-resolution studies of limited regions of the sky.

A rather curious arrangement of the reflectors has been developed. It is an extension of the method of suppressing the unwanted grating responses of the north–south arm proposed in the previous design[1]. The situation is more complicated in the new proposal, since grating responses must be suppressed in both directions, east–west as well as north–south, and it must

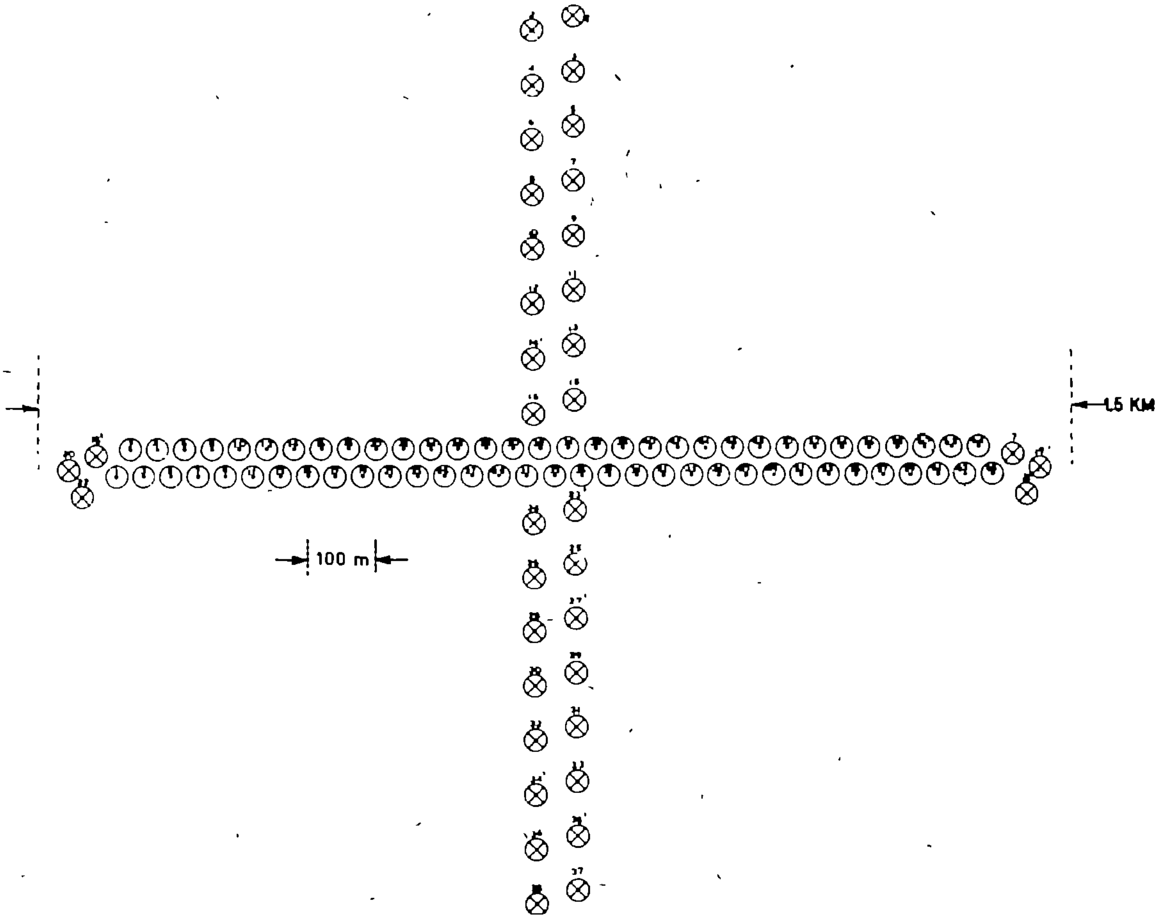

Fig. 2. The proposed arrangement of the reflectors

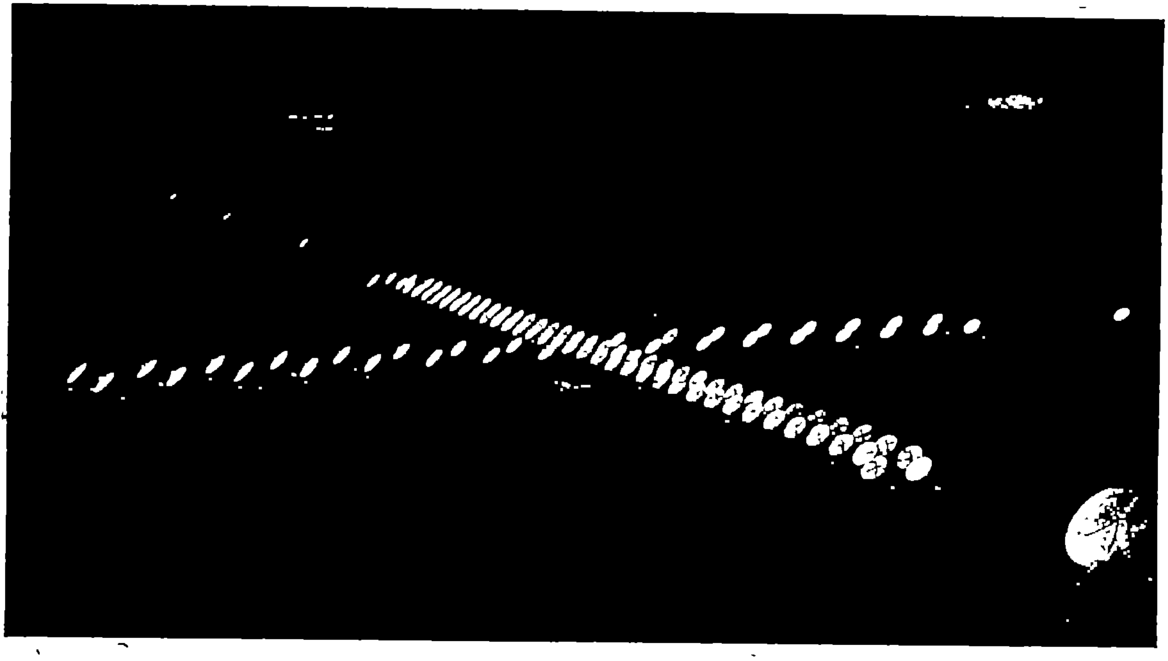

Fig. 3. An impression of the completed radio telescope

be possible to steer the reflectors without having them 'shadow' each other. The arrangement shown in Fig. 2 fulfils these requirements.

A new method will be used to overcome the geometrical difficulties in the central region of the cross where the two arms overlap. As shown in Fig. 2, three reflectors belonging to the north–south arm are placed at each end of the east–west arm. These gather most of the information which is lost by the omission of two north–south arm reflectors which would conflict with the east–west arm at the centre. Some information is still missing, but this will be gathered by a single, large reflector of about 70 m diameter. Therefore, the design involves a single large reflector as well as the cross of 30-m reflectors. No correlated components are needed between the large reflector and the cross. It could be located at a different site and run at different times. In fact, it can gather the information required for restoration of the components missing from the cross in a fraction of the cross's observing time. Therefore, this large reflector will be available most of the time for independent investigations as well as for operation as a 'finding instrument' for the delineation of interesting regions which will be subjected to detailed study by the cross. Fig. 3 gives an impression of the appearance of the antenna when completed.

The design of the electronic system is very similar to that of the previous proposal. Amplifiers will be distributed throughout the antenna, and multiple beam operation[3] is still planned. Somewhat greater use of the methods of aperture synthesis[4] is envisaged. That is, rather than physically connecting the outputs from all the reflectors in a number of differently phased combinations, the phase and amplitudes of the correlated signals between various pairs of reflectors will be measured. This information will then be processed by a digital computer to form a map of the area of sky under observation. Many directions in the sky will therefore be measured simultaneously, and this makes the effective sensitivity of the instrument comparable with that of the corresponding filled aperture antenna.

Funds for the design studies were provided by the Organization for European Co-operation and Development Committee on Scientific and Technical Personnel, the Netherlands Organization for Pure Scientific Research, and the Belgian Ministère de l'Instruction Publique.

HISTORY, SAND WAVES AND NEAR-BED CURRENTS OF LA CHAPELLE BANK

By Dr. J. N. CARRUTHERS
National Institute of Oceanography, Wormley, Godalming, Surrey

It has rightly been urged that those who study the shifting sands beneath shallow near-shore waters should make direct observations of water movements virtually on the sea-bed. This can easily be done.

Now that the presence of sand ripples beneath very great depths of water has been revealed by submarine photography, it is of considerable interest to discover what speeds of water movement can occur very close down to the deep ocean floor at such places. One way of measuring such deep near-bed currents from an unanchored ship with little trouble and at small cost has recently been described[1]. Though the single observations provided by that simple method are easily repeatable, they cannot yet be carried out hourly beneath great depths of water.

Particular interest is attached, therefore, to places where much is known about convolutions of the sea-bed thanks to detailed operations with echo-sounding sets of high quality and modern echo-ranging technique, and where the depth is small enough for it to be possible to repeat the easy single bottom current measurements at hourly intervals. Such a possibility means, of course, that continuance of the observing 'round the clock' takes account of changing tidal streams.

For a variety of reasons La Chapelle Bank is eminently such a place. Centred at a point 100 miles from Ushant Light in the direction 240° true, the shoalest part of the bank is shown on the French chart No. 4735 as a small area of soundings ranging from 151 to 158 m. The bank lies very near to the edge of the continental shelf which has a general direction of south-east to north-west over a wide extent in the Bay of Biscay. The declivity towards south-west is such that the isobaths for 200 and 4,000 m are separated often by no more than 25 miles. A French fishery chart which embodies the results of surveys made from 1956 to 1960 and which portrays the bottom topography by isobaths drawn at 200-m intervals shows that, proceeding in a direction about 210° true from the region of the 150-m soundings, a depth of 3,600 m is reached in about 16½ miles. This is equivalent to an overall slope of 1 in 9 over that distance measured down what is in effect quite a marked canyon. A bathymetric chart of the shelf edge west of Ushant prepared by my colleague Miss L. Hadley shows that over a distance of 23 miles along a course trending south-west from the shoalest part of La Chapelle Bank, the depth increases to 2,000 fathoms—which implies an overall slope of about 1 in 12 over that greater distance in a more westerly direction. When Commandant L. Beaugé surveyed the bank in summer 1935 he moored a buoy at the shoalest point sounding 150 m and ran lines of soundings in all directions from it. He recorded that the bottom fell away to more than 1,000 m in less than two miles towards south; it did so in fact towards all directions between east-south-east and west-north-west. Thus, near to the bank, he found bottom declivities of the order of one in four.

There has recently become available an underwater relief model of the North Atlantic Basin on the scale of 1 : 5½ M with an exaggeration of 20 : 1. This, prepared by the U.S. Naval Interpretation Center in December 1960 and marked *NPIC* 910/60–*U*, shows La Chapelle Bank located very near the edge of a virtually vertical 'cardboard cliff' the foot of which is marked for the depth of 2,500 fathoms.

So far, because of its close bearing on what follows, we have been concerned to discuss the bed macrotopography of the region in some detail.

It is relevant now to mention that the region has quite a considerable history in terms of vigias. This Spanish word literally signifying 'watch' or 'look-out' was customarily placed on charts to convey a navigational warning in respect of possible pinnacles, rocks or shoals of uncertain position, and it is on record that Le Sieur La Chapelle Richard claims to have seen there, at 4 p.m. on the Shrove Tuesday of 1695, a rock standing 15 ft. proud of the water at pistol shot distance from his ship. It is recorded that he had a nearby sounding made without finding bottom at "130 brasses", that is, at some 130 fathoms. On a chart of 1766 the rock was marked because of an alleged re-sighting of it in 1764, and the repetition was made on a later chart. The detailed surveys made by Beaugé in our times have revealed no trace of any rock at the stated position. He found merely an '*éminence légère*' carrying 151 m of water with surrounding depths of 160–170 m. Because the position of this shoalest point was the same as that where the rock was allegedly seen in 1695, it was given the name of La Chapelle Bank. In 1822 discoloured water was reported at the position, and a depth of 4 ft. was reported in 1842 and one of 2 or 3 ft. in 1857.

I mention these vigias here as likely evidence of the occurrence at times of surface turbulence at the position of the bank notable enough to have made old-time mariners report the existence of shoals.

E. Le Danois has written much about the Chapelle Bank area in his two books *Les Profondeurs de la Mer* (Paris, 1948) and *L'Atlantique: Histoire et Vie d'un Océan* (Paris, 1938). He deals lightly with the vigia question already mentioned, and, after telling a good deal about the constitution of the bed, elects to explain the presence of the characteristic carpet of coarse sand by regarding it as "le cône de déjection de l'ancien estuaire de la Seine". He gives a map depicting his views of the drowned river drainage system and of the aforetime coastlines of the area now covered by the Celtic Sea. The ancient débouchure of the Seine is shown lying between the positions of the Castor and Parson banks. Because of the existence of other banks of insular nature to the west of La Chapelle, Le Danois sees in this assemblage of such shoal areas the former islands of the Cassiterides. He points out that a north/south line drawn on the chart between the richest tin-yielding areas of Wales and Spain passes through the region, and he discusses the subsidence to be held accountable for the drowning of the presumed former islands beneath their present water cover of the order of 150 m and less.

The matters so far discussed are all of relevance when an explanation for the convolutions of the sea-bed which will be described has to be advanced. Le Danois makes a statement which bears on one aspect of sediment movement when he writes: "Entre le banc du Castor et le banc Parson et sur le banc de La Chappelle s'effectue en effet du printemps jusqu'en août un véritable déversement d'eaux continentales provenant du Canal de Bristol et de la Manche. Au delà du plateau ces eaux froides et peu salées continuent leur course et s'enfoncent jusqu'au dela de 800 mètres". This process would nowadays go under the label 'cascading'.

Turning now to the sand formations on La Chapelle Bank and its immediate environs where the tidal range at springs is 3 m, the first reference must be to a short paper by Cartwright and Stride about five years ago[2].

An echo-sounding survey over the bank revealed to them the presence of a patch of sand waves about 12 miles long which ended abruptly at the edge of the continental shelf but which had a rather ill-defined eastern limit. The patch had a lateral extension of at least 5 miles, and the sand wave crests were on the average 25 ft. high with a maximum height of 40 ft. Though they found considerable variation in the distance between crests, the average separation was about 2,800 ft. The crest trend was from 290° to 110° true, which put their direction parallel to the general line of the shelf edge. On sampling the bottom both on a ridge and in a trough sand was found with some shell gravel, the median grain size being of 0·5 mm diameter. In a paper by Berthois to which reference will later be made, additional information is given regarding the nature of the bottom in the area.

Cartwright and Stride naturally inferred that the presence of the large sand waves required the existence of bottom currents on La Chapelle Bank sufficiently strong to transport along the floor the rough sand and gravel which they had found there. A slight measure of asymmetry of the ridge profiles was taken to indicate the existence of a net westwards transport of sediment, and the abrupt western limit of the sand ridges at the edge of the shelf showed that once the material reached there it was presumably carried over into deeper water—perhaps periodically. As bearing on this last expectation the cascading effect dwelt on by Le Danois is relevant, and so too are my own deep-current measurements made on the slope which were reported earlier[1]. It is of interest to mention at this stage that Stride has since discovered sand waves of comparable inter-crestal distance (though less high) on the shallower Parson Bank about 50 miles away to the north-east and so well behind the shelf edge. Others of similar wave-length have been mapped by him still farther towards the English Channel entrance.

These latter had profiles indicating oceanwards movement but the lines of their crests were not straight but convex towards the Channel. It seems that there may be something unusual about the height of the very large sand ridges on La Chapelle Bank, and, seeking to produce an adequate explanation for their formation, Cartwright[3] worked out a theory by which they could be considered generated as a result of stationary internal waves in the layer of sharp temperature gradient seasonally found between the warm surface water and colder water near the bottom. Such internal waves can be due to the tidal currents being disturbed as they travel landwards over the edge of the shelf. On Cartwright's theory, the sand waves built in summer would not be altered in height during the winter and spring when the thermocline is absent. A harmonic analysis of the sand wave profiles agreed fairly well with the proposed theory.

Independently, Dr. C. S. Cox of the Scripps Institution of Oceanography (California) had found some indications that internal waves of tidal periods are closely coupled with irregularities of the sea floor. The stationary internal waves adduced by Cartwright in explanation of the large sand waves on La Chapelle Bank would be equivalent to lee-waves found on the down-wind side of a mountain. Internal waves (not necessarily stationary) which develop in the thermocline as the tidal currents moving landwards feel the constraining influence of the shelf are the only possible explanation of the abnormal oscillation of a scattering layer later reported on by Stride and Tucker[4]. These observers were using this Institute's narrow-beam fish-finding transducer on La Chapelle Bank from R.R.S. *Discovery II* at the end of July 1960 while proceeding on a course approximately normal to the known crest direction of the large sand waves, when, at a distance some 8 miles within the oceanwards flank of the bank, they observed undulations in the scattering layer of length and height about the same as those of the stationary internal waves predicted by Cartwright from his theoretical studies.

This new information which seemed to support Cartwright's theory has since been followed by another line of supporting evidence. My colleague, Mr. R. Bowers, has since made runs over La Chapelle Bank while towing from R.R.S. *Discovery II* a thermistor chain having six sensing elements which reached 0, 15, 23, 31, 46 and 62 fathoms depth respectively at a steaming speed of 3 knots. Every 5 sec a temperature plot at each of these depths was made on a 'Mufax' recorder, and 48 h of continuous record were obtained over the bank. The records revealed undulations of the isothermal 'surfaces' having a wave-length such as to afford further support to Cartwright's theory, although it is still not known for certain how far the latter waves may be regarded as stationary.

An obvious requirement was to know everything possible about the tidal currents over the bank. Prior to 1961 all that was known was the information printed on the French chart No. 4735 to which reference has already been made. This information, which is in the form of the usual table of hourly speeds and directions for both springs and neaps, relates to the position 47° 40′ N.–7° 10′ W. The tidal currents at springs are shown as running fastest over La Chapelle Bank (at 1 knot) during 4 h straddling the time of high water at Brest. They are then directed towards between 50° and 130° true. During 6 h straddling low water Brest they are shown running towards between 228° and 340° true. The surface tidal stream data in question, which would not be claimed to be of the high quality produced by modern tidal stream surveys, came from observations made as long ago as 1891 when a French surveyor repeatedly measured the direction and speed of the drift away of his ship from an anchored buoy. Allowances for windage had necessarily to be made.

The cited table does, however, show that the surface tidal currents over the bank often head in a direction more or less normal to the shelf edge. The other long and curved sand waves mapped by Stride nearer to the English Channel lie beneath tidal currents which attain their fastest speeds at surface in the north-east/south-west directions.

In November 1961 Messrs. Cartwright and Woods (A. J.) made current observations over La Chapelle Bank working from R.R.S. *Discovery II* (unanchored) with a couple of Kelvin–Hughes direct-reading current meters. The work occupied almost three days, and the operation details will be reported elsewhere. Their observing depths were 40 ft. below surface and 30 ft. above bottom, but not enough observations were made at the deeper level.

From the results obtained, Cartwright produced a smoothed M 2 ellipse which shows the main directions of surface current flow to have been 30° and 210° true. These are more or less normal to the above-stated direction of the sand wave crests as would be expected if they reflect the water movements near bottom.

Picking out the fastest speeds actually measured at the nominal depth of 40 ft. one finds: 1·8 knots towards N. 17° E. true and 2·1 knots towards S. 17° W. true.

Thus, the latest information on near-surface water movements shows that the fastest rates were normal to the sand wave trend—with the greater speed in favour of direction towards the depths, that is, off the shelf. Cartwright's current measurements were made when the tides were about half-way between average and springs, that is, at a time when the coefficient was 80 to quote from the French tide tables. It is, of course, very useful to have the tidal current information gathered by Cartwright in order to know at what speeds the uppermost water can flow over the line of the shelf edge, but an urgent need had remained for actual measurements of the near-bed currents on the bank. These would be expected to be of major importance even if not powerful enough actually to erode the bed themselves. Their function would be to transport the sand from the places where the internal waves exert their major excavating power and deposit it along lines beneath the crests of the internal waves where these cause least movement of the bottom water.

Measurements of the currents close to bottom were made on La Chapelle Bank on November 7 and 8, 1962, from the research vessel *Sarsia* belonging to the Marine Biological Association of the United Kingdom. I had the assistance of my colleagues Messrs. L. A. Baxter and C. L. Gulliver in making seventeen single observations 1 h apart with my leaning-tube bottom current indicator ('Pisa'). These observations, which absorbed the entire ship time available, were all made as nearly as possible to the position 47° 40′ N.–7° 14′ W. under depths of water varying little from 155 m, and it can be taken that they relate on the average to a distance of about 10 in. above the sea-bed. The ship's officers were able always to move the vessel suitably between observations to keep to the shoalest part of the bank. In respect of bottoming gear the operations were as already described[1] but the indicating unit used in the 'Pisa' tube was not the directional inclinometer then used. Instead, the original 'Pyrex' bottle filled half with jelly and half with coloured castor oil was used. This, containing the usual compass disk suspended on a terylene thread from the bottom tip of an axial rod within the bottle, differed but slightly from the form first used[5]. Though this initial version of the 'Pisa' cannot be used down to depths much in excess of 1,400 m, its use has advantages at lesser depths which permit hourly repetitions. One merit is that the bottle indicator can give evidence of the presence of turbulence because, when the bottom current is not laminar, a clear-cut interface between the set jelly and the oil will not result even though the 'frozen-in' compass may give an acceptable overall direction as proved by experiments conducted in turbulent mill streams.

The results obtained were first plotted against clock hours in the form of two curves drawn for the north–south and east–west components respectively. These curves were then smoothed somewhat and supplied with new ordinates relating to Brest high water and hours from that time.

The components were then read off and re-compounded to relate to the tide times at Brest. Table 1 presents the results which start at about 1400 h G.M.T. on November 7 and end at about 0600 h the next day. Speeds are given in hundredths of knots and the directions are magnetic (declination 10° W.). The plus and minus figures denote hours after and before Brest high-water respectively.

Table 1

+2	+3	+4	+5
42 S. 21° W.	33 S. 16° W.	42 S. 13° W.	55 S. 20° W.
+6	−6	−5	−4
50 S. 50° W.	40 S. 81° W.	30 N. 78° W.	29 N. 18° W.
−3	−2	−1	H.W.
39 N. 18° E.	42 N. 37° E.	23 due E.	30 S. 23° E.
+1	+2	+3	+4
41 S. 10° W.	37 S. 45° W.	46 N. 63° W.	49 N. 61° W.
+5			
36 S. 16° W.			

No explanation is attempted why the directions for the second values at +3 and +4 have veered a dozen points.

The directional spread of the near-bottom current vectors is best seen from the accompanying plot wherein the single plus and minus signs have the same meaning as in Table 1. The four double plus signs mark the second observations made at the concerned tidal hours, and the circles measure tenth-knots successively from two to six proceeding outwards.

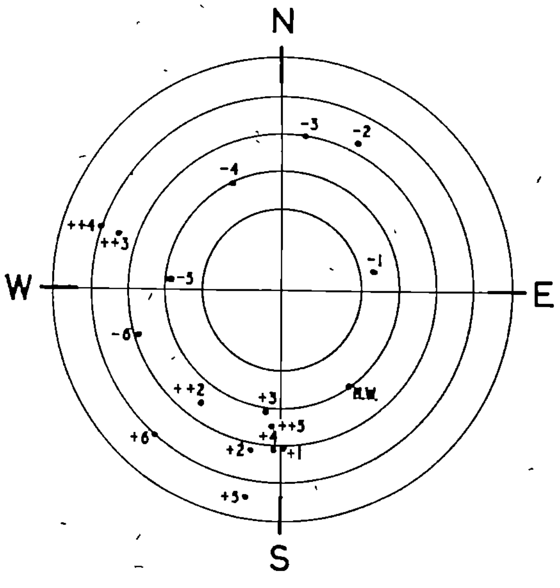

Fig. 1

We were working at a time when the tides were about half-way between neaps and average—at a time when the coefficient was about 65 to quote again from the French tide tables. Thus, the upper water observations made by Cartwright were carried out when the tide had a range about one-quarter greater than at the time of our measurements made just off bottom.

The briskest near-bed water movement measured was towards 190° true at 0·55 knot and the fastest about 6 h later was towards almost a reciprocal point at the rate of 0·42 knot. Thus, the fastest current was normal to the known direction of the crest line of the sand waves. Several other features of the results are noteworthy. The most remarkable thing about them is the absence of any current weaker than about 0·25 knot. The overall average speed is 0·40 knot and, although there is a large spread of direction with a good deal of near-bed water movement into the north-west quadrant, flow towards south and west much outweighs that towards the two opposite directions.

On all occasions save one the interface between the set jelly and the oil was clear-cut. The odd occasion was when the current was heading north-west, that is, in a direction parallel to the shelf edge. Perhaps the surge of water flowing at the time out of the deep funnel of the inner Bay of Biscay was pressed against the steep shelf by Coriolis effect sufficiently to thrust up the canyon of which we wrote earlier and cause an overspill of turbulence reaching somewhat landwards of the shelf edge. Cooper has called such a happening a submarine eagre and much of what he has written about "eagre spurts" of canyon water into shelf water is suggestive in this connexion[6].

The satisfaction of having been able to make actual measurements of near-bottom currents on La Chapelle Bank is all the greater when one considers the difficulties experienced by L. Berthois[7] in attempting to explain the large sand waves there. Agreeing with Cartwright and Stride[8] as to their size and crest orientation Berthois concluded that the big sand waves cannot have been produced by present-day currents but must be fossil features produced by much more powerful water movements existing in times long past. This conclusion he founded on some rather extraordinary decisions that the near-bottom tidal current probably does not reach one-fifth of the speed of that at the surface, and went on to argue that when it is in the "most favourable" direction. that is, normal to the ridge orientation, its speed will not exceed 0·16 knot. He came to this conclusion after applying some surprising ratios to the surface speeds as he knew them. This latter knowledge was restricted to the table on French chart No. 4735 already mentioned. yet Berthois declares that possession of the said table amounts to knowing the surface tidal streams over the region of the sand waves with precision. In spite of the fact that the speeds in knots which the table gives for the surface streams must be very imprecise, Berthois converts them into m/sec speeds expressed to three places of decimals.

All in all, the subject of the La Chapelle sand waves and their causation is of such interest as to prompt the desire for future expeditions there. One of these should be at the time of spring tides in September and the other similarly in February. That would provide for observations when the stationary internal waves invoked by Cartwright would be respectively at their greatest and least development for vertical density gradient reasons; but difficulty is naturally seen in arranging for the observing to be at exactly the same place both times. On both occasions the sand waves should be carefully measured and observations to reveal any undulations in scattering layers carried on. Besides measuring the near-bottom currents hourly, the towed thermistor chain should be used for reason already shown. What is also advocated is that, along courses normal to the ridges, sand traps should be used as frequently as possible just above bottom in order to learn something about the amount of sand actually in movement above different parts of the sand waves.

Doubtless, in these days, however, the sediment burden in the water just off bottom could be more speedily assessed by other means than the use of sand traps.

I thank Dr. F. S. Russell for the use of the research vessel *Sarsia*; Captain C. A. Hoodless and his ship's company for help; my colleagues Messrs. L. A. Baxter and C. L. Gulliver for sharing the work at sea; and Messrs.

D. Cartwright and A. H. Stride for helpful discussions during the writing of this article.

DIFFERENTIAL RESPONSES OF *PARAMECIUM AURELIA* TO CIGARETTE COMPONENTS

By PROF. HARRY WANG

Department of Anatomy, Stritch School of Medicine, Loyola University, Chicago

ALTHOUGH the use of *Paramecium* in cigarette research is not readily conceivable, the idea is nevertheless encouraged by two findings that the organism is highly sensitive to traces of metallic ions[1] and it reacts specifically to proteolytic enzymes of diverse origins[2]. A programme was thus started with its initial phase aimed primarily at determining whether *Paramecium* can also respond differentially to isolated cigarette components. This article presents observations concerning the protozoon's responses to cigarette toxins with special emphasis on the specificity of manifestation patterns this organism is capable of eliciting under the present experimental conditions.

A kappaless strain of *Paramecium aurelia* (stock No. 51, courtesy of Dr. T. M. Sonneborn) was used. Pure-line clone cultures of this organism were raised in sterilized Petri dishes, using 10 raw grains of rice for each culture. A culture was considered 'ripe' when the population in a single micropipette drop (1/40 ml.) consisted of several hundred organisms. Water used for all purposes was obtained from a Stokes distiller, model 171–*E*.

From six domestic and one imported brands of non-filter cigarettes, four components were separated for experimental analyses: tobacco, mainstream smoke, ash of whole cigarette, and ash of its paper alone. Cigarettes were smoked by means of a simple device—a suction-filter flask attached to a tap. Hydraulic pressure was adjusted so that a cigarette was consumed in 3½ min, during which time the mainstream smoke was directed to bubble through 20 ml. water in a test-tube placed inside the flask. It was estimated on the basis of cigarette smoke solubility in water and the present method of getting it dissolved that less than 10 per cent of the smoke so produced actually went into solution. The resulting ash was collected in 20 ml. water, filtered after 1 h with occasional shaking. A second cigarette was separated into tobacco and paper. The former was placed in 20 ml. water, filtered after 1 h. The cigarette paper was burned on a Bunsen flame for 1 min, the resulting ash (white) made into a 20-ml. solution in like manner. I designated these test solutions, each in 20 ml., as having an arbitrary concentration 1·0, which was found to be the most suitable as well as critical (see below) for our experiments.

For each experiment 1-ml. test solution was transferred to a depression slide (3 in. × 1½ in. with a central 1⅛-in. concavity) into which two drops of a culture were introduced with the micropipette. Continuous observation was made on these organisms from this point until their death. The concentration of the test solutions was regarded as critical because only at that concentration (1·0) could meaningful quantitative and qualitative data be obtained. The former represents an overall toxicity of the solution and is measured as 'survival time', or time required to kill a whole population. To estimate the percentage of the population killed at spaced intervals was almost impossible. The latter are manifest in motility and morphological changes undergone by the organism before death occurred. In general, as might be expected, higher concentrations shortened survival time. For example, when the concentration of a test solution was tripled, almost instant death to the organisms resulted, and the differentials in survival time of the four components normally obtained at concentration 1·0 (Fig. 1) became nullified. Conversely, at concentration 0·3 or lower, the components were no longer lethal.

Another important factor was temperature. Our experiments were carried out at a range of 23°–31° C within which tobacco and smoke were each completely lethal to *Paramecia* as contrasted to cigarette ash, whole or of the paper alone, which was incompletely lethal, that is, always leaving survivors behind. The latter may amount to 10–20 per cent of a population. Again, it is to be noted that this differential between tobacco and smoke, on one hand, and ash on the other, disappeared at higher temperatures, that is, 38° C and upwards. This phenomenon of survival is interpreted as probably denoting a low toxicity; but apart from this, it has raised a very interesting question. Is the resistibility exhibited by these individuals the result of somatic superiority of some kind over the others, which succumb, or is it the result of a germinal variation? Experiments are now being conducted to resolve this problem. The data showing the effect of temperature at concentration 1·0 are presented in a graph (Fig. 1). It was ascertained that *p*H was not a factor. The *p*H of the four components ranged from 6·0 (tobacco) to 8·1 (whole ash), which is well within the range of tolerance by *Paramecium*[1].

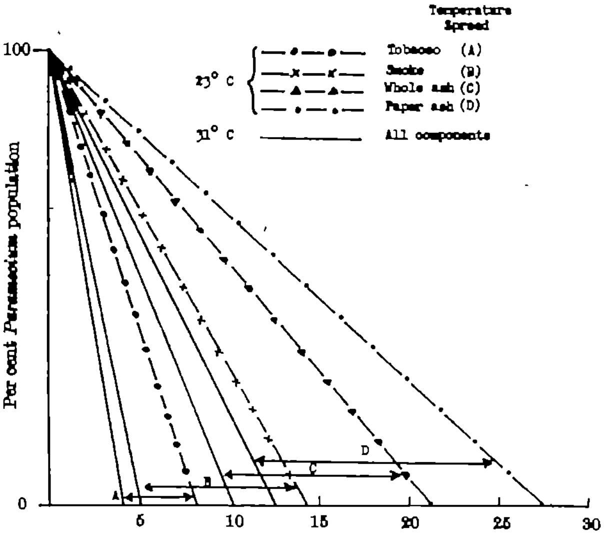

Fig. 1. Survival time of *Paramecium aurelia* in cigarette components at 23° and 31° C. Graph is based on data from all seven brands of cigarettes used: average of 20 experiments for each component

The remaining observations deal with changes in motility and morphology of *Paramecium*. All photomicrographical illustrations used in this article were from fresh preparations neither fixed nor stained (Figs. 2–9). It should be emphasized that these changes constitute patterns which are component-specific under our experimental conditions and that they are definitely not subject to alteration or modification by either temperature or concentration, or both. For these reasons, they are assumed to be qualitative rather than quantitative expressions of the toxicities under consideration. That is, most likely they are caused by the action of specific chemicals present in each of the components isolated[8]. If death represents terminal action of a toxin, the events described here are those which lead to the death of the organism as a result of impairment or disruption of some vital function. However, there is no apparent relation between the nature of responses and the overall toxicity of the solution on the basis of survival time. In other words, the events leading to death appear to bear no direct influence on the time required for evident lethality.

Tobacco. The action of this component was one of powerful tranquillization. The animals became motionless and died in the solution within a few minutes (Fig. 2). They appeared to have suffered from no gross deformity of any kind apart from a slight shrinkage, and the dead organisms remained intact, little disintegrated if at all. A unique phenomenon, however, occurred to most of them. The protrusion of a single ectoplasmic blister occurred at one pole of the animal. It is noteworthy that this happened in no other components studied.

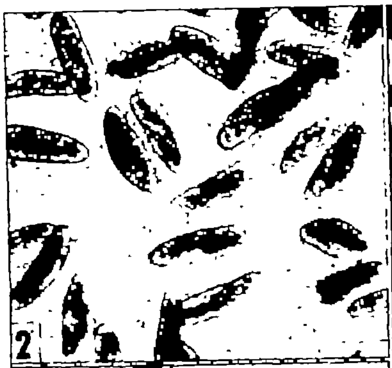

Fig. 2. Dead *Paramecia* showing typical manifestation pattern on 1 0 concentration tobacco solution at 23° C, 25 min after immersion. Note polar ectoplasmic blisters and a mild body shrinkage

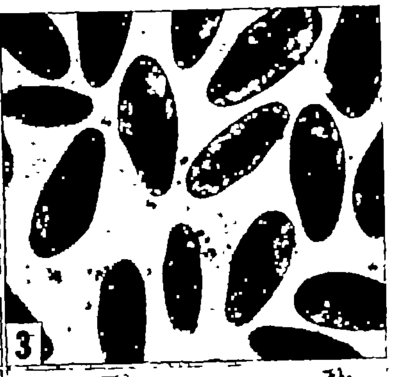

Fig. 3. *Paramecia* killed in 1·0 concentration smoke solution at 23° C, 25 min after immersion, revealing flattened swollen but intact bodies. Two contractile vacuoles were clearly shown in some of them

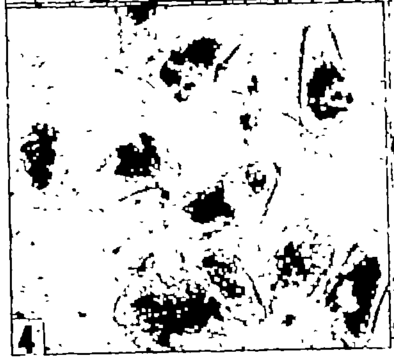

Fig. 4. Dead and partly burst *Paramecia* in 1·0 concentration cigarette ash (whole) solution at 23° C 10 min after immersion. Note clumping and centrally aggregated endoplasmic granules (dark), and slightly deformed bodies. Point of break-through marking the beginning of post-mortem disintegration was clearly indicated

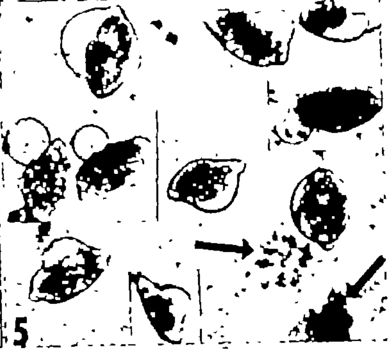

Fig. 5. *Paramecia* in 1·0 concentration cigarette paper solution at 23° C, 12 min after immersion. The photograph has incorporated 3 rectangular inserts taken from the same print in order to show greater varieties of blistering and body deformation. The organism in the insert at right has a polar endoplasmic blister, the rest all having ectoplasmic blisters. Arrow points to debris left over by disintegrated *Paramecia* which had succumbed earlier. These four illustrations portray the specificity of manifestation patterns evoked by the four cigarette components. They are taken at the same magnification (× c. 110)

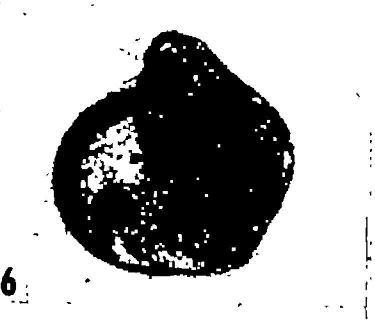
Mainstream smoke. Smoke solution also forcefully tranquillized *Paramecia* and quickly halted motility. No blistering was evident, but instead a considerable degree of body swelling coupled with some endoplasmic clumping took place (Fig. 3). The contrast in size of animals shown in Figs. 2 and 3 (same magnification) is evidence for the opposite effect of tobacco and smoke on plasma membrane permeability. Post-mortem disintegration, if any, was also mild. Thus, the death of *Paramecia* in both tobacco and smoke solutions was quiet and uneventful.

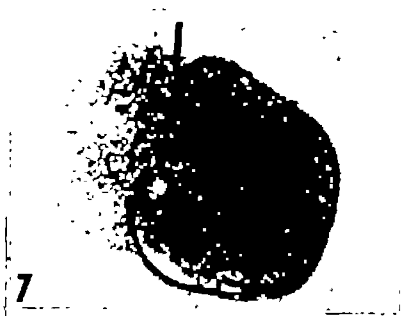
Ash of whole cigarette. Unlike tobacco and smoke, it stimulated the organisms to greater activity. The effect began almost from the moment of contact. Several motility patterns, all deviating far from the normal, followed in this order: first, an accelerated 'avoiding reaction'[4], changing to a spiral forward motion with either end of the animal whirling a circle, ending up with stationary circling of the body as if the latter were firmly anchored at its centre. After a while they settled down and died with a characteristic translocation and aggregation of endoplasmic granules (Fig. 4). The latter phenomenon so noticeable from Fig. 4 is believed responsible for the death of the animal. Moderate disintegration followed, which, however, was not preceded by any deformation or blistering such as invariably occurred following the action of cigarette paper ash.

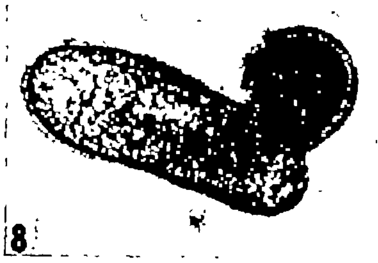
Ash of cigarette paper. The effect it has on the motility of *Paramecia* is closely comparable with that exerted by the ash of whole cigarette. But the morphological manifestations evoked by it are most fascinating to watch under the microscope. Attendant to active motility, blistering and bizarre types of deformation set in (Figs. 5, 8 and 9). The most severe cases, for example, sausage- or banana-shaped bodies with additional irregular protrusions involving both ecto- and endo-plasm, together with one or more blisters, were frequently observed (Figs. 8 and 9). Sooner or later, they slowed down and succumbed with an exploding type of disintegration (Figs. 6 and 7). Characteristically, the body burst at one point, resulting in collapse of the blisters and reduction of the cell to a mass of debris (arrows, Fig. 5). In fact, most of the scattered dots and particles seen in this photomicrograph represent this debris from completely disintegrated (cytolysed) *Paramecia*. The physiology of body deformation and blistering will be treated elsewhere; it probably involves changes of sol–gel relationships of the cell surface (cortex of *Paramecia*) brought about by specific chemical action.

The reason for the difference in effect between whole ash and that of cigarette paper alone may be sought in terms of combustion temperature[5,6]. In our experiments the cigarette paper was burned at a temperature much higher than that of smoking the cigarette on the artificial device, or naturally. In line with this, we found that when a paper was burned for a few seconds to a black (instead of white) ash, its solution was scarcely toxic to *Paramecia*. It is further assumed that certain combustion products, which are responsible for the toxicity phenomenon characteristic of the paper ash, may be masked or inhibited by certain organic compounds. The amount of the latter, of course, would decrease with increasing combustion temperatures. Another observation in this connexion seems significant: the paper solution, even after filtering, was slightly cloudy owing to the suspension of a fine particulate matter. On standing, the latter slowly settled out as a precipitate, which became partly afloat and partly smudging the wall of the container. Coincident with this precipitation, the solution lost toxicity appreciably. These observations strongly suggest that the active causative agents here involved may be polycyclic aromatic hydrocarbons[3,6].

In conclusion, this work has shown mainstream smoke to be the most toxic of the cigarette components. This is true of all the brands tested (so are all other findings of this work, with a variability among the brands that is well expected). The fact that this finding is in agreement with the literature constitutes an endorsement of *Paramecium aurelia* as a useful assay organism. The ultimate realization of the significance of this fact comes from the consideration that mainstream smoke is what should directly concern the smoker. Within the past decade or so, evidence for deleterious effects of cigarette smoke on the epithelial cells of the respiratory tract has been fast accumulating from both *in vivo* and *in vitro* experiments[7-13]. *Paramecium* is a ciliated unicellular animal, and as such it is likely to bear certain physiological resemblance to human respiratory epithelium[14,15]. On this ground alone the use of this organism in future research may be viewed as a desirable new approach to cigarette toxicity problems.







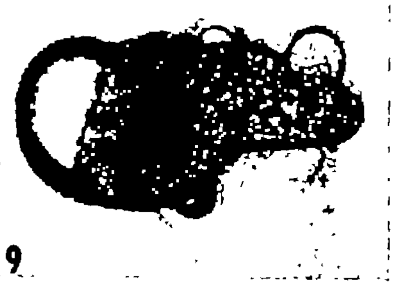


Fig. 6. A deformed *Paramecium* bearing an endoplasmic blister almost the size of body in 1·0 concentration cigarette paper solution at 25° C 15 min after immersion

Fig. 7. The same organism in Fig. 6, 3 min. later showing the blister collapsing and releasing its contents following a break-through some distance above (arrow)

Fig. 8. Another deformed *Paramecium* with a typical sausage-shaped body with a round protrusion near one end; the latter is not a blister since it was filled with endoplasm from the start. Later, however, blisters may be formed anywhere along the body surface. Note deranged cilia. This organism was in 1·0 concentration cigarette paper solution at 25° C, 11 min after immersion

Fig. 9. A 'monster'-like *Paramecium* afflicted by 1·0 concentration cigarette paper solution at 31° C, showing a combination of body deformation and blistering. At this stage all its blisters were of ectoplasmic kind, although the one at top right-hand corner of this figure was just about to be converted into an endoplasmic blister. (× c. 330)

CORAL GROWTH AND GEOCHRONOMETRY

By PROF. JOHN W. WELLS

Department of Geology, Cornell University, Ithaca, New York

ABSOLUTE age determinations of points on the geological time-scale, based on radioactivity, are generally accepted as the best approximations now known, even though they rest on a series of assumptions, any one of which may be upset at any time. At present there is no means of confirming or denying the accuracy of these determinations by independent methods. Can palæontology provide anything by way of verifying the pronouncements now emanating, at very considerable expense, from the black boxes? Can palæontology give any support to the shaky chronometric creation of the geophysicists and astronomers?

Except for providing a relative geochronology, palæontology has thus far offered no data on absolute geochronometry. Several geochronologists have noted that there is no fossil evidence concerning variations in the length of the day[1], the rotation of the Earth, or diurnal variations, in the geological past—variations that are linked to the passage of time, whereas the changes of the seasons have left indelible records in such things as tree rings, fish scales, stalactites, anhydrite bands, and other kinds of varves, all of which have little or no bearing on the problem of age or position in geological time. Organic evolutionary rates provide no evidence for they are wholly dependent for their values in isotopic age estimates.

It seems not unlikely, however, that if we lower our sights on suitable units of time for expression of age from the generally used year to the humbler day, we might find data in palæontological material for estimates of absolute age. How nice it would be if instead of paying a large sum for an isotopic analysis we could examine a fossil and estimate directly, with luck, not only its relative, but also its absolute age—every palæontologist a geochronometrist; every fossil a geochronometer!

The two chief approaches to geochronometry are based on radioactive isotopes and on astronomical data. The

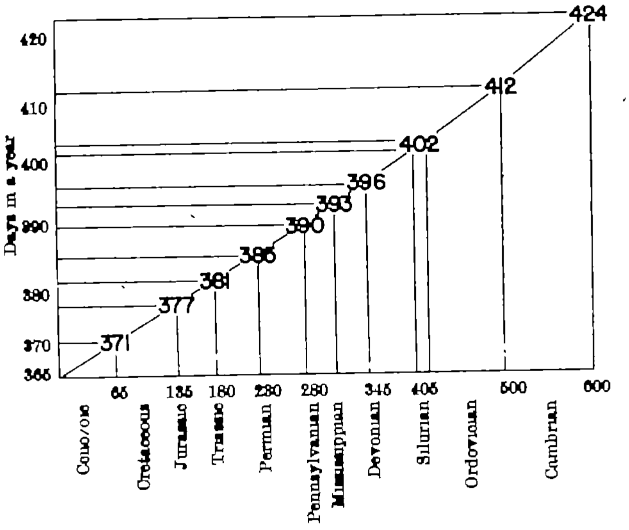

Fig. 1. Relation between days in each year and geological time (radioactive age data from Kulp, 1961)

most recent estimates[1] of geological time based on the rates of radioactive decay give the Cenozoic a length of 65 million years, the Mesozoic 165 million years, and Palæozoic 370 million years, and so on. The beginning of the Cambrian is placed about 600 million years ago. To accept these figures is an act of faith that few would have the temerity to refuse to make. The other approach, radically different, involves the astronomical record. Astronomers seem to be generally agreed that while the period of the Earth's revolution around the Sun has been constant, its period of rotation on its polar axis, at present 24 h, has not been constant throughout Earth's history, and that there has been a deceleration attributable to the dissipation of rotational energy by tidal forces on the surface and in the interior, a slow-down of about 2 sec per 100,000 years according to the most recent estimates. It thus appears that the length of the day has been increasing throughout geological time and that the number of days in the year has been decreasing. At the beginning of the Cambrian the length of the day would have been 21 h (ref. 1). After the first, a second act of faith is easy, and we can develop a simple relation between the geological time-scale and the number of days per year (Fig. 1).

Accepting this relation, in the absence of evidence to the contrary, it now follows that if we can find some means of determining the number of days per year for the different geological periods, we have a ligation between the results of geophysical and astronomical deductions. If we could determine, for example, that the number of days in the Cambrian year was of the order of 420, it would seem to confirm an indicated age of 600 million years based on tidal friction and in turn that since isotopic methods give the same result they too are in harmony. Is it possible to obtain estimates of the number of days per year from data preserved in recent and fossil organisms ? I would like to think so.

Among the several groups of organisms which have an additive mode of skeletal formation, the corals—tabulates, rugosans and scleractinians—are fairly well known, and there is a good deal of empirical information on rates of growth of recent forms, and a very little on the factors governing growth.

The earliest notice of annual fluctuations in coral growth is fairly recent. In 1898, R. P. Whitfield[3] described a large colony of the reef coral *Acropora palmata* from the Bahamas that showed regular undulations on the upper surface of the flat, spreading branches and suggested that these represented annual growth increments which he ascribed to seasonal temperature changes. The late T. Wayland Vaughan's experiments[4] a few years later with the same species in the Bahamas gave virtually the same result: 40–100 mm per year compared with 50–100 mm one gets from measurements of the undulations shown in Whitfield's specimen.

It has since been speculated that the growth annulations so common on many Palæozoic corals (Fig. 2) were the result of yearly fluctuations in growth produced by seasonal temperature change, variations in supplies of nutrients, or periodic reproductive activity. Beginning in 1934, T. Y. H. Ma[5] undertook investigations of variation of annual growth increments in recent and fossil corals as a means of determining the temperatures and latitudes of

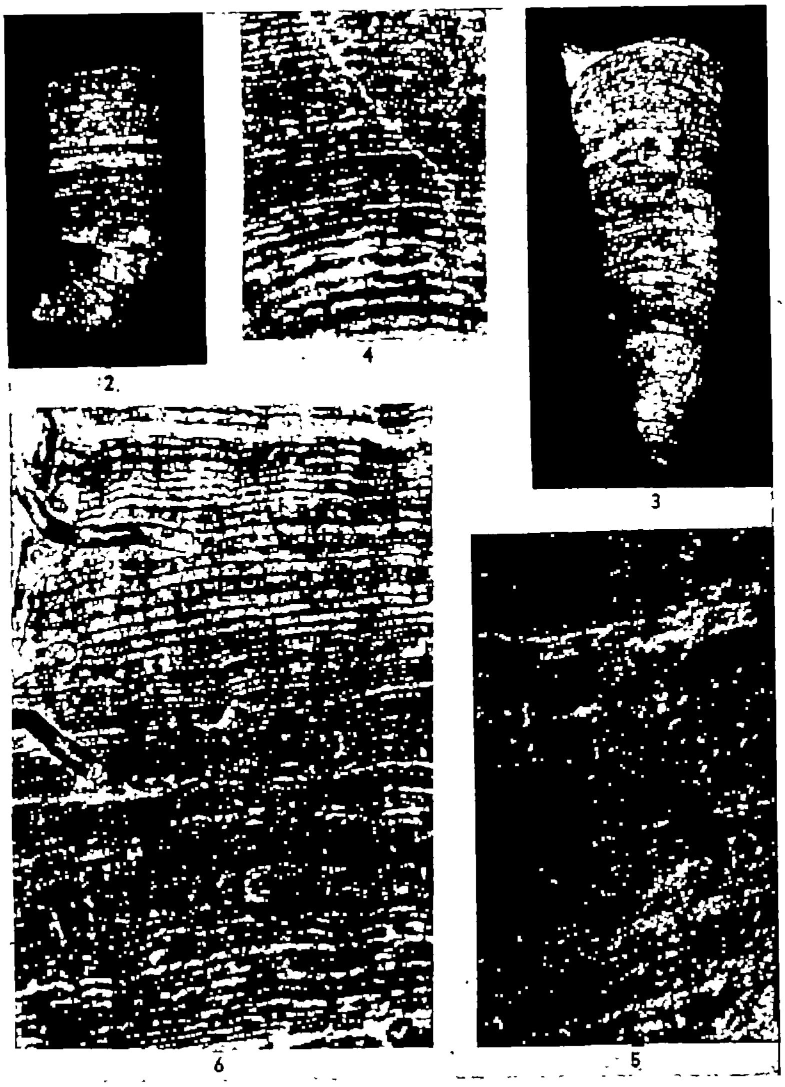

Fig. 2. *Heliophyllum halli*, Middle Devonian, western New York, showing 18 annual growth increments (× c. 0 5) Figs. 3 and 4 *Holophragma calceoloides*, Lower Silurian, Gothland · (3) corallum about 240 days old, showing growth-lines on epitheca (× c 2 7), (4) growth-lines on epitheca (× c. 13). Fig. 5. *Manicina areolata*, Recent, Dry Tortugas, Florida, growth-lines on epitheca (× c. 40). Fig. 6. *Eridophyllum archiaci*, Middle Devonian, western New York growth-lines on epitheca (× c 21)

the ancient seas, and assembled an appalling mass of very raw data on which he has leaped, with the agility of Raphael Pumpelly's mouflon, from assumption to assumption to heights of speculation where few would care to follow. But Ma's basic idea that annual growth-rates can be determined for many fossil corals appears to be sound.

Others have concluded that annulations or related internal variations in some Palæozoic corals have an annual basis, but no experiments have been undertaken on living corals to determine directly whether or not there is a causal relation between such annulations and annual variations in temperature or other factors. I do not know why such an obvious and simple test has not yet been attempted. There are some experimental data on allometric and volumetric growth-rates but these have little bearing on the problem of annulations, nor do these data tell, or are likely to tell, much more than: (1) that reef corals grow more rapidly in warmer waters; (2) that some corals grow faster than others. There is some evidence that fluctuations in nutrient supplies and reproductive activity have little or no effect on the overall growth-rate of corals.

We must now make an act of faith and assume that the major annulations on corals represent annual growth increments or varves. This, however, is of no direct value in geochronometry, even though it can thereby be shown that some large fossil coral colonies endured for a couple of hundred years, and that some living colonies of reef corals have been growing for the past thousand years or so. There is nothing in these values to orient them in time. A closer look at certain coral structures is necessary.

A number of people have noticed the fine ridges (Figs. 3 and 4) on the surface of the coral epitheca, a fundamental skeletal structure in tabulates, rugosans, and scleractinians, the basic material not only of the exterior of the corallum but in various guises as septa and dissepiments. Whenever epitheca is present and unmodified these ridges are present, although in many fossil specimens they are obliterated by post-mortem wear. The ridges are parallel to the growing edge of the corallum and are tacitly accepted as growth increments variously termed striæ, ridges and growth-lines. I cannot find, however, that anyone has concerned himself with their significance in growth-time. They clearly indicate regular variations in the rate of calcium carbonate secretion, but what is the relation of these to the passage of time? Hourly, daily, circadian, weekly, lunar monthly, periodic reproductive activity, yearly?

I submit that they indicate daily or circadian variation in skeletal deposition, and there is some slender evidence in this direction. Physiological studies on calcium carbonate secretion in recent corals, first made some years ago by Kawaguti and Sakumoto[6], and recently and more elegantly by Goreau[7], who used the isotope calcium-45, show that in reef corals the rate of calcium carbonate uptake in coral tissues falls at night or in darkness and rises during the day, but the reflexion of this in the skeleton has not yet been investigated. A much less-sophisticated approach would be to compare the number of ridges with the annual growth-rate; but this has not been directly tried on living corals in the field. I have tested it indirectly on one or two recent corals the annual linear growth-rate of which is fairly well known, and to my gratification found that the number of ridges on the epitheca of the living West Indian scleractinian *Manicina areolata* (Fig. 5) hovers around 360 in the space of a year's growth. This strongly suggests, subject to experimental confirmation, that the growth-lines are diurnal or circadian in nature. It may be noted in passing that they may provide a much more sensitive caliper for measurement of annual growth-rates than the larger yearly annulations.

The next step, of course, is an attempt to determine the number of growth-lines per annum in fossil corals. Here, as is usually the case, hypothesis is easier than practice. Few fossil corals are sufficiently well preserved to show clearly the supposed diurnal growth-lines, and it is not easy to determine the annual rate. In epithecate recent corals the growth-lines are commonly abraded or corroded even before death of the polyp. The best of the limited fossil material I have examined so far is from the Middle Devonian of New York and Ontario, especially specimens of *Heliophyllum*, *Eridophyllum* (Fig. 6) and *Favosites*. Diurnal and annual growth-rates vary in the same individual, adding to the complexity, but in every instance there are more than 365 growth-lines per annum, usually about 400, ranging between extremes of 385 and 410. It is probably too much, considering the crudity of these data, to expect a narrower range of values for the number of days in a year in the Middle Devonian; many more measurements will be necessary to refine them.

A few more data may be mentioned: *Lophophyllidium* from the Pennsylvanian (Conemaugh) of western Pennsylvania gave 390 lines per annum, and *Caninia* from the Pennsylvanian of Texas, 385. These results imply that the number of days a year has decreased with the passage of time since the Devonian, as postulated by astronomers, and hence that values of the isotopic dates of the geophysicists agree well with the astronomical estimates of the age of the Earth. It is not claimed that coral growth proves that either is right; but it is suggested that palæontology may well be able to supply a third stabilizing, and much cheaper, clue to the problem of geochronometry, and that further search for diurnal or circadian records in groups other than corals may result in strengthening this weak anthozoan prop.

OBITUARIES

Prof. H. Graham Cannon, F.R.S.

HERBERT GRAHAM CANNON, Beyer professor of zoology in the University of Manchester, died in St. Bartholomew's Hospital on January 6 at the age of sixty-five. He had been in poor health for some time.

Born in London, Graham Cannon was educated at Wilson's Grammar School, Camberwell, and Christ's College, Cambridge. Having suffered compound fractures of his wrists during a fall in his youth, he was declared unfit for military service, and on graduation in 1918 became biologist to the then Board of Fisheries. A brief period of research at Cambridge soon followed, and in 1920 he was appointed demonstrator, and later lecturer, in zoology in the Imperial College of Science and Technology. In 1926 he became professor of zoology in the University of Sheffield, and in 1931 Beyer professor of zoology in the University of Manchester. He was elected a Fellow of the Royal Society in 1935.

Graham Cannon's early zoological work, influenced by Doncaster, concerned the spermatogenesis of lice and the nature of the centrosomal force, but he soon turned to an active interest in the Crustacea, which was to last for the greater part of his life. At first his work consisted of embryological and anatomical studies on Cladocera and Conchostraca, but in 1926 he published a paper on the feeding of an ostracod, *Pionocypris*, which was the first of a long series of detailed investigations into the complex filtratory feeding mechanisms found in a wide range of Crustacea. He recognized clearly the essential functional components of these mechanisms, describing current producing, filtering, scraping, and transporting limbs, and illustrated them with minute accuracy. The small size of many of these animals, and the difficulty of direct observation of feeding currents, compelled him to rely in large measure on deduction based on the details of structure. His strong interest in functional morphology generally clearly arises from these researches. Papers on feeding mechanisms were followed by a return to internal anatomy, and outstanding papers were those on the ostracods *Doloria* and *Gigantocypris* and the cirripede *Lithotrya*. In spite of the injuries to his wrists, Cannon showed great skill in fine dissection, and became a zoological artist of distinction. His early papers show the steady development of his technique, and by 1930 his illustrations could truly be described as unequalled. Furthermore, he had the ability to communicate his skill to others, and zoologists generally profited greatly by his publication of a book on methods of drawing and illustration.

In 1948 Graham Cannon was president of Section D (Zoology) of the British Association for the Advancement of Science, and his presidential address on undergraduate zoology marked the beginning of a new interest. From this time on he frequently wrote and spoke on educational matters, and rebelled against increasing specialization in teaching in schools and universities. He turned this interest to practical account by serving on the Northern Universities Joint Matriculation Board, and played an active part in the development of the University of Keele.

Towards the end of his life Cannon became increasingly occupied with thinking and writing on the relationship between Lamarckian and Mendelian inheritance, an interest which clearly had its origin in his work on crustacean feeding mechanisms. He came to hold the view that the fundamental property of protoplasm is its ability to adjust itself to changes in the environment always in the manner optimum to its survival, and that inheritance by the mechanism of the Mendelian gene complex was to be regarded as a later addition to this fundamental property.

In addition to his research and teaching, Graham Cannon played a full part in University administration. He undertook in Manchester periods of office as dean of the Faculty of Science and as pro-vice-chancellor, and was for many years chairman of the Manchester Museum. He served on the Council of the Marine Biological Association, and was well known as an examiner in the University of London. His range of interests was wide, and embraced such diverse interests as music, angling in his early years, cookery, and practical building. But his overriding passion was his love of Japanese objects of art, particularly swords and their furnishings. He was always ready to talk on this topic, publicly or privately, with enthusiasm and understanding.

As a man, Graham Cannon was direct in speech and expressed his views forcibly. He did not easily accept compromise. But those who knew him well saw a genial and kindly scholar who took a real interest in his students and staff. They will remember him with gratitude and affection. Their sympathy and that of his friends will go out to his wife and sons and daughters. R. DENNELL

Mr. A. D. Cotton, O.B.E.

ARTHUR DISBROWE COTTON, who for nearly sixty years was closely connected with the affairs of the Royal Botanic Gardens, Kew, died, after a long spell of ailing health, at Hertford, on December 27, 1962, at the age of eighty-three. He was born in London on January 15, 1879, and received his early education at King's College School, London. During his schoolboy days he developed a strong interest in the British flora, and he built up a considerable collection of pressed plants. His first botanical tuition was received from lectures arranged at Chelsea Physic Garden by J. B. Farmer, and these may well have fostered his liking for gardens and garden plants, an attachment which remained and indeed increased throughout his career. At one time Cotton seems to have determined on a career in horticulture, and he undertook three years' practical training which led to a first-class certificate in the Royal Horticultural Society's general examination.

Later, he decided to follow botany as a vocation, and to this end he spent three years at the Royal College of Science, London, where, under the influence of J. B. Farmer, he specialized in the study of the lower plants. In 1902 he obtained his first post at Owens College, Manchester, where he became an assistant lecturer and, under the influence of O. V. Darbyshire, became interested in fungi and did some research on orchid mycorrhiza. Two years later he entered Government service as an assistant in the Herbarium at Kew under George Massee, the distinguished mycologist. His general duties and research were mainly concerned with the algae, but he also worked with the fungi and lichens, and during this period he published several papers on these groups including his very important contribution to algal ecology in the Clare Island Survey. In 1915, Cotton was placed in charge of advisory services and research on plant diseases in a new laboratory installed at Kew, and indeed he was the first plant pathologist to be appointed in Government service in Great Britain. The laboratory which he initiated was later transferred to Harpenden and has become the Plant Pathology Laboratory of the Ministry of Agriculture, Fisheries and Food. Cotton's continuing interest in mycology is reflected in his sixty years' membership of the British Mycological Society of which he was president in 1913.

Cotton returned to Kew in 1922 when he succeeded Otto Stapf as the keeper of the Herbarium and Library, a post he held until his retirement in 1946. This was a period of active development in the Herbarium with an ever-increasing flow of material to be identified, incorporated and distributed, and about a million specimens were added to the collections during Cotton's keepership. While he retained his interest in the algae and fungi, he turned more to the study of flowering plants. He became an expert on the cultivated lilies, published a number of papers on this attractive group, and largely wrote the botanical text of the *Supplement to Elwes' Monograph of the Genus Lilium* of which latterly he was joint author. For a short time he was editor of *Curtis's Botanical Magazine*, and for this and other services to horticulture he was awarded the Victoria Medal of Honour by the Royal Horticultural Society. Cotton attended the meeting of the British Association in South Africa in 1929 and during his return journey visited Kilimanjaro. The extraordinarily bizarre vegetation of the alpine slopes fired a new interest and he undertook a critical study of the arborescent species of *Senecio* of the East African mountains. One species which he collected on Kilimanjaro bears his name.

He became a Fellow of the Linnean Society in 1902, served for several periods on the Council and was president during 1943–46. In 1934 he was awarded an O.B.E. Cotton was a man of gentle, unassuming manner who will be remembered gratefully by all who had the pleasure of his friendship as a genial, kind and obliging man.

GEORGE TAYLOR

Prof. Karel Hrubý

PROF. KAREL HRUBÝ, professor of genetics in the Charles University in Prague, died in a motor-car accident in Jihlava on December 10, 1962. He was one of the few outstanding Mendelian geneticists in eastern Europe.

Karel Hrubý was born in Prague on September 30, 1910. He received all his education in that city, studying genetics at the Charles University under Prof. B. Němec and Prof. A. Brožek. In order to broaden his genetical outlook, he worked for eight months as a Rockefeller Fellow at the John Innes Horticultural Institution in London in 1938; this greatly influenced all his later work and strengthened his regard for classical genetics when the Lysenko wind became most severe. After the Second World War he again visited Britain, this time on invitation by the British Council, to study the progress of genetics in the Western World during the War. He participated in the genetics congresses in Stockholm (1948) and Montreal (1958), and was at his death member of the Genetical Section of the International Union of Biological Sciences.

Prof. Hrubý lectured in genetics at the Charles University, at which he succeeded Prof. Brožek, first as *docent*, in 1937, and later as professor, in 1945. He also lectured in his subject for some time after the War at Brno and Bratislava, but otherwise all his active academic life was spent at his own Alma Mater.

Prof. Hrubý was an ardent worker in different fields of genetics, in animals and plants and even humans, but he also made significant contributions to the taxonomy of certain plant groups. He was the author of about 170 papers. In addition, he published four books which were widely distributed in his own country. The last of these, *Genetika*, published in 1961, is a masterly treatment of classical and modern Mendelian cytogenetics, the only recent publication of its kind in the Soviet part of the world. Naturally, it is widely used in academic teaching in Czechoslovakia and neighbouring countries, and it is being translated into Russian.

Though very active in scientific research and academic teaching, Prof. Hrubý also found time to take part in many outside activities. At his death he was a member of scientific committees of several academic and practical institutions, on the editorial staff of several journals and the editor of the horticultural publications of the Czechoslovak Academy of Sciences. He was also president of the large Czechoslovak Botanical Society and the chief organizer of its very successful symposium on experimental taxonomy held at its fiftieth anniversary jubilee meeting in July 1962, with several hundred participants from home and abroad.

Prof. Hrubý is survived by his wife, Anna, a son and four daughters. He is remembered as an energetic supporter of scientific cytogenetics during times of bureaucratic suppression of Mendelian ideas, as a scientist of unusual ability, but above all for his character and personality and untiring helpfulness to others.

Áskell Love

Dr. Thomas Bedford, O.B.E.

Dr. Thomas Bedford died on January 24 in his sixty-ninth year. His sudden passing will have come as a great shock to a wide circle of friends and colleagues.

Dr. Bedford had been engaged on problems of occupational hygiene for the past 44 years, and he will rank as one of the pioneers in this important field. He was appointed to the staff of the then Industrial Fatigue Research Board in January 1919. A year later he joined forces with the late Dr. H. M. Vernon, and their conjoint working continued until the latter's retirement in 1933. During this period a wide range of investigations were concerned with problems relating to rest pauses and accident rates in many industries, and the influence of atmospheric conditions on the working capacity and the comfort of workers was also studied.

From 1933 Dr. Bedford began to specialize in the field of thermal studies. His researches into the physiological reactions of the human being to thermal stresses established basic principles and methods of measurement and evaluation which became accepted as standard practice internationally. As director of the Environmental Hygiene Research Unit of the Medical Research Council he attained great eminence and became an outstanding authority in his particular field. In 1953, by which time Dr. Bedford had long felt that a society should exist in Great Britain to represent those engaged in the field of occupational hygiene, his personal effort and enthusiasm were responsible for the founding of the British Occupational Hygiene Society. This now flourishing body will continue to be a fitting tribute to his memory. Although he retired from the service of the Medical Research Council in 1959, when he was awarded an O.B.E., Dr. Bedford maintained his many contacts on Government and other official committees. Personally, Tom Bedford was of a quiet and unassuming nature. His dedication to work was always blended with qualities of marked benevolence and kindness that endeared him to all who had the good fortune to be associated with him, privately and professionally. Many will remember with gratitude the help that he gave them so generously in dealing with their problems.

So has ended a full life of distinguished contribution to the science of occupational hygiene, in which Tom Bedford's guiding principle was always service before self.

C. G. Warner

NEWS and VIEWS

Deputy Principal at the University of Birmingham: Dr. T. Alty

Dr. Thomas Alty, retiring vice-chancellor of Rhodes University, South Africa, has been appointed deputy principal of the University of Birmingham as from May 8. Dr. Alty was appointed master of Rhodes University College in 1948 and became first principal and vice-chancellor of Rhodes University on its establishment in 1951. Dr. Alty was educated at the University of Liverpool, where he was Oliver Lodge Fellow in 1921, and at the University of Cambridge. He was a lecturer in physics at the University of Durham from 1924 until 1925, and in 1925 was appointed to the chair of physics at the University of Saskatchewan, Canada. He held this chair until 1932 when he was appointed research professor of physics in the same University. In 1935 he returned to Britain when he was appointed to the Cargill chair of applied physics at the University of Glasgow. This he held until 1945 and thereafter the Cargill Chair of Natural Philosophy in the same University until 1948. From 1958 until 1960 Dr. Alty was chairman of the Association of Universities of the British Commonwealth. From the date of Dr. Alty's appointment as deputy principal the office of vice-principal will be known as the office of pro-vice-chancellor and vice-principal.

Electronic Engineering at Leeds: Prof. P. J. B. Clarricoats

Dr. P. J. B. Clarricoats has been appointed professor of electronic engineering in the University of Leeds. He was educated at the Imperial College of Science and Technology, where he obtained the degree of B.Sc.(Eng.) in 1953 and five years later was awarded the degree of Ph.D. Following graduation, Dr. Clarricoats was employed by the General Electric Company at Stanmore until 1958, when he was appointed lecturer in the Department of Light Electrical Engineering in the Queen's University of Belfast. There he created a microwave research group and arranged contracts with the Department of Scientific and Industrial Research and the Ministry of Aviation, which provided apparatus and grants. In 1962, he was appointed lecturer in the Department of Electrical Engineering at the University of Sheffield. He was awarded two premiums by the Institution of Electrical Engineers for his work on microwave ferrites. He has been a consultant with Messrs. Short Bros. and Harland since March 1961. He was awarded a senior visiting fellowship of the Organization for European Co-operation and Development by the Swedish Natural Science Research Council in December 1962.

Director of Dounreay: Mr. R. R. Matthews

Mr. Roy R. Matthews, formerly deputy director, reactor design in the Reactor Group of the United Kingdom Atomic Energy Authority, has been appointed to succeed Dr. R. Hurst as director of the Dounreay Experimental Reactor Establishment. Dr. Hurst is leaving the Authority to become director of research of the British Ship Research Association. Mr. Matthews was educated at Lindisfarne College, Westcliff-on-Sea. A scholar of Queen's College, Cambridge (1940–42), he graduated with honours in mechanical sciences. In 1942 he joined the Royal Navy and served on H.M.S. *Indefatigable* in the Atlantic and the Pacific until 1946 as a temporary lieutenant (E.), R.N. In 1947, after a short period with E. S. and A. Robinson, Ltd., Bristol, he joined the London Office of the Anglo-Iranian Oil Co. Ltd. In 1948 he went to Abadan, Iran, for three years, holding various posts in the maintenance and development engineering departments. Returning to England in 1951, he joined Monsanto Chemicals design department as a senior project engineer. He joined the Atomic Energy Authority in 1955 as assistant chief engineer in the Fast Reactor Design Office, becoming deputy chief engineer in 1956 and chief engineer in 1957. In 1961 he was appointed deputy director of the Reactor Design Branch. His qualifications include Associate Membership of the Institutions of Mechanical, Chemical and Electrical Engineers.

Marine Nuclear Propulsion

In a speech in the House of Commons on the Brussels negotiations on the European Economic Community on February 11, the Prime Minister said that Britain had always been anxious not merely to build a nuclear engine which could propel a merchant ship but to get a nuclear reactor which is economically attractive. This point was now near at hand and the Minister of Transport would very soon be discussing with all those concerned the arrangements for the construction, ownership and operation of such a vessel. In a written answer on February 13, Mr. E. Marples stated that those talks had now begun, but it was too soon to say what type and size of vessel would be selected if the Government decided that one should be built, nor was it possible at this stage to say how the order would be placed. If suitable financial and other arrangements could be agreed with industry, Mr. Marples hoped that a firm decision whether a ship should be built would be taken before the end of the year.

In a further written answer (in the House of Commons) on February 15, the Minister of Transport stated that since December 20 research had progressed to a point where it became clear that it would be possible to decide before the end of the year whether a prototype nuclear ship would be built. In these circumstances, the Government had decided that the time had come to have discussions with the shipping and shipbuilding industries about the arrangements for such a ship. It was expected that it would be possible to decide before the end of the year which reactor system should be installed in a prototype nuclear ship, if one is built. The Civil Lord of the Admiralty, Mr. C. Ian Orr-Ewing, added that the Admiralty had no present plans for building a nuclear-powered surface vessel, but was keeping in close touch with the latest developments and applying the knowledge gained from them to studies of possible future warships.

Teaching Machines and Programme Learning

In an adjournment debate in the House of Commons on February 12, Mr. R. Gresham Cooke and Mr. G. M. Thomson raised the question of teaching machines and urged the support of further research into programmed learning and the use of such machines. In replying for the Government, the Parliamentary Secretary to the Ministry of Education, Mr. C. Chataway, welcomed the debate and said that this development was being very carefully studied. Although almost all the research on programmed learning was being carried out in the United States, there was in Great Britain a shortage of thoroughly validated programmes. The Government particularly welcomed the work being undertaken by the Association for Programmed Learning—a professional body mainly of practising teachers. Research was still proceeding into the efficiency of the linear type of programmed learning and of the multiple choice variety, and so far the results were rather inconclusive. Mr. Chataway thought that Mr. Cooke had overestimated the amount of research so far carried out. The first significant research in Great Britain was in the Psychology Departments of the Universities of Aberdeen and Sheffield, supported by grants from the Department of Scientific and Industrial Research, and was directed mainly to the industrial application of programmed learning. However, within the past few months research into educational aspects of the subject had commenced in the Department of Education at the University of Sheffield. Work had also commenced at Sheffield in October 1962, on methods of using programmed learning in secondary school mathematics up to the Ordinary Level of the General Certificate of Education, with the view ultimately of Advanced Level. This was made possible by a grant from the Ministry of Education of £12,000 over three years. The Ministry had also offered a grant of £1,000 a year for three years to support research under the Department of Education, University of Leicester, with simple linear machines and programmes suitable for use by primary school children, especially in arithmetic and reading. Replies to an inquiry of all local education authorities, colleges of advanced technology and institutes of education in October indicated that only 20 authorities out of 146 had anything positive to report. Three colleges of advanced technology and the College of Aeronautics at Cranfield were experimenting with machines, and in several institutes of education programmed learning was beginning to play a part in teacher training.

River Authorities and Land of 'Special Interest'

At the report stage of the Water Resources Bill in the House of Lords on February 14, the Government accepted an amendment moved by Lord Hurcomb which inserted a new clause. Under this clause the Nature Conservancy, when of the opinion that any area of land not managed as a nature reserve but which is of 'special interest', and which may at any time be affected by schemes, activities or operations of a river authority, has the duty of notifying the river authority that the land is of special interest by reason of its flora, fauna, geological or physiographical features, etc. It is already the duty of the Nature Conservancy to notify the local planning authority of any area which in its opinion is of special scientific interest, and, for the Government, Earl Jellicoe agreed that such early information should help to avoid possible clashes of interest between the river authorities and the Conservancy. He wished to consider further, without prejudice, whether it would be reasonable for the Minister to give a directive to the river authorities requiring them to consult the Conservancy at the earliest possible stage about any scheme, operations or activities likely to affect the areas of which they have been notified. An amendment moved by Lord Conesford and proposing to insert specific reference to the use of sea-water and extracting the salt as a means of augmenting water resources was, by leave, withdrawn on Earl Jellicoe pointing out that the matter was covered more comprehensively elsewhere in the Bill under a clause which made the Water Resources Board responsible for considering desalination along with other means of augmenting water supplies.

Emperor Tandem Van de Graaff Accelerators

AN *Emperor* tandem Van de Graaff accelerator, costing 3 million dollars, for the University of Rochester has been financed by the largest single grant ever made by the U.S. National Science Foundation. The accelerator is being made by the High Voltage Engineering Corporation, Burlington, Mass. This is the fourth *Emperor* recently built by the Corporation. All the machines will be used to conduct research on the structure of the atomic nucleus. The most precise, powerful and versatile instrument yet developed for the study of nuclear structure, the *Emperor* tandem accelerates protons and heavy atomic nuclei to energies of 20 million eV and velocities close to the speed of light. The highly stabilized and homogeneous accelerated ion beams, at currents rated up to 25 μamp, will permit many experiments to be carried on simultaneously. Two of the 187-ton accelerators were recently purchased by the U.S. Atomic Energy Commission to be installed at Yale University and the University of Minnesota. A third will go to the Chalk River Nuclear Laboratory of Atomic Energy of Canada, Ltd., in Ontario. Other large radiation machines for physics research have been supplied by the Corporation to West Berlin, the Laboratoire Joliot-Curie de Physique Nucléaire, Orsay, France, and the Universities of Washington, Pittsburgh, Virginia and Kentucky.

Science and the Welfare of Mankind

IN a lecture, "Science, State and Society", delivered at Dynevor School, Swansea, on October 18, 1962, Prof. B. H. Flowers dealt with the potentialities of science for good and ill on lines that are strikingly reflected in Dr. C. P. Haskins's subsequent presidential report to the Carnegie Institution of Washington (see *Nature*, 197, 729; 1963). Beyond the possibilities which the development of nuclear energy, of synthetic materials, of satellites, of biotechnology have put in our reach, science has profoundly affected the political and sociological atmosphere of the world through radio and television, as well as through the use of electronic computers. Many of the technical problems of world government are disappearing and the time-interval between scientific discovery and full-scale use is now so short that the scientist himself can be involved from the moment of discovery to the final application. Further, scientific endeavour now absorbs a very large proportion of the intellectual and industrial skill of the State, so that it is a matter of public importance whether one venture is undertaken rather than another. Endorsing Sir John Cockcroft's comment to the British Association about wrong priorities in the context of space research, defence and the under-developed countries, Prof. Flowers urged that it is not enough for universities simply to provide the scientists and technologists needed and to carry out the fundamental research on which progress in technology depends; they must also prepare a far larger fraction of the population for intelligent participation in the democratic way of life and must foster the study of man himself. Copies of the lecture (Pp. 16) are obtainable from Dynevor School, Swansea, price 1*s*. 6*d*.

The Southern Regional Council for Further Education

THE fifteenth annual report of the Southern Regional Council for Further Education expresses concern at the additional accommodation problems which may beset colleges where more workshop space is required to implement some of the new engineering courses, and has already recommended to the National Advisory Council that some financial help should be given by the Ministry to local education authorities through an additional minor projects allocation specifically for engineering workshop accommodation (Pp. 38. Reading: Southern Regional Council for Further Education, 1962). A conference of teachers and representatives of the engineering industry was organized in July to discuss the organization of the new courses. Full-time students in the 1961–62 session numbered 8,034 compared with 7,437 in 1960–61; for part-time day students the corresponding figures are 46,996 and 37,329, and for part-time evening students 41,214 and 33,357. Notes are included on progress and developments in the colleges in the area, and the Regional Academic Board has expressed to the Ministry of Education the view that some new agency is needed to give financial assistance in the development of research in technical colleges. The report includes also the accounts for the year ended March 31, 1962, lists of chairmen and changes in membership of the Council, the Regional Academic Board, Executive Committee and Advisory Committees as at September 30, 1962, evidence submitted to the Robbins Committee and a list of 42 research projects notified by colleges in the region during the session 1961–62.

Fellowship Programme in Nuclear Science

THE Fellowship Programme of the International Atomic Energy Agency has, since the inception of the fellowship activities of the Agency in April 1958, provided with the Exchange Programme a variety of training opportunities relating to the peaceful uses and applications of nuclear energy and its technology. The Fellowship Programme operates through the award of several types of fellowship to qualified applicants and is financed from three different sources: (*a*) member States making contributions to the Agency's General Fund, allocations of which are made every year to the Fellowship Programme by the General Conference; (*b*) direct from the member States which make fellowships available to the Agency for training at their national institutions and universities; (*c*) the Expanded Programme of Technical Assistance of Unesco according to the usual procedure of country programming. Stipends and other allowances are determined mainly by the scale of monthly stipends agreed on by Unesco in consultation with its specialized agencies. Travel expenses of the candidates are expected to be borne by the nominating Government. A brochure entitled *The Fellowship Programme in Nuclear Science* deals with the following aspects of the Programme: types and periods of training; training opportunities; application and nomination of candidates; documents required for submission to the Agency; selection of candidates and award of fellowships; financial considerations; insurance; reports and control; vacation leaves; extensions; obligations of Governments; statistics; general list of institutions; opportunities at the International Atomic Energy Agency Laboratories. Copies of the brochure and further information can be obtained from the International Atomic Energy Agency, Karntner Ring, Vienna 1, Austria.

New Research Project for Mental Health

In 1962 Mrs. Rees-Thomas donated £50,000 to the National Association for Mental Health. It has now been decided to use the income from this donation in the first instance to finance a research project concerning the adequacy of present training methods for teachers working in training centres for the mentally handicapped. The Association at present runs courses of training for these workers and its diploma is so far the only recognized certificate of competence for these workers. The Scott Committee has made certain recommendations about these trainings and its report is at present before the Minister of Health. No validation of present teaching methods has so far been undertaken and research is generally felt to be desirable. This might cover not only the suitability of present training schemes but also the most suitable methods of approaching the children at various stages of their development. The donation now enables the National Association to appoint research workers in this important field. It is hoped that a university department will be prepared to co-operate with this inquiry. The successful applicant will be expected to undertake detailed and systematic surveys of work at present in progress. Further information can be obtained from the National Association for Mental Health, Maurice Craig House, 39 Queen Anne Street, London, W.1.

Fellowships for Scientific Research

The Department of Scientific and Industrial Research awarded a total of 92 postdoctoral research fellowships during the year 1962–63, almost twice as many as in the previous year. The awards enable scientists and technologists to study abroad, either through their own scheme of awards or through the science studentship and fellowship scheme of Nato, including 48 D.S.I.R. fellowships, and 44 awarded by the Department under the Nato scheme. Twenty-five of this year's Nato fellowships were for study abroad and 19 to enable British scientists who had been studying in North America to return to Great Britain. Thirty-four postgraduate studentships were granted by the Department of Scientific and Industrial Research under the Nato scheme, these being held in nine different European countries, the United States and Canada. The awards, which are tenable for two to three years at universities, colleges and other approved institutions in any part of the world, can be either at postgraduate studentship or postdoctoral level. Details of these awards and methods of application are given in a new edition of the booklet, *D.S.I.R. Studentships and Fellowships, 1963*, published by H.M.S.O. (price 3*s*.), which also gives the particulars of such awards tenable in Great Britain.

Endeavour Prizes

Prizes totalling 100 guineas are offered by Imperial Chemical Industries, Ltd., publishers of the international scientific review *Endeavour*, for essays submitted on scientific subjects. In addition to the cash prizes, the prizewinners will receive invitations to attend the whole of the British Association meeting at Aberdeen during August 28–September 4. Accommodation will be provided in Aberdeen, and travelling expenses within the United Kingdom will be paid. As the primary purposes of these awards are to stimulate younger scientists to take an interest in the work of the British Association and to raise the literary standard of scientific writing, the competition is restricted to those whose twenty-fifth birthday falls on or after June 1, 1963. Five prizes will be awarded, namely: a first prize of 50 guineas; a second prize of 25 guineas; a third prize of 15 guineas; two special prizes of 5 guineas each for competitors who have not passed their eighteenth birthday on June 1, 1963. The subjects for the essays are as follows: (1) Space research: its scientific significance. (2) Response to viral infection. (3) Photosynthesis. (4) The mechanism of muscular contractions. (5) High-temperature chemistry. (6) The concept of aromaticity in chemistry. The essays, which must be in English and typewritten, should not exceed 4,000 words in length, and only one entry is permitted from each competitor. All entries should be addressed to the Deputy Secretary, British Association for the Advancement of Science, 3 Sanctuary Buildings, Great Smith Street, London, S.W.1, and the envelope should be clearly marked 'Endeavour Prize Essay'. The latest date for receipt of entries is June 1, 1963. The essays must be submitted without signature, and the competitor's full name and address and date of birth should be disclosed in a sealed covering letter attached to the essay and addressed to the Deputy Secretary of the British Association, who will acknowledge all entries.

Announcements

Prof. W. H. Pearsall and Dr. Sidnie Manton have been awarded Linnean Gold Medals as an expression of the Society's estimate of their services to science. Mr. J. E. Lousley has been awarded the Society's Bloomer Award in recognition of important contributions to biological knowledge made by an amateur naturalist.

Monsieur P. M. J. Ailleret, deputy director-general of Electricité de France, has been awarded the Faraday Medal of the Institution of Electrical Engineers for his contributions to the techniques of the high-voltage long-distance transmission of electric power and the economic integration of national and international electricity supply networks. The Rt. Hon. Lord Fleck, formerly chairman of Imperial Chemical Industries, Ltd., has been elected an honorary member of the Institution.

Dr. K. P. Oakley, of the British Museum (Natural History), has been awarded the Prestwich Medal of the Geological Society of London, for his researches on fossil man and the development of physical and chemical methods for the dating of fossil mammalian bone.

A conference on "Inert Gas Compounds" will be held at Argonne National Laboratory during April 22–23. Further information can be obtained from Herbert H. Hyman, Argonne National Laboratory, 9700 South Cass Avenue, Argonne, Illinois.

A one-day colloquium on "Electrical Properties of Flames", organized by the Committee of the British Section of the Combustion Institute, will be held at the College of Advanced Technology, Birmingham, on April 19. Further information can be obtained from Dr. W. G. Parker, Department of Chemistry, College of Advanced Technology, Gosta Green, Birmingham 4.

Under the sponsorship of NATO a summer school will be organized at the University of Ghent during July 29–August 9. The topics to be treated will be concerned with the surface properties of semi-conductors. Further information can be obtained from Prof. W. Dekeyser, Laboratorium voor Kristallografie en Studie van Vaste Stoffen, Rozier, 6, Ghent, Belgium.

The College of Advanced Technology, Birmingham, is arranging the following courses in metrology and quality control: metrology and quality control (April 29–May 10); advanced metrology (May 20–24); statistical quality control and acceptance sampling (September 9–27). Further information can be obtained from the Secretary, College of Advanced Technology, Gosta Green, Birmingham.

The second bionics symposium on "Information Processing by Living Organisms and Machines", sponsored jointly by the Aeronautical Systems Division and the Aerospace Medical Division, United States Air Force Systems Command, will be held in Dayton, Ohio, during March 19–21. Further information can be obtained from the Information Office, Aeronautical Systems Division, Wright-Patterson AFB, Ohio.

U.S. EDUCATIONAL SERVICES INCORPORATED

EDUCATIONAL Services Incorporated of Watertown, Mass., a non-profit educational research organization which originated as the Physical Science Study Committee under the auspices of the Massachusetts Institute of Technology in 1956, has been awarded a grant of 1,000,000 dollars by the Ford Foundation.

Responding to the need for improving curricula in American schools, Educational Services Incorporated has initiated the improvement of projects in many disciplines; it also participates in various educational programmes overseas, including the new Indian Institute of Technology, at Kanpur, and in emergent countries in tropical Africa.

Curriculum reform programmes are now being conducted in the teaching of science in the elementary grades and in developing a social studies and humanities curriculum applicable at all grade levels. In addition to these and other programmes in the primary and secondary schools, Educational Services Incorporated is assisting in the development of new techniques and methods of teaching science and engineering in the universities. The organization also offers administrative support to the National Commission on Engineering Education.

Educational Services Incorporated was founded in 1958 to handle the expanding Physical Science Study Committee programme and to provide administrative guidance and support for other course content improvement projects. The Committee course, formed in 1956 by Prof. Jerrold R. Zacharias, professor of physics in the Massachusetts Institute of Technology, and the late Prof. Francis L. Friedman, also a professor of physics in the Institute, has revolutionized the teaching of high-school physics. The course is now being taught to about 135,000 students in the United States, or approximately 30 per cent of those taking high-school physics.

Physicists and educators at many universities contributed to this course, including groups from the University of Illinois, Cornell University, Bryn Mawr College, Educational Testing Service of Princeton, New Jersey, Harvard University, the Massachusetts Institute of Technology, and other schools. Material supplied by the course has been translated into Swedish, Norwegian, Italian, Japanese. Hebrew, Spanish and Portuguese. It has also been translated into French for use in Canada. Further translations are being prepared in Danish and Turkish.

The Physical Science Study Committee course is notable not just for the text-book which stresses basic concepts of physics and carries high-school students into modern physics, but also because of the coherence and variety of the accompanying teaching aids, including films, examinations, laboratory apparatus and laboratory experiments. So far, fifty-three films made by the course have been produced by Educational Services Incorporated with many of the nation's leading physicists serving in principal roles in demonstrating some of the basic concepts of physics. Some of the films are now being adapted for college use.

The Science Study Series, published by Doubleday Anchor Books with the editorial counsel of Educational Services Incorporated, provides collateral reading for science students. This series of paperbacks includes biographies of famous scientists and their roles in the development of fundamental physical concepts. Teacher-training institutes for high-school physics teachers in the United States and in many nations overseas have also been organized.

In addition to the Physical Science Study Committee, Educational Services Incorporated is now developing programmes in the following areas.

Elementary Science Study. Physicists, chemists, biologists, mathematicians and scientists from other disciplines are participating in the preparation of material for the elementary grades. This material includes text, films, the development of experiments for classroom use, and the inauguration of teacher-training programmes to introduce a study of science in the elementary school curriculum. Some of the topics being studied this year in experimental classes at selected schools in New Jersey, Pennsylvania, Delaware, Oregon, New York and the District of Columbia, include micro-ecology, plant growth, elementary physics, and laboratory science. More than one hundred scientists and educators in the United States and overseas are associated in the preparation of preliminary material.

Kanpur Indo-American Programme. The Indian Institute of Technology at Kanpur, about two hundred miles south-east of New Delhi, is being developed by the Government of India into a major centre for education and research in engineering and science. Now in its second year of operation, the Institute offers undergraduate programmes in physics, chemistry, mathematics, and civil, electrical, chemical, mechanical and metallurgical engineering. It is expected that graduate courses will be given in the next few years.

At the request of the Government of India, nine leading American universities are assisting in the development of the Indian Institute. Because the resources of a single American university would be severely overtaxed if it were to furnish the sustained effort required to carry out the United States commitment at the Institute, a consortium of universities was formed in April 1962. Educational Services Incorporated administers the project contract which is financed by the United States Agency for International Development. The participating universities are California Institute of Technology, Carnegie Institute of Technology, Princeton University, the University of Michigan, the University of California, Purdue University, Ohio State University, Case Institute of Technology, and the Massachusetts Institute of Technology. Twelve American staff members are now teaching at the Institute. It is expected that this number will be doubled towards the end of 1963.

Indian plans for the Institute, which now has a staff of 40 and approximately 200 undergraduates, provide for 1,600 undergraduates, 400 graduate students, and a staff of about 250.

African Education Study. Educational Services Incorporated, following two major conferences in Africa at Accra, Ghana, in 1961, and at Entebbe, Uganda, in 1962, is engaged in a broad programme designed to help emergent countries in tropical Africa to assess their educational needs in the future in mathematics, in the sciences, in languages, and in the social studies and humanities.

Text material in mathematics, prepared by Educational Services Incorporated, including representatives from the Stanford University Arithmetic Programme, is being used in preliminary trials in many African schools now beginning.

The African Education Programme is developing as a partnership between the African educationists and those from the United States and Great Britain. In this endeavour Educational Services offers especially the organization's experience with course content improvement programmes.

Commission on Engineering Education. Members of this Commission include many leading representatives from industry, Government, and education. The Commission was formed at a meeting at Boulder, Colorado, in 1961.

The headquarters of the Commission in Washington function as a point of co-ordination for the members. The Commission is developing educational resources of particular relevance to fundamental fields of engineering, including all types of educational resources and procedures which involve both students and faculty in the areas of design, data processing and decision making.

Semiconductor Electronics Education Committee. The teaching programme of this Committee—now being used for the first time, in its preliminary form, at eleven universities in the United States and Great Britain—demonstrates introductory semiconductor physics, the principles of semiconductor devices, and the most important features of electronic circuit design and construction which use semiconductor devices. It is intended that the final material produced by the Committee will be used in either the junior or senior year of college.

The Committee's presentation includes text material in the form of a series of six paperback books on the principles and applications of semiconductors; the development of home laboratory experiments; take-home laboratory kits; a series of formal laboratory experiments; and a set of films both complementary and supplementary to the texts.

National Committee for Fluid Mechanics Films. The films in fluid mechanics produced by this Committee are being used at more than sixty universities and Government institutions in improved teaching of aeronautical and astronautical engineering, and in chemical, civil, mechanical and marine engineering. The films are also being used in the instruction of meteorology, applied mathematics, and in medicine. The first two major films produced, *The Fluid Mechanics of Drag* and *Vorticity*, are being used at universities in the United States, Ghana, Great Britain, Australia, Canada, Israel and Holland.

Social Studies and Humanities. This programme evolved from a conference sponsored by Educational Services Incorporated at Dedham, Massachusetts, in the summer of 1962. Participants at the conference represented the humanities and the social sciences, including literature, history, art, music, Latin and Greek, as well as sociology and psychology. The consideration of the possible revision of the present social studies and humanities curricula is the aim of this programme, which is not yet fully implemented. Investigations are being made of the individual humanistic disciplines with the view of focusing the major ideas of the past and present into a presentable, coherent framework which may then, using some of the techniques developed by the behavioural scientists, be taught most effectively.

SOLVENT EXTRACTION CHEMISTRY

A SYMPOSIUM on "Solvent Extraction Chemistry" was held at Gatlinburg, Tennessee, during October 23–26, by invitation of the Oak Ridge National Laboratory. The purpose of the symposium was to bring together persons engaged in investigating solvent extraction and to provide for the interchange of information, not merely through the papers presented, but also in an open session and by informal discussions.

The presentation of thirty-two papers submitted from laboratories in the United States, Great Britain, France, Sweden and Italy in a programme which filled four days is a measure of the expansion of work in this field since the one-day symposium (*Nature*, **172**, 149; 1953), arranged by Atomic Energy Research Establishment, Harwell, in 1953. In the intervening period, the chemistry of solvent extraction has been included in conferences of wide scope, such as the International Conferences on the Peaceful Uses of Atomic Energy at Geneva in 1955 and 1958; in these, the chemical aspects have generally taken second place to flowsheets and processing problems.

Dr. F. L. Culler, head of the Chemical Technology Division, Oak Ridge National Laboratory, in his opening remarks pointed out that the progress achieved by research in the past decade had made solvent extraction an important and powerful technique for solving the separation, purification and recovery problems that occurred in the field of atomic energy. Solvent extraction had moved forward from the use of diethyl ether to separate uranium from contaminating metals to being a versatile technique applied to the separation of closely related inorganic compounds in a variety of acid media: separations could if necessary now be achieved in a matter of seconds rather than minutes. Dr. Culler foresaw the time when its use for separations of biological substances would be greatly extended.

Organo-phosphorus compounds, which were grouped as 'neutral' or 'acidic', formed the subject of several papers presented by the members of the Argonne National Laboratory, Atomic Energy Research Establishment, Harwell, Oak Ridge National Laboratory and the General Electric Co. Laboratories at Hanford. The neutral class extract metals and acids: the former mainly by solvation $\equiv P{=}O \rightarrow M$, there being replacement of aquo groups from the co-ordination sphere; the latter by hydrogen bonding. The extractive power of these compounds has been correlated with their basicity, which is reflected in a number of properties such as the frequency of the infra-red stretching vibration of the PO group: the extraction order is phosphine oxides > phosphinates > phosphonates > phosphates.

The phosphates, though relatively weak as extractants, are ideal for many separation processes as recovery from the organic phase is usually easy: tributyl phosphate (TBP) has been extensively studied on account of its versatility, and the part played by ions and ion-pairs in TBP systems has been recognized. Increased attention has been paid to the influence of the polarity of the diluent, often a hydrocarbon, on the distribution coefficients. Among these neutral compounds, phenyl phosphonates have been found to have enhanced selectivity for the separation of certain metals, while phosphine oxides are suitable for small-scale laboratory separations and for analytical purposes. Other compounds included in the reviews were certain diphosphonates found to be very powerful extractants, and thiophosphates.

The main impression given by the papers dealing with the acidic organo-phosphorus compounds as extractants was the variety of mechanisms that have been found to occur. Thus the metal complexes obtained with the monoacidic phosphates, HX, may contain: (1) the unit X^- as a monodentate or as a bidentate group; (2) the group HX_2^- derived from the dimer of HX; (3) the neutral group, HX, co-ordinated through its phosphoryl oxygen; (4) the anion, for example, NO_3^-, present in the aqueous phase. In view of the interaction of the neutral compounds (for example, TBP) with HX and of their ability to form solvates, it is not surprising that the extracting power of a mixture of a neutral compound and HX is often considerably different from that of HX alone.

Amines and quaternary ammonium compounds have not yet been applied so extensively as organo-phosphorus compounds, but the five reviews devoted to them suggested they will be found increasingly useful for the extraction of acids and for the separation of the platinum group metals and of the transuranium elements. Other papers surveyed developments in the application of solvent extraction to analytical purposes and to the extraction of fission products from the waste liquors that occur from the treatment of irradiated fuels.

The final session was of particular interest to those concerned with the operation of tributyl phosphate processes for the separation of fissile material from irradiated reactor fuels. The papers and the discussion which followed dealt with chemical aspects of the degradation (by thermal and radiolytic reactions) of tributyl phosphate itself and of the hydrocarbon diluent which form the bulk of the organic phase. Complementary studies at the Atomic Energy Research Establishment, Harwell, and at Windscale Technical Works have identified the class of compounds responsible for the retention of fission product zirconium in the organic solvent after it has been in use for several months; the compounds are certain hydroxamic acids, present at less than 10^{-5} M and derived from the nitration of the diluent.

The symposium was organized by a committee under K. B. Brown as chairman. The papers are to be published in *Nuclear Science and Engineering*. J. M. FLETCHER

HYDRAULICS AND FLUID MECHANICS

A CONFERENCE on "Hydraulics and Fluid Mechanics" was held at the University of Western Australia, Nedlands, during December 6–13. It was sponsored by the Faculty of Engineering and is to be the forerunner of a triennial series. These will be held initially in Australia or New Zealand and will be known as Australasian Conferences on Hydraulics and Fluid Mechanics.

The inclusion of both the terms was for the purpose of attracting a wide variety of papers. This aim was fulfilled and the conference assisted in bringing applied mathematicians, physicists and engineers closer together in a most co-operative atmosphere. It also helped to make the attendance sufficient for all activities associated with such conferences to be undertaken. This is a particular problem presented to conference conveners in Australia and New Zealand, where travel distances are so great and specialists in any field so few. In these circumstances, most attenders must be authors to warrant travel subsidy by an employer, and a wide variety of topics must be accepted so that the gathering warrants the outlay to attend.

The open invitation resulted in 57 papers being presented or tabled during the course of the five working days. In each session of one and a half hours three papers were generally presented. Each author had twenty minutes for presentation, which left half an hour for discussion of all papers. Some concurrent sessions were necessary.

The proceedings of the conference are to be published by Pergamon Press and should be available about May 1963. The volume will contain approximately half the papers submitted, together with the inaugural address delivered by Prof. Hunter Rouse, director of the Iowa Institute of Hydraulics Research. It was appropriate that Prof. Rouse should be guest at this first conference of a new series having been inaugurator of the renowned series of Iowa Hydraulics Conferences.

Reference was made to the Iowa series and the different approach made in it and the present conference. For example, the former had specific themes with solicited speakers while the latter covered a wide range of topics with unsolicited papers. Prof. Rouse recommended experimentation in the various facets of organizing the conference. As future gatherings are to be the sole responsibility of the university which chooses to hold it, such variations are likely. The only probable common denominators are the need for a wide variety of papers, for the reasons given here, and the desirability of having as many overseas visitors as possible.

Prof. Rouse's address was entitled "On the Art of Advancing the Science of Hydraulics", emphasis being placed on 'science' as distinct from applications, and 'hydraulics' which connoted a specific branch of fluid mechanics—the sturdy offspring which the original empirical experimentation of hydraulics begot. Speaking on the part played by the university, Prof. Rouse submitted that fundamental research was as essential to it as was higher education. He accepted that product or process development had its creative or instructive sides, but that routine testing, involving no new procedures or concepts, should be reserved for the commercial laboratory or the technical institute. Other requirements in the art of advancing any field of knowledge were free exchange of ideas among research workers and emphasis on good staff above all else—equipment, buildings, maintenance, funds, etc.

The conference papers of more direct interest to engineers have been summarized elsewhere[1,2] and hence only those of general scientific interest will be included here. The topics on which two or more papers were received included flow through porous media, the effect of vortices, waves and guided weapon research.

Porous Media

R. A. Wooding (Applied Mathematics Laboratory of the Department of Scientific and Industrial Research, Wellington, New Zealand) presented a paper entitled "Mixing Layers in Flow Through Porous Media". It treated properties of steady vertical convection from a source of heat, or of heated fluid in a saturated porous medium, when the Rayleigh or Péclet number was very large. The effects of thermal diffusion were important only in zones of mixing between fluids at different temperatures. Flows of this type could be expected in geothermal regions.

J. de Yong (Commonwealth Scientific and Industrial Research Organization, Division of Forest Products, Melbourne) discussed the merits of applying capillary or drag models to flow through media of high porosity. The paper was aimed specifically at paper pulp pads, and emphasized consideration of rheological properties in evaluating permeability. Various theories were described and tests reported, from which it was concluded that the 'drag equations' described the permeability flow-rate relationship most accurately.

Vortices

A paper entitled "Sink Vortices and Whirlwinds" was presented by E. K. Webb (Commonwealth Scientific and Industrial Research Organization, Meteorological Physics Division, Melbourne). Whirlwinds develop only over smooth ground when there is strong thermal convection (ground hotter than air) with a light wind. The criterion for the formation of a whirlwind was developed in terms of inflow and an effective turbulent viscosity. It was only when a significant portion of the inflow shrank into the molecular conduction boundary layer that this criterion was satisfied. The equation was derived which satisfied this latter condition. It corresponded to a wind less than one metre per second over bare ground on a summer's day.

E. Inoue (Division of Meteorology, National Institute of Agricultural Sciences, Tokyo) discussed the "Horizontal Diffusion over the Sea Surface". He applied the techniques of analysing the diffusing smoke puffs and plumes in the atmosphere to similar phenomena in the sea. In this way oceanic turbulence can be gauged. Two types of diffusion were considered; that generated instantaneously and that from a fixed source over time. Equations were presented for the variation of area with time and the vanishing time of the dye patch. These results are applicable to problems of sea pollution, such as ship discharge, sewage outfalls and the marine disposal of radioactive wastes.

A paper from the University of New South Wales, Sydney, entitled, "The Motion of a Two-Dimensional Buoyant Vortex" was presented by I. R. Wood. The theory of the vortex pair was modified to include the effect of walls and for the case of sloping walls the component of the buoyant force. Tests were conducted in a 'Perspex' flume with coloured dye identifying a vortex of salt solution entering a fresh-water medium.

Waves

The paper "An Exact Theory of Simple, Finite Shallow Water Oscillations on a Rotating Earth" approached the problem from the unusual angle of taking a simple form of liquid motion and finding the shape of basin necessary to produce it. The author, F. K. Ball (Commonwealth Scientific and Industrial Research Organization, Meteorological Physics Division, Melbourne), discussed two simple types of motion: "pure displacement" and "pure distension". The former is a lateral displacement without change in depth profile and was found to occur only in a paraboloid. The latter consists of a combination of a uniform, two-dimensional isotropic dilation and a rotation, and could only occur in a paraboloid of revolution if the underlying surface were axially symmetric. The governing equations in both cases were simple linear differentials with constant coefficients.

J. W. Miles (Australian National University, Canberra) presented a review paper on the generation of surface waves by shear flows, especially with regard to wind blowing over water. Theories were cited which involved the direct action of turbulent fluctuations in pressure on the water surface and those concerned with an instability mechanism whereby energy was transferred from shear flow to the surface wave. Observational evidence by Longuet-Higgins[3] was discussed from which it was shown that energy transfer to ocean waves was probably produced through the instability mechanism. Other topics pertaining to transfer of energy were presented.

H. C. Levey (University of Western Australia, Perth) presented a paper entitled "Diffraction in Fluid Mechanics". The acoustic equations that are used to discuss the propagation of small disturbances in a gas are only approximations. They govern, in fact, the first-order terms that arise from an assumed regular perturbation expansion in the maximal disturbance strength. It was shown that in pulse diffraction problems the acoustic approximation always leads to a singularity of a kind unacceptable in gas dynamics in the shadow boundary. It was submitted, therefore, that although such problems were of a singular perturbation type they required different techniques from those usually applicable in wave propagation problems.

Guided Weapons Research

Two papers were submitted on this topic from the Weapons Research Establishment at Salisbury, South Australia.

The first, by H. C. Newbigin, was concerned with aerodynamic data obtained from a wind tunnel from which a comprehensive mathematical model was derived. This model was later corrected with the aid of flight trial data, which could not be adequately analysed until a high-speed computer became available. It was found that important aerodynamic derivatives obtained from the wind-tunnel tests were incorrect. Although these could be readily adjusted from the prototype tests, the reason for the discrepancy had not yet been found.

The second paper, submitted by B. Goodwin, referred to the mathematical modelling of the fuel system of a guided weapon. The fuel flow to the engines of a missile determines its effective range, it must therefore be known to a high degree of accuracy. In one weapon under consideration the fuel flow was a function of the Mach number and ambient conditions. A control system with a number of feed-back loops controlled this flow, and was devised from a comprehensive mathematical model based on an examination of the various physical components.

THE NATIONAL RESEARCH DEVELOPMENT CORPORATION

THE annual report and statement of accounts of the National Research Development Corporation for the year ended June 30, 1962 *, surveying the thirteenth year of the Corporation's activities, discusses at some length, in view of the attention which is at present being given in Government support of civil development work in industry, the extent to which the Corporation is achieving its purposes and the main disabilities under which it has to operate. For the rest, the report stresses the progress made in furthering the hovercraft project; four prototypes of the second generation are undergoing trials, including experimental operational use in ferrying passengers on selected routes. However, much development is still required before this new form of transport becomes fully established commercially, and further development would be greatly advanced if commercial or other operators who have specific operational requirements which hovercraft can meet were to place orders now. In the *Dracone* project for flexible barges, development of the larger sizes is still proceeding and commercial sales of the sizes already developed doubled, largely for export. A major advance is noted in the administrative arrangements for the fuel cell project; further development will be supported by a company formed for the purpose, Energy Conversion, Ltd. Commercial interest in cephalosporin c has been fully maintained and the Corporation is even more hopeful that this antibiotic, which is resistant to penicillinase, will play a useful part in medical therapy. Other major revenue-earning inventions listed include the alignment of light projectors; anemometers; anti-carcinogenic compounds; anti-thyroid compounds; Bailey bridge; collet chucks; electrically conductive films; electronic computers; exploders for firing charges electrically; fog detectors; glass fire and heat detectors; gyroscopic apparatus; hecogenin; ignition systems; ionization gas detectors; insecticidal fumer; manufacture of cheese;

* National Research Development Corporation. Report and Statement of Accounts for the year 1st July, 1961, to 30th June, 1962. Pp. ii+34. (London: H.M.S.O., 1963.) 2s. 3d. net. (See also p. 929 of this issue of *Nature*.)

microdensitometer; navigational wireless system; photosensitive cells; polarograph; potato harvester; resonant electronic circuits; selective weed killers, triiodothyronine; universal joints; variable speed induction motors; and visual flying aids.

Between them these major inventions earned £209,662, of which £104,701 came from two only, both concerned with drugs and mostly from the United States. Exploitation receipts by way of royalties, option payments and the like increased to £279,435, compared with £259,902 in 1960–61. The Corporation now holds the rights in 1,064 United Kingdom patents and patent applications and in 2,491 overseas ones, while the Corporation's Development Companies hold a further 705 United Kingdom and overseas patents and patent applications. A further 42 licence agreements with United Kingdom firms brought the total in force to 516, while 6 further licence agreements with overseas firms raised the latter total to 53. At the end of the year the Corporation was providing financial and other assistance for 35 development projects, of which 5 were new, and expenditure on development was £1,099,030, compared with £811,730 in 1960–61, and forward commitments amounted to £850,000. Most of this expenditure was concerned with the hovercraft, electronic computer (*Atlas* and *Emidec*) and *Dracone* projects. Some £140,000 was written off when work was stopped on a number of projects.

Of 911 inventions communicated to the Corporation during the year (compared with 973 in 1960–61), 161 were from universities in the United Kingdom (115 in 1960–61), but only 257 were from Government Departments and Research Councils, compared with 312. For nationalized industries the figure was 19 (2), industrial research association 11 (8), and for private firms and individuals in the United Kingdom 406 (466). At the end of the year 23 potential development projects in a wide range of technological fields were under consideration, more than half of these deriving from private firms and individuals. Of 243 patent rights assigned during the year, 167 were from Government Departments and Research Councils and 69 from universities. The new projects reported for the first time include equipment for the rapid and automatic analysis of raw milk and other emulsions; development of a refrigerator for temperatures in the region 4°–20° K using expansion turbines with helium as the working substance and running on helium bearings; *JASTAC* fastening techniques; multiple fixed speed motors; and water control in arid zones.

THE INSTITUTE FOR NORTHERN STUDIES, UNIVERSITY OF SASKATCHEWAN

THE Institute for Northern Studies, University of Saskatchewan. was authorized and the director appointed in January 1960 to aid original research and academic work on northern problems and to assist the training of humanists, scientists, engineers and others interested in northern problems and in the inhabitants of this part of Canada. The Institute possesses no research staff of its own, and research will be carried out under the supervision of the various University departments.

The first annual report of the Institute* summarizes the work carried out during the summer of 1960 on seven projects: a plant ecology study, with special reference to the forest vegetation; a systematic collection of small mammals and another of biting insects; a study of the history and economics of water transport on the Athabasca–MacKenzie River system and another of some factors in the economics of the Lake Athabasca mining area; a study of the trace elements in the Coronation mine, Flin Flon, and one of a radio-communication system in the very-high-frequency field which, it is believed, will operate even under conditions where electric storms are prevalent.

Further accounts of these projects are included in the second annual report, 1961–62†, as well as ornithological studies in the Lake Athabasca district; the commercial fishing industry of Northern Saskatchewan; Saskatchewan's role in a changing fur industry; an investigation of the sand dunes in the vicinity of the William and McFarlane Rivers on the south shore of Lake Athabasca; and of the deep seismic sounding of the Earth's crust in the vicinity of Flin Flon. A list of publications resulting from work assisted by the Institute is included.

MAGNETO-TELLURIC EFFECTS OBSERVED IN DALLAS, TEXAS, FROM THE JULY 9, 1962, HIGH-ALTITUDE NUCLEAR EVENT

By JACK J. BURCH and ARTHUR W. GREEN, Jun.

Texas Instruments Incorporated, Dallas, Texas

THE U.S. Atomic Energy Commission detonated a megaton-range nuclear device over Johnston Island at an altitude of 250 miles on July 9, 1962, at about 09 h 00 min 09 sec, U.T.

It was expected that magnetohydrodynamic waves generated by the expanding blast plasma would propagate in various modes across and down the lines of force of the Earth's field, as well as through the exospheric ducts postulated by Bomke *et al.*[1]. Expected velocities of propagation range from several hundred to several thousand kilometres per second[2]. At the base of the ionosphere, where magnetohydrodynamic wave propagation is no longer possible, some of the wave energy would be converted to ordinary electromagnetic waves which would then propagate around the world at the speed of light. Thus, the electromagnetic waves resulting from the various magnetohydrodynamic modes would be seen by magnetometers and Earth current (telluric) sensors several seconds after the detonation. In addition to these delayed signals, Troitskaya (U.S.S.R.), during the 1958 *Argus* test series, observed direct, speed of light, signals which marked the instants of the events[3]. Because these instantaneous signals suffered great attenuation in travelling as electromagnetic waves through the highly conductive ionosphere, they were seen only on very sensitive Earth current systems.

Fig. 1 shows magnetic field and electric field variations at Dallas, Texas, produced by the event of July 9, 1962. The magnetic field was measured with an optical pumping magnetometer (metastable helium type) and the electric field was measured by orthogonal pairs of Earth current electrodes aligned in magnetic north–south and east–west directions.

The main phase magnetohydrodynamic wave-derived signal which arrived at 09 h 00 min 11 sec, two seconds after the detonation, can be seen very clearly on trace 2, which is the north–south telluric field (bandpassed from 0·01–2·0 c/s), and on trace 3, which is the total magnetic field (bandpassed from 0·3–2·0 c/s). It is interesting to note that the total field record (trace 3) and the east–west electric field (trace 4) correlate quite well. This is to be expected since a bandpassed total field magnetometer measures, to a good approximation, the dot product of the geomagnetic micropulsation vector and the Earth's total field vector; thus in a region of horizontal homogeneity, and for vertically incident waves, the magnetic wave components are in direct proportion to the orthogonal electric wave components, and a total field magnetometer will measure the north–south horizontal magnetic component times a constant. Since horizontal homogeneity is thought to exist at the Dallas site, traces 3 and 4 probably represent orthogonal *E* and *H* components of the same electromagnetic wave. The nominal period of this wave was about 2 sec.

The 'first arrival' noted on trace 2 of Fig. 1 which propagated at the speed of light, and thus marks the time of the event, may be seen more clearly on traces 1 and 2 of Fig. 2. A similar instantaneous arrival was also noted by Roquet, Schlich and Selzer[4].

Fig. 3 is a display of instantaneous power in the east–west telluric field as a function of both frequency and time for an interval of several hours which includes the nuclear event. The sinusoidal variations before and after the event are typical of the 60-sec period micropulsation

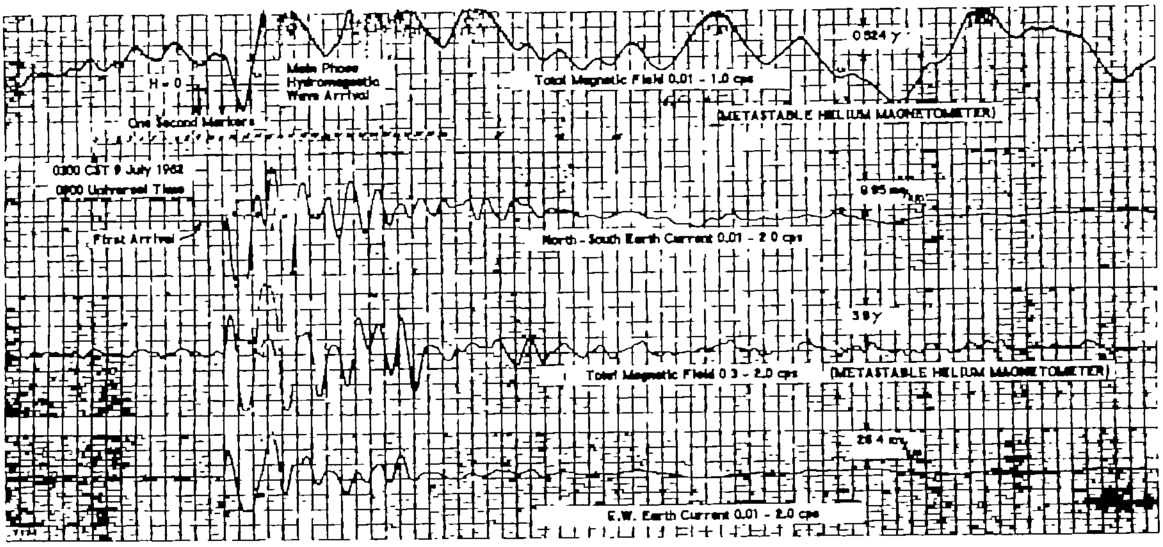

Fig. 1. Magneto-telluric effects of the Johnson Island high-altitude nuclear event of July 9, 1962, recorded at Texas Instruments Geomagnetic Observatory near Dallas, Texas (The direction of increasing magnetic field and positive north and east electrodepotentials is downward)

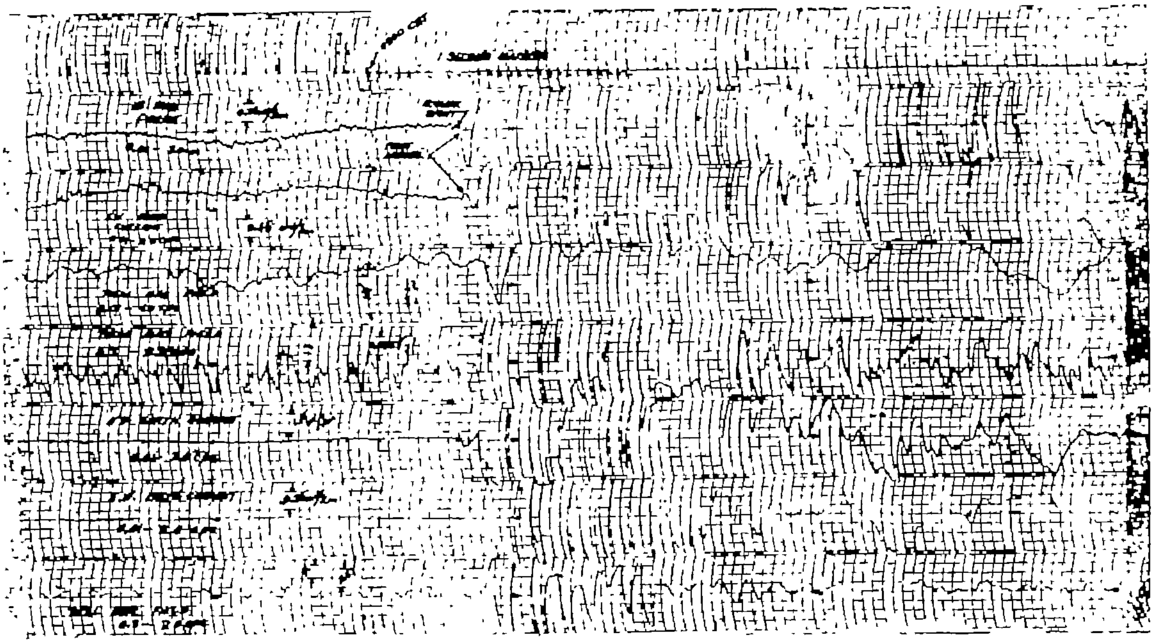

Fig. 2. High-resolution trace showing details of first arrival (speed of light)

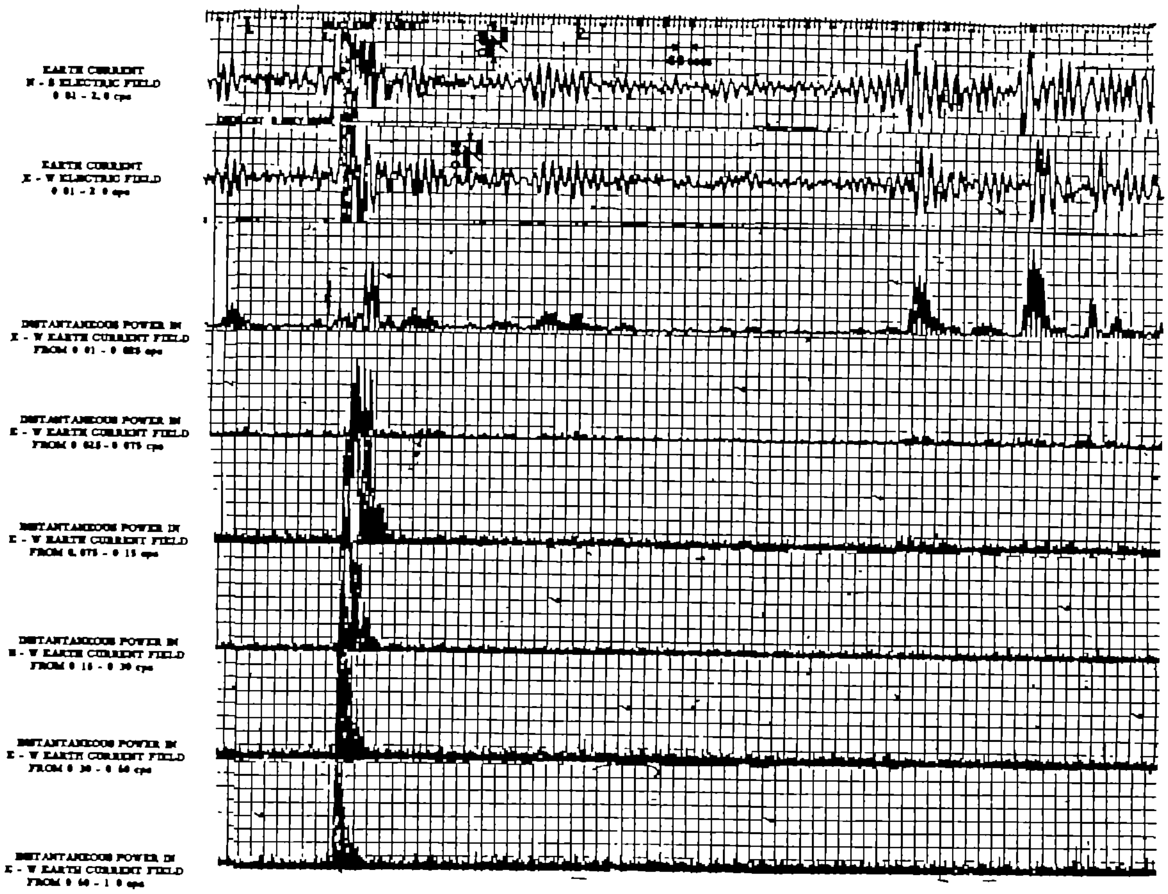

Fig. 3. Instantaneous power as function of frequency and time for an interval including the July 9, 1962, nuclear event and background detail

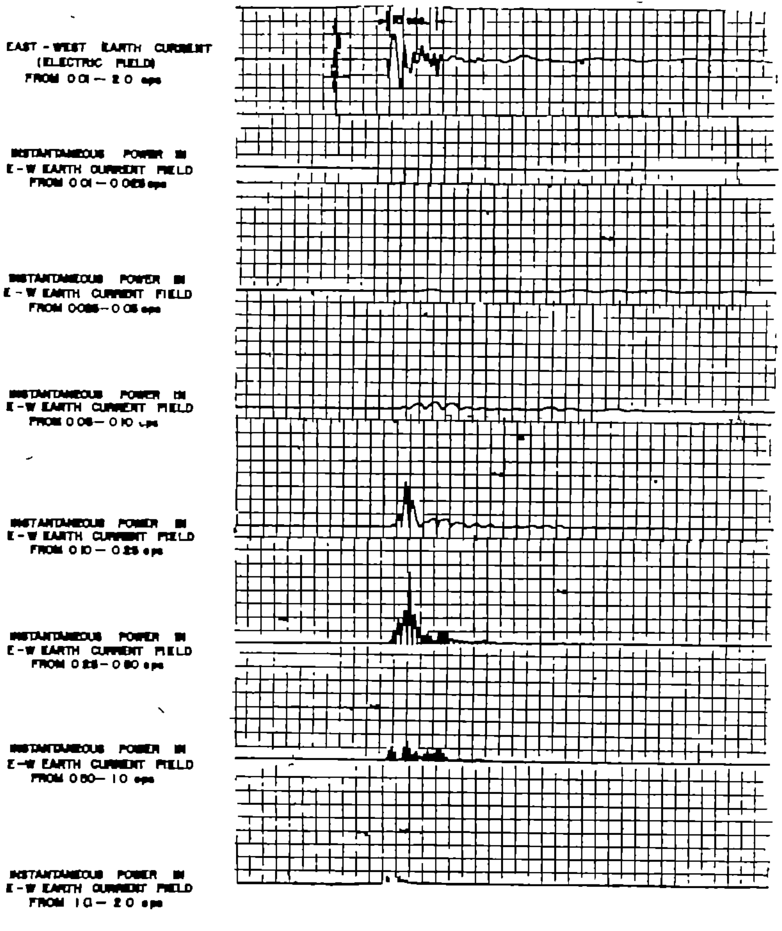

activity seen in Dallas at night. It may be seen from Fig. 3 that the main spectral elements of the micropulsation activity are concentrated well below those of the bomb signal.

Fig. 4 shows instantaneous power as a function of both time and frequency for the bomb signal only, as seen on the east–west telluric field. The predominant 2-sec period of the magneto-telluric wave is attested to by the large amount of energy concentrated in the band from 0·25 to 0·50 c/s. This tendency toward 2-sec periodicity was also noted by Roquet *et al.*[4] and by Plesset[5].

Irregular magnetic field activity having no apparent electric field counterpart was observed on the low-frequency magnetic record (Fig. 1, trace 1). This trace differs only from trace 3 in that it is bandpassed from 0·01 to 1·0 c/s instead of from 0·3 to 2·0 c/s. Similar activity was also noted by Breiner[6], who reconstructed some rubidium vapour magnetometer records on which the strong signal had exceeded the dynamic range of the recording equipment. Breiner reported oscillations with periods of 5–7 sec, but apparently failed to see the 2-sec period, magneto-telluric wave. This failure was undoubtedly due to saturation of the recorder rather than any fundamental lack of high-frequency response in the rubidium vapour device.

Fig. 4. Instantaneous power as a function of frequency and time for the signal from the nuclear event of July 9, 1962

We thank Mr. Charles E. Lewis and Mr. Charles M. Tilley, who were responsible for much of the recording site instrumentation.

SEASONAL VARIATION OF TURBULENCE IN THE UPPER ATMOSPHERE

By R. G. ROPER and Dr. W. G. ELFORD

Department of Physics, University of Adelaide

THE measurement of the motion of the atmosphere at heights between 70 and 110 km by the radio observations of meteor trails is now a well-established technique. Systematic observations have given accurate data on the diurnal and seasonal variation of the air motion at these levels in medium and high latitudes[1-3].

By using one transmitting site and three or more receiving sites the relative motion of three or more points on the same meteor trail can be studied. In the system at present in operation at Adelaide four receiving sites are used; receiving sites 2 and 3 are 4·8 km north and east of receiving site 1, and the fourth is at a distance of 14 km approximately south-east of site 1. The transmitter is 23 km south of site 1. The equipment is a combination of continuous wave and pulse, operating on 27 mc/s.

The orientation of the trail in space is determined by the time differences between the commencement of an echo at the receiving sites 1, 2 and 3, and the velocity of formation of the trail is obtained from the diffraction wave-form associated with the build-up of the echo at any one of the receiving sites. Thus the spacial separation of the four reflexion points can be determined for each meteor trail observed.

The absolute position of one of the reflexion points is measured from site 1, thus fixing the absolute position of the trail in the atmosphere.

During 1961 a turbulence survey was run in conjunction with the routine wind velocity measurement programme which has been in operation since 1952. This wind programme has shown that winds over the height range of 75–105 km are well correlated; the method of data collection and reduction ensures the measurement of a true mean motion. The subtraction of the mean wind component (given as a function of time and height) in the direction of measurement yields four turbulent line-of-sight velocities for each meteor trail observed. Preliminary computations have been carried out using data from the three close-spaced stations. The final analysis will utilize the data from all four receiving sites, and will extend the direct investigation of eddy sizes up to 7 km.

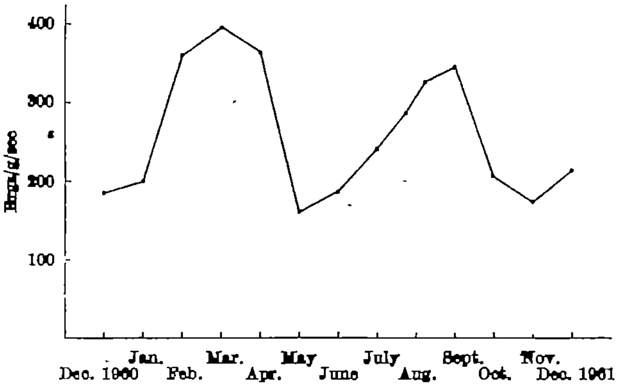

Fig. 1. Seasonal variation of the turbulent dissipation rate at 90 km

The magnitude of the turbulent component of the wind velocity has been found to vary from some 15 m/sec to 60 m/sec, and is, in general, less than 1/3 of the magnitude of the mean wind.

The variation of the differences in velocity at two points on a meteor trail as a function of their separation can be explained in terms of a modified Kolmogoroff spectrum, at least for the scales measured (up to 3 km). The departures from the spectrum of an isotropic inertial region can be explained in terms of a buoyancy sub-range of characteristic scale 0·5–1·0 km. Once allowance is made for this buoyancy sub-range, the velocity differences measured as a function of separation r follow the relation:

$$\overline{[u(x) - u(x + r)]^2} = 4{\cdot}82\alpha(\varepsilon r)^{2/3} \text{ (ref. 4)}$$

where ε is the rate of dissipation of turbulent energy and α is the constant of proportionality in the expression relating the energy spectrum function to the wave-number space vector $\mathbf{k}$, namely:

$$E(k) = \alpha\varepsilon^{2/3}k^{-5/3}$$

To determine an absolute value for ε from the velocity differentials, α has been taken as 1·0.

The turbulent dissipation rates shown in Fig. 1 represent an average for each month over the height-range of 75–105 km. The seasonal variation in the turbulent dissipation is quite marked, ε having a minimum value of some 150 ergs/g/sec in summer and winter, and rising to over 350 ergs/g/sec in autumn and spring. Diurnal variations have also been observed. The magnitude of these diurnal variations is dependent on the season, but as yet no simple daily pattern has been found. Further analysis to examine the turbulent motions as a function of height is contemplated.

The velocity differences at separations less than 500 m are affected most by the action of buoyancy forces. If the buoyancy forces are neglected and the velocity differences at these scales as measured at Adelaide are interpreted in terms of an isotropic inertial spectrum, values of turbulent dissipation of 30–100 ergs/g/sec are forthcoming. These are in excellent agreement with the results obtained from photographic observations of meteor trails[5] and sodium trails[6] which are limited by visibility to scales of < 1 km.

While the mean squares of the velocity differences associated with spacial separation follow the Kolmogoroff 2/3 power law, those associated with height difference, regardless of separation, follow the 4/3 power law characteristic of a turbulence subjected to shear. Zimmerman[7] has pointed out that similar velocity-height differentials measured by Blamont and de Jager follow the shear theory developed by Tchen[8], which predicts a 4/3 power law. Extrapolation of the height shears as measured at Adelaide to a velocity difference equal to the characteristic velocity of the energy-bearing eddies of the Kolmogoroff spectrum yields a vertical correlation distance of 5–9 km, which is quite comparable with the generally accepted value of 7 km.

This work is being supported by the Radio Research Board, Australia.

FRACTIONATION PHENOMENA IN HIGHLY RADIOACTIVE FALL-OUT PARTICLES

By T. MAMURO, K. YOSHIKAWA, T. MATSUNAMI, A. FUJITA and T. AZUMA

Radiation Centre of Osaka Prefecture, Shinkecho, Sakai, Osaka, Japan

HIGHLY radioactive fall-out particles were found throughout Japan, resulting from the series of large-scale nuclear test explosions carried out by the U.S.S.R. during September and October 1961 [1-3]. It was revealed by γ-ray spectrometry that radiochemical compositions of these particles were different from those of smaller fall-out particles. This was considered to have been caused by the so-called fractionation effect[7-10]. In order to express the extent of the fractionation effect, a fractionation factor f for a given nuclide A is defined in the following way:

$$f = \left[\frac{N(\mathrm{A})}{N(^{95}\mathrm{Zr} + {}^{95}\mathrm{Nb})}\right]_{\mathrm{exp}} \times \left[\frac{N(^{95}\mathrm{Zr} + {}^{95}\mathrm{Nb})}{N(\mathrm{A})}\right]_{\mathrm{theor}} \qquad (1)$$

where N is the radioactivity of the nuclide in question. The first bracket contains the experimental and the second the theoretical values as obtained from fission yield values if the age is known[9].

Previously[3] we showed the γ-ray spectrum of the filter-paper on which air-borne dusts were collected on November 8, 1961, and that of a highly radioactive particle which was found in the yard of our Laboratory at that time. On comparison of these spectra, it was found that the radiochemical composition of the highly radioactive particle was much enriched in ^{95}Zr + ^{95}Nb and impoverished in ^{103}Ru, ^{140}Ba + ^{140}La, ^{131}I and ^{141}Ce + ^{144}Ce, compared with that of the dusts on the filter-paper.

Fig. 1 is another example from which the fractionation phenomenon can be seen clearly. Curves (*a*) and (*b*) are the γ-ray spectrum of a highly radioactive particle and that of the dust sample (*b*) which was taken in an air-filter in February 1962, respectively. Curve (*c*) is the γ-ray spectrum of the dust sample (*c*) which was prepared in the following way. The dusts which were taken in the same air-filter were spread uniformly on a gummed paper and this was autoradiographed on an X-ray film (Fuji X-ray Film No. 200) exposing for two days. On the autoradiograph were found many relatively small spots. Only the parts of the gummed paper which did not produce any spot on the autoradiograph were punched out. The dust sample (*c*) was the collection of the punched small pieces of gummed paper. This dust sample, therefore, was not thought to contain any fall-out particles so high in radioactivity as to produce a visible spot on the autoradiograph. On comparison of (*a*) with (*c*), it is clearly seen that the radiochemical composition of the highly radioactive particle is strongly enriched in ^{95}Zr + ^{95}Nb and impoverished in ^{103}Ru and ^{141}Ce + ^{144}Ce. On careful comparison of (*b*) with (*c*), it is seen that the radiochemical proportions of ^{103}Ru and ^{141}Ce + ^{144}Ce in the dust sample (*b*) are somewhat smaller than those in the dust sample (*c*). Photo-peaks of ^{131}I and ^{140}Ba + ^{140}La are not seen in these spectra, which were measured in the middle of March 1962. The peak found at about 210 keV is mainly due to the back-scatter peak produced by the γ-rays of about 750 keV of ^{95}Zr + ^{95}Nb and the photo-peak of 231 keV of ^{95}Nb.

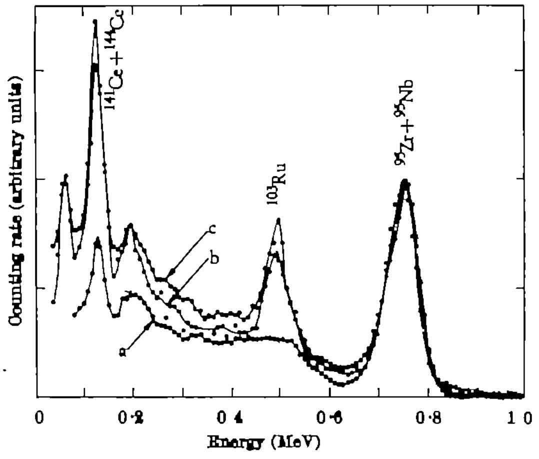

Fig. 1. (*a*) γ-Ray spectrum of a highly radioactive particle (Particle *P* in Table 1), measured on March 13, 1962; (*b*) γ-ray spectrum of the dust sample collected at an air-filter, measured on March 13, 1962; (*c*) γ-ray spectrum of the dust sample which was prepared by excluding larger fall-out particles, measured on March 16, 1962

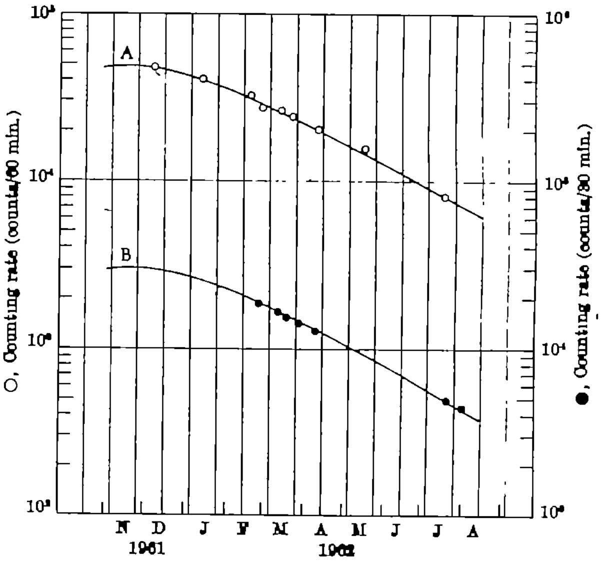

Fig. 2. Decay characteristics of activity of ^{95}Zr + ^{95}Nb. ○, Particle *P*; ●, dust sample.

The decay characteristics of activity of ^{95}Zr + ^{95}Nb were followed for the particle and the dust sample by measuring the photo-peak of about 750 keV, the measured points being expressed as white and black circles in Fig. 2,

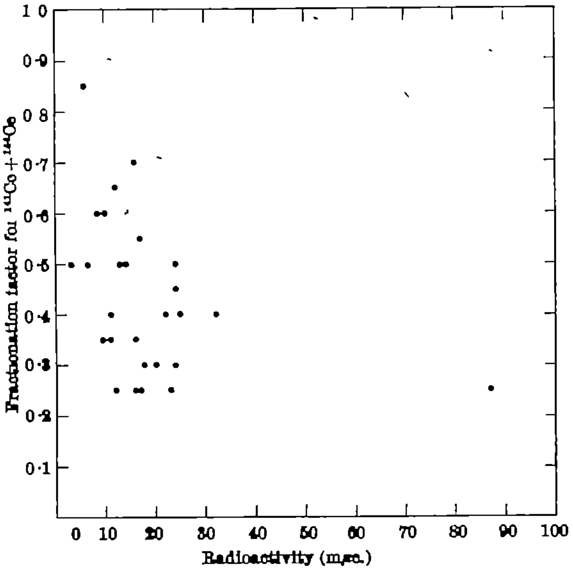

Fig. 3. Relation between particle radioactivity and fractionation factor for ^{141}Ce+^{144}Ce

respectively. Curves *A* and *B* are the decay curves which were theoretically obtained assuming the date of explosion was October 30, 1961. The good agreement between theory and experiment indicates that both the particle and the majority of the radioactive dusts contained in the dust sample were produced on October 30, 1961.

γ-Ray spectra of many highly radioactive particles were measured and fractionation factors defined by equation (1) were calculated. The results are summarized in Table 1. The yield values for fast fission of ^{238}U, as shown in Table 2 (refs. 8 and 11), were used on carrying out the calculation. The date of explosion was assumed to be October 30, 1961, because almost all the particles given in Table 1 were thought to have been produced on that day. The half-lives of ^{131}I and ^{140}Ba + ^{140}La are so short that fractionation factors for them could not be measured. The highly radioactive particles Nos. 1–21 in Table 1 were actually isolated from among non-radioactive dust particles and examined microscopically[9].

Table 2. Assumed Fission Yield for Fast Fission of Uranium-238

Nuclide	Yield (per cent)
^{95}Zr	5·7
^{103}Ru	6·6
^{141}Ce	5 6
^{144}Ce	4·5

Fractionation factors for ^{103}Ru are smaller than 0·1 for all the particles and those for ^{141}Ce + ^{144}Ce are smaller than 0·6 for almost all of them. Fig. 3 shows the relation between particle activity and fractionation factor for ^{141}Ce + ^{144}Ce, indicating roughly that particles of higher activity are more affected by the fractionation effect. The fractionation factors obtained for the dust sample (*b*) and (*c*) are shown at the bottom of Table 1.

The fractionation factor for ^{103}Ru of the dust sample (*c*) is about 0·6, while that for ^{141}Ce + ^{144}Ce is 1·0, suggesting that the fractionation effect for ^{103}Ru is present even in this dust sample, which contains only fine fall-out particles. If the yield values given in Table 2 are reasonable, this may be possibly explained in the following way. The dust sample (*c*) was taken at a wire-mesh air-filter through which very fine fall-out particles might pass out. The distribution of fall-out particles in the dusts caught by the air-filter might be biased towards larger size. The fractionation effect is not only much more remarkable but also seems to extend to much smaller particles for ^{103}Ru than for ^{141}Ce + ^{144}Ce.

There was a rainfall of 37·6 mm at our Laboratory on September 17, 1961. About 100 ml. of rain-water was collected at the beginning, using a rain collector of 1,000 cm^2 in collecting area. The concentration of radioactivity in this rain-water was abnormally high compared with that in average rain-water. Curve *X* in Fig. 4 is its γ-ray spectrum. The γ-ray spectrum of average rain-water of about 30 l. on the same day was measured and is shown as curve *Y*. An appreciable difference is seen between the two spectra, suggesting that some highly radioactive particles were present in the rain-water collected at the beginning of the rain-fall. It may be generally considered that from a test sample of small quantity in which the fractionation effect is remarkable a higher measured value of the concentration of fall-out may be obtained than that which would be obtained from an average sample of much larger quantity. It may be also possible that rain-water at the beginning of a rain-fall has not only a higher concentration of fall-out than that of average rain-water, but also shows a radiochemical composition different from that of average

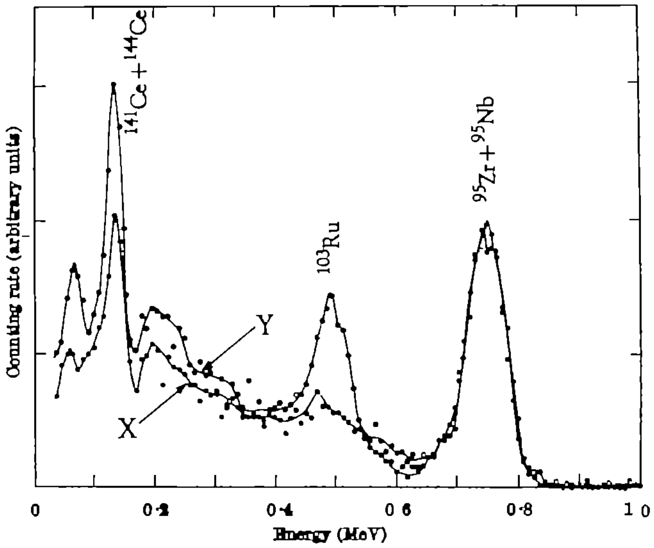

Fig. 4. Fractionation effect observed in rain-water on November 17, 1961, measured on February 22, 1962. ○, Average rain-water; ●, rain-water at the beginning of the rainfall

rain-water, especially just after a large-scale nuclear detonation.

COMPACTION OF BURIED SANDS

By I. J. SMALLEY

Northampton College of Advanced Technology, London, E.C.1

MAXWELL and Verrall[1] have investigated the consolidation of quartz sand to sandstone under experimental conditions simulating deep burial. Compaction was produced by compressing a sample in a steel cylinder with a tightly fitting piston driven by a hydraulic jack while a second hydraulic system maintained a high hydrostatic pressure inside the cylinder. Cementation was produced by keeping the specimen at high pressure and temperature for several days. Their results for the compaction of sand at room temperature and one atmosphere fluid pressure for various directed pressures show a steadily decreasing fall in the porosity from about 35 per cent at 10,000 lb./in.^{2} to about 25 per cent at 50,000 lb./in.^{2}. At 50,000 lb./in.^{2}, which represents a depth of about 45,000 ft. the rate of decrease of porosity with increase in depth is zero.

Jane Taylor[2] has suggested that for the efficient investigation of the factors producing consolidated sediments each variable must be investigated separately. The behaviour of sand under a range of directed pressures has been examined using a simplified version of the Maxwell and Verrall apparatus. The fluid pressure has been neglected and the compaction of the specimen carried out by a standard hydraulic testing machine (Amsler *SZBDA* 699) which gives a steady rate of deformation with the load shown as the dependent variable. The experiments were designed to show the nature of the deformation process rather than the change in porosity. Borg and Maxwell[3] have examined the nature of the deformed product but have ignored the variation in particle size caused by the various pressures. The simulated weight of overburden has been so great in previous experiments that specimens have been virtually completely deformed although possibly incompletely compacted and cemented.

The stages in the deformation process are illustrated by a typical load versus deformation (piston travel) curve as shown in Fig. 1. This can be divided into three stages; stage I represents elastic compression and the beginning of yield; stage II represents the continued breaking of the sand grains which diminishes as the pores are filled with the fracture product; stage III occurs when the pores are filled and the aggregate becomes effectively a solid mass. The sand was compressed in a 2-in.-diameter steel cylinder by a steel piston. Samples of 100 g were used and various loads were applied up to a pressure of 20,000 lb./in.^{2}. The sand used was quartz from Leighton Buzzard which had been graded so that 95·5 ± 2 per cent passed a No. 16 and was retained by a No. 18 B.S. sieve. Before each test a sieve analysis was carried out to ensure the correct initial grading, the sand was then compressed at a chosen pressure and analysed again. The results of the analyses after deformation, for three particular sizes, are shown in Table 1.

Fig. 2 shows the variation in amount of these three sizes plotted against load. The 18-sieve curve shows a point of inflexion at the load value representing the transition

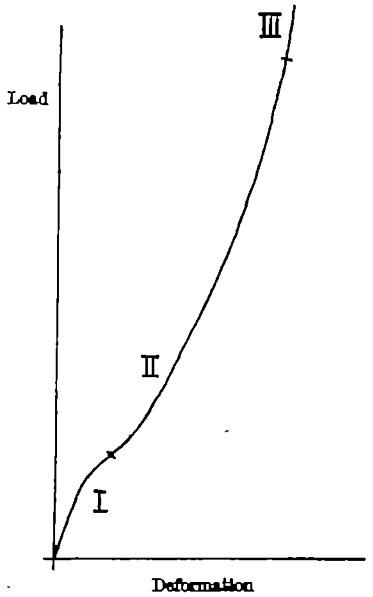

Fig. 1. Shape of load versus deformation curve for sands compacted by direct pressure only

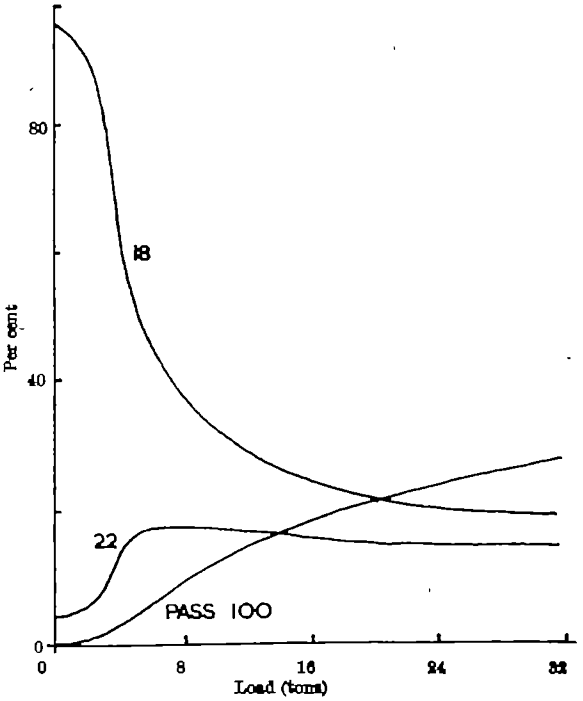

Fig. 2. Variation in particle size percentage in sands compacted at different pressures

Table 1. PARTICLE SIZES IN COMPACTED SANDS

Compacting load (tons)	Compacting pressure (lb./in.²)	% on 18 sieve	% on 22 sieve	% passing 100 sieve
0	0	95·5 ± 2	4·0 ± 2	0
2	1,426	91·0	5·5	0·5
4	2,852	61·0	15·5	2·5
6	4,278	45·5	18·5	7·5
8	5,704	37·0	17·5	10·5
10	7,130	32·0	18·0	12·5
14	9,982	28·0	16·5	17·5
26	18,538	20·5	15·5	25·5
29	20,677	20·5	15·5	27·5

from type I deformation to type II. The pass 100 curve steadily increases. The 22-sieve curve flattens out very early and remains at a fairly constant percentage value. It appears from these curves that the sand particles which break form a very fine fracture product and it is this which fills the pores during stage II of the deformation. Also it appears that 20 per cent is a limiting value of the 18-sieve curve; further increases of pressure will not change the amount of the starting size sand. Assuming that the initial porosity was of the order of 35 per cent measurements of the volume of the specimen after compression show that a porosity of the order of 25 per cent is produced by a pressure of about 20,000 lb./in.².

Tests have also been carried out to see if different starting sizes in the sands cause any noticeable variation in the pressure required for various stages of the deformation process. Table 2 shows the pressure at the I–II transition point in sands with different starting sizes.

Table 2. I–II TRANSITION PRESSURES IN COMPACTED SANDS

B.S. Sieve Nos.	14–16	16–18	22–25	25–30	30–36	44–52
I–II Pressure	2,570	2,670	3,200	3,750	4,050	4,800

There is a steady increase in the I–II transition pressure with decreasing particle size over the range examined.

A VISCOSITY/DENSITY RELATION FOR SOLUTIONS OF STRONG ELECTROLYTES IN WATER

By A. D. BRAMHALL

'Shell' Research Ltd., Thornton Research Centre, P.O. Box 1, Chester

THE relative viscosity (η/η_w) of electrolyte solutions can be described empirically by the well-known Jones and Dole equation:

$$\frac{\eta}{\eta_w} = 1 + A\sqrt{c} + Bc$$

where c is the concentration of electrolyte in moles/l., and A and B are empirical constants for a given electrolyte.

Falkenhagen and his collaborators related the term $A\sqrt{c}$ to the electrostatic interactions of the ions. Although the coefficient B has received a great deal of attention from various workers, it has not as yet, in our view, been satisfactorily accounted for. Thus Kaminsky[1] explains it in terms of structure-making and structure-breaking tendencies of the various ions; Robinson and Stokes[2] interpret it through the Einstein thickening effects of hydrated ions; Gurney[3] considers it as the result of a loosening of the water structure in the neighbourhood of an ion.

All such explanations imply that the presence of ions will change the specific volume of the water fraction of the solution. The object of this article is to present a correlation between the volume change of the water fraction, represented by a parameter α, and the viscosity B-coefficient.

The parameter α I define as:

$$\alpha = \frac{\bar{V}_2^\circ - V_s^\circ}{1{,}000}$$

where $\bar{V}_2^\circ$ is the partial molar volume of the salt at infinite dilution, and V_s° is the intrinsic volume of the salt and is calculated from the van der Waals radii of the ions, as given by Pauling[4]. Since both $\bar{V}_2^\circ$ and V_s° are additive properties of the individual ions it is possible to calculate α for the individual ions. Values of α for a number of ions at 25° C have been obtained from published data on partial molar volumes[5]. (The partial molar volumes given in reference 5 were calculated by taking $\bar{V}_2^\circ$ = 18·0 c.c./mole for the chloride ions.) The B-coefficients are also additive. Kaminsky[1] gives the B-coefficients of many ions at 25° C based on $B = -0{\cdot}0070$ for the chloride ion.

Our correlation is shown in Fig. 1. Here the values of α are plotted against values of the term ($B - V_s^\circ/400$). There is a very strong correlation which is independent of the sign and size of the charges on the ions.

Since the line in Fig. 1 passes through the origin the correlation embodies only one empirical constant, equal to the slope of the line. The correlation can be used for calculating the B-coefficient of the viscosity equation for a salt solution at concentrations up to about 1 mole/l. from known values of the partial molar volumes and the van der Waals radii of the ions.

We arrived at the foregoing correlation by making the following four assumptions.

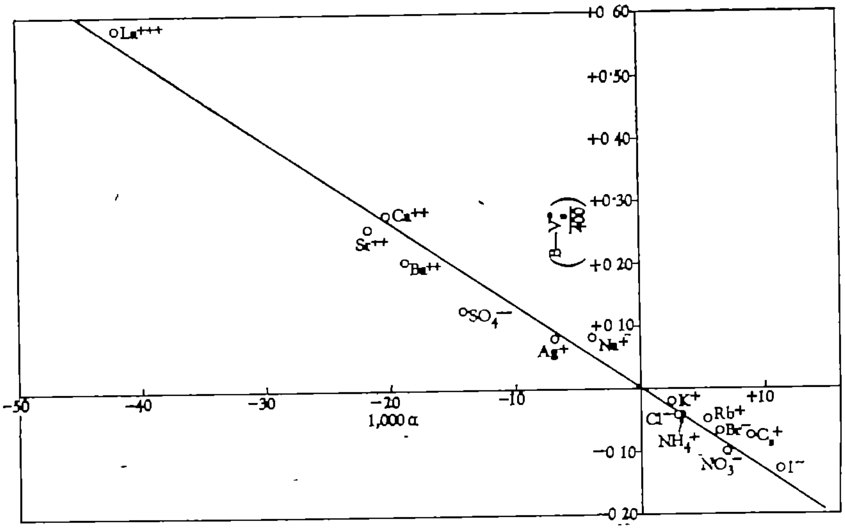

Fig. 1. Correlation between change of volume of water fraction (α) and the viscosity B-coefficient

(1) That the molar volumes of both the salt and the water fraction in a solution can be represented as a function of concentration by the equations:

$$V'_w = V_w\,(1 + \alpha c) \qquad (1)$$

$$V'_s = V_s^{\circ}\,(1 + \beta c) \qquad (2)$$

where V_w is the molar volume of pure water; V_s° is the molar volume of the salt in solution at infinite dilution; α is the expansion coefficient of the water; β is the expansion coefficient of the salt.

Although on purely phenomenological grounds the volume of a solution cannot be split up into volumes occupied by the two components, such a separation is justifiable on the basis of a particular model such as I am using here.

α and β are constant for any given salt. The α-coefficient will take into account changes in the volume of the water fraction caused by such factors as electrostriction, changes in the amount of ice-like structure, etc. The β-coefficient will account for the changes in the volume occupied by the salt in solution caused by such effects as ion-pair formation.

(2) That V_s° is equal to the volume calculated from the crystal radii of the ions. The view that an ion in solution occupies a volume equal to that of a sphere of radius approximately equal to the crystal radius is supported by the refractive index studies of Böttcher[6]. For example, Böttcher calculates a value of 1·82 Å for the radius of the chloride ion in solution, which is in good agreement with Pauling's value of 1·81 Å obtained from the crystal data.

(3) That Einstein's equation can be applied to ions. Robinson and Stokes[2] applied Einstein's equation to calculate the volume fraction φ occupied by the ions from the B-coefficients, assuming the viscosity of the water fraction is unchanged. They concluded that since φ was usually larger than the partial molar volumes, the ions must be hydrated. I differ from Robinson and Stokes in that I do not believe that the whole of the B-coefficient is accounted for by Einstein thickening but that the viscosity of the water fraction η^{*} is changed and is not equal to the viscosity of pure water η_w. In order to calculate the relative viscosity of the water from the B-coefficient I use the intrinsic volume of the ions V_s° (assuming no hydration).

Einstein's equation incorporating the above assumptions becomes:

$$\eta = \eta^{*}\left(1 + \frac{V_s^{\circ}.c}{400}\right)$$

where η is the observed viscosity, and η^{*} is the viscosity of the water fraction. Thus, for a solution:

$$\frac{\eta^{*}}{\eta_w} = \frac{1 + Bc}{1 + V_s^{\circ}.c/400} \simeq 1 + Bc - V_s^{\circ}.c/400$$

The errors introduced by the foregoing approximation are usually negligibly small at concentrations up to 1 mole/l. In the worst case, the approximation introduces an error of only 0·009 into the calculated value of η^{*}/η_w.

Thus at a nominal concentration of 1 mol/l.:

$$(B - V_s^{\circ}/400) = \frac{\eta^{*}}{\eta_w} - 1$$

that is, the factor $(B - V_s^{\circ}/400)$ represents the change in the relative viscosity of the water fraction.

(4) That the relative viscosity of the water fraction is a function only of the amount of expansion or contraction that the water fraction undergoes.

According to equation (1) the relative amount of expansion of the water fraction is given by:

$$\frac{V'_w - V_w}{V_w} = \alpha c \qquad (3)$$

Therefore, at a concentration of 1 mole/l., α gives a direct measure of the relative expansion or contraction the water fraction has suffered.

According to equations (1) and (2) the volume V of a solution containing m_1 moles of water and m_2 moles of salt is given by:

$$V = m_1 V_w\,(1 + \alpha c) + m_2 V_s^{\circ}\,(1 + \beta c) \qquad (4)$$

Equation (4), on differentiating partially with respect to m_1 and m_2, yields the partial molar volumes of the water and the salt, respectively $\bar{V}_1$ and $\bar{V}_2$, in terms of α, β, m_1 and m_2. Taking the limiting values as $m_2 \rightarrow 0$ we obtain the partial molar volumes at infinite dilution $\bar{V}_1^{\circ}$ and $\bar{V}_2^{\circ}$, these are found to be:

$$\bar{V}_1^{\circ} = V_w \qquad (5)$$

$$\bar{V}_2^{\circ} = V_s^{\circ} + 1000\,\alpha \qquad (6)$$

Hence α can be obtained from the partial molar volume data at infinite dilution by using the equation:

$$\alpha = \frac{\bar{V}_2^{\circ} - V_s^{\circ}}{1000}$$

Thus the correlation shown in Fig. 1 is a plot of the change in the relative viscosity of the water fraction against the relative expansion of the water fraction. This interpretation leads to the conclusion that salts which expand the water fraction decrease the viscosity of the water fraction and vice versa.

The correlation can be used for testing the validity of the various theories of the viscosities of solutions.

For example, Robinson and Stokes interpret the viscosities of aqueous solutions of electrolytes in terms of the Einstein thickening effect of hydrated ions. However, my correlation shows that ions which increase the volume of the water fraction (that is, α-positive), lie on the same straight line as ions which decrease the volume (α-negative). This suggests that the same mechanism operates for all ions regardless of whether they increase or decrease the viscosity of the solution. Hence, although Einstein thickening by hydrated ions could explain the viscosity data for ions which increase the viscosity, Robinson and Stokes's theory is incapable of explaining the data for the ions which decrease the viscosity.

On the other hand, Kaminsky supposes that salts which increase the viscosity increase the amount of ice-like structure. They would, therefore, be expected to increase the specific volume of the water fraction. However, my correlation shows that those salts which increase viscosity decrease the specific volume, in direct contradiction to Kaminsky's supposition.

Fig. 1 includes all the ions for which the data were available with the exception of the lithium ion. This point was omitted because it lies outside the normal scatter about the correlation line. α × 1000 for the lithium ion is − 1·6 and $(B - V_s^{\circ}/400)$ is 0·1480. The interpolated value of $(B - V_s^{\circ}/400)$ corresponding to this α value is, from the correlation line, equal to + 0·02. Lithium could be brought into line if it were assumed that its ions are strongly hydrated, and hence that the volume that should be used for the Einstein correction is not that of the bare ion but the volume of the ion plus its solvated water molecules, $V_s^{\circ\prime}$. Hence $(B - V_s^{\circ\prime}/400) = 0{\cdot}02$. From this it is found that $V_s^{\circ\prime} = 51{\cdot}2$ c.c./mole. Since $V_s^{\circ} = 0{\cdot}60$ c.c./mole, this difference is accounted for if 2·8 water molecules are strongly attached to each lithium ion.

I thank Mr. R. P. Bell for advice and criticism.

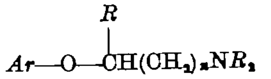
THYMOL BASIC ETHERS AND RELATED COMPOUNDS: CENTRAL NERVOUS SYSTEM DEPRESSANT ACTION

By A. ASHFORD, C. J. SHARPE* and F. F. STEPHENS*
Research Department, Crookes Laboratories, Ltd., Park Royal, London, N.W.10

During routine toxicity investigations of the well-known drug β-dimethylaminoethyl thymol ether ('Tastromine') and its homologue β-diethylaminoethyl thymol ether (also known as '*F.929*') conducted in these laboratories in 1958, it was observed[1] that the animals (mice) became sedated. Further pharmacological investigation[1] of these two compounds indicated that they possessed properties characteristic of central nervous system depressant drugs, since they were found to depress spontaneous motor activity, produce hypothermia, potentiate hexobarbitone and alcohol hypnosis and re-induce hexobarbitone sleep. Although these and related compounds have been extensively investigated in the 'pre-tranquillizer era', particularly by Fourneau[2], Bovet[3] and Staub[4], it was thought worth while to re-investigate this series of basic phenol ethers using the more recently developed pharmacological methods for the discovery of central nervous system depressant properties. Recent reports[5-7] of similar investigations prompt us to report such results as we have so far obtained.

A series of basic ethers of the general structure:



$$Ar{-}O{-}\overset{R}{\overset{|}{\mathrm{C}}}\mathrm{H(CH_2)}_n\mathrm{N}R_2$$

was prepared (usually as crystalline citrates) in which *R* was either hydrogen or a lower alkyl group and in which *Ar*O represents a phenoxide radical. Initially the phenols used for these preparations included: phenol; *o*-cresol; *p*-cresol; *o*-isopropyl phenol; *p*-isopropyl phenol; *p*-tertiary butyl phenol; 6-chloro-2-methyl phenol; thymol; isothymol; 2,4,6-trimethyl phenol; carvacrol; 4-chloro-2-isopropyl phenol; 3-isopropyl phenol; 2,3,5,6-tetramethyl phenol; and 2-*cyclo*hexyl phenol.

It was found that significant central nervous system depressant activity only appeared when the basic ethers were derived from thymol (specifically, 1-methyl-3-hydroxy-4-isopropyl benzene). Compounds derived from isomers of thymol (for example, carvacrol and isothymol) were relatively inactive and there was a very considerable loss in activity (of the order of a twenty-fold diminution) when they were obtained from 2-isopropyl phenol. The alicyclic compound β-diethylaminoethyl menthol ether possessing the same skeleton as the most active thymol ether was quite inactive. Further substitution in the thymol nucleus (specifically 6-chloro, 6-benzyl, 6-amino, and 6-methoxy) also lead to considerable reduction in activity. In the basic ethers derived from thymol itself it was found that maximum activity was obtained when a β-diethylaminoethyl side-chain was attached; if this chain was extended (γ-dialkylamino-*n*-propyl ethers) or the chain was branched (β-dialkylaminoisopropyl ethers) or the N-diethyl groups were exchanged for hydrogen, methyl[8], *n*-propyl or *n*-butyl groups, or the basic side-chain was part of a piperidine ring, there was always a considerable loss in activity. A partial resolution of the asymmetric β-dimethylaminoisopropyl thymol ether, resulting in the preparation of the pure laevorotatory isomer, indicated no detectable difference between this and the racemic form. From this work we concluded that significant activity only appeared in this series when the nucleus was aromatic, the basic ether was ortho to an isopropyl group, the nucleus carried a methyl group para to the isopropyl group, the number of carbon atoms between oxygen and nitrogen was two, the nitrogen was tertiary and the alkyl groups attached thereto were ethyl.

It is interesting to compare these structural requirements with those suggested[9-11] for morphine-like analgesics, when it will be seen that most of these are met in the active basic ether (β-diethylaminoethyl thymol ether, which will hereafter be referred to as '*CR* 127').

The construction of molecular models (Catalin) of '*CR* 127' shows that a strainless conformation can exist which might be expected to fit the hypothetical receptor surface described by Beckett[11] and in which ether–oxygen and nitrogen are in close proximity. In any conformation the oxygen atom should be influenced by the relatively bulky ortho isopropyl group[12], and indeed thymol itself possesses cryptophenolic properties. We considered, therefore, that such juxtaposition of oxygen, nitrogen and the hydrocarbon (isopropyl) group might allow some mutual interaction either in the molecule itself, a metabolite or at the receptor surface and that this might be electronically influenced by the methyl group in para position to the isopropyl group. This was an attractive hypothesis since it would account for the absolute necessity of the 1-methyl group, the general orientation of the molecule and the necessity for a two-carbon chain between oxygen and nitrogen. In this context the work of H. C. Brown[13] on the rate of solvolysis of tertiary cumyl chlorides appeared relevant; these reactions proceed

0·0025	N.S.	<0·05	N.S.

through a carbonium ion and are considerably affected by the nature of the para substituent. These considerations led to the preparation of 1-methyl-3-diethylamino-ethoxy-4-tert. butyl benzene ('*CR* 256')[14] and 1-methoxy-3-diethylaminoethoxy-4-isopropyl benzene ('*CR* 299'). In compound '*CR* 256' the steric hindrance is increased and the molecule more closely fits the requirements for a morphine-like analgesic; in '*CR* 299' the 1-methyl group has been replaced by the more powerfully electron-donating methoxy-group. At the same time, *N*-2'thymoxy ethyl norpethidine ('*CR* 235') was prepared.

Pharmacological examination of these compounds showed that '*CR* 256' was somewhat more active than '*CR* 127' and that '*CR* 299' was inactive. The pethidine derivative ('*CR* 235') possessed no analgesic action. Structural modifications in the tertiary butyl series (as done for the thymol series) again showed the same specificity of structural requirements for central nervous system depressant activity.

A small selection of the pharmacological results obtained in this work is given here; active compounds '*CR* 127' and '*CR* 256' are described and '*CR* 277' is included to show the effect of the para methyl group.

Schneider mice (in groups of five) weighing 18–22 g were used in these experiments, and all injections were given by the intraperitoneal route.

Acute toxicity. Over a 5-day period the following LD_{50} values were obtained (calculated by Karber's method).

Table 1. LD_{50} VALUES INTRAPERITONEAL

Drug	LD_{50} mg/kg
'*CR* 127'	350
'*CR* 256'	332
'*CR* 277'	245
Chlorpromazine	140
Pethidine	150

Reduction in motor activity. Motor activity was measured by the photoelectric cell technique of Siegel[15] as modified by Dews[16]. For measurement of effect on spontaneous motor activity a range of doses from 0·0025 to 0·1 of the LD_{50} was used, the drug being injected 15 min before the mice were placed in the observation cage, where they remained for a period of 30 min (Fig. 1). *P* values refer to differences from controls.

Further tests were carried out at a dose-level of 0·1 LD_{50} in animals made hyperactive by the injection of cocaine hydrochloride (20 mg/kg) or amphetamine sulphate (5 mg/kg) given immediately before the test started. The results are given in Table 2 (figures in parentheses refer to the degree of significance).

Table 2. PERCENTAGE REDUCTION IN HYPER-MOTOR ACTIVITY

Drug	No. gps. mice	Cocaine	Amphetamine
'*CR* 127'	6	40 (N.S.)	57 (<0·05)
'*CR* 256'	13	28 (N.S.)	72·5 (<0·001)
'*CR* 277'	7	26 (N.S.)	0
Chlorpromazine	13	90 (<0 001)	94 (<0 001)

Potentiation of hexobarbitone and alcohol sleep. Drugs were administered at one dose-level (0·1 LD_{50}) at various intervals of time before the mice received an injection of either hexobarbitone (100 mg/kg) or 30 per cent ethanol (0·3 ml./20 g). Regaining of the righting reflex was taken as the end-point of the test. The results are given in Table 3.

Table 3. PERCENTAGE PROLONGATION OF SLEEPING TIME

Drug	Total No. mice		Interval in min between injection of potentiator drug and hypnotic			
			0	30	60	120
'*CR* 127'	60	Hexobarbitone	149 (<0·01)	133 (<0·001)	130 (<0·001)	51 (N.S.)
'*CR* 256'	95		212 (<0·01)	117 (<0·001)	143 (<0 001)	105 (N.S.)
'*CR* 277'	65		47 (<0·02)	10 (N.S.)	48 (<0·01)	5 (N.S.)
Chlorpromazine	80		266 (<0·001)	394 (<0·001)	318 (<0·001)	290 (<0 001)
'*CR* 256'	25	Alcohol	1,137 (<0·001)	188 (<0 01)		
'*CR* 277'	40		0	0		
Chlorpromazine	20		987 (0·001)	1,412 (<0 001)		

Hypothermia. The rectal temperatures of mice were taken by thermistor at intervals of 30 min following the injection of the drug in a dose of 0·2 LD_{50}.

Table 4. EFFECT OF DRUGS ON RECTAL TEMPERATURE

Drug	Maximum fall (°C)	Time of max. effect (min)	Recovery time (h)
'*CR* 127'	5 6	30	5
'*CR* 256'	5·1	30	5
'*CR* 277'	1·0	60	3–4
Chlorpromazine	6 9	90–180	>6

Analgesia. This was measured by the clip test of Bianchi[17]. Drugs were administered in a dose of 0·2 LD_{50}. At this level both '*CR* 127' and '*CR* 256' were equipotent and possessed 1/3 of the activity of pethidine. '*CR* 277' was inactive. All three drugs potentiated pethidine.

In other pharmacological tests the following results were obtained for '*CR* 127' and '*CR* 256'.

(*a*) They exhibit only slight anticonvulsant activity against strychnine, but their effect against leptazol is more marked although still inferior to that of phenobarbitone. Chlorpromazine has approximately the same degree of activity as '*CR* 127' and '*CR* 256'.

(*b*) They reduce the pressor effect of adrenaline in the rat but are weaker adrenolytic agents than chlorpromazine.

(*c*) They cause a sharp fall in blood pressure in the rat and cat and inhibit respiration following intravenous injection. These effects are short-lived.

(*d*) They cause a hypersecretion of corticotrophin from the pituitary gland on initial injection and do not prevent the stimulant effects of an ether stress on corticotrophin. In this they resemble chlorpromazine.

(e) They antagonize only slightly the increased toxic effect of amphetamine in grouped mice, in contrast to the powerful antagonism of chlorpromazine.

(f) '*CR* 127' is not anti-emetic in contrast to chlorpromazine.

(g) They do not antagonize the increased capillary permeability in the rat caused by anaphylactoid agents. Again this is in sharp contrast to chlorpromazine.

There are several points of similarity between '*CR* 127', '*CR* 256' and chlorpromazine among which is the observation that, following an intraperitoneal injection, mice rapidly become quiet and appear to be in a state of catalepsia, in which they can be placed in bizarre positions. The drugs similarly potentiate the effects of hypnotics and reduce spontaneous activity and hyper-motor activity caused by amphetamine. However, they differ in their effects against cocaine excitement and amphetamine toxicity. The lack of effect of '*CR* 127' and '*CR* 256' against cocaine is rather surprising in view of the strong effects of the same dose against amphetamine hyperactivity. Differences in the mode of action of cocaine and amphetamine on the central nervous system evidently exist and the lack of effect of '*CR* 127' and '*CR* 256' against cocaine may be related to the weakness of the adrenolytic properties of these drugs, since it has been shown that at least peripherally cocaine may act by inhibiting the uptake of noradrenaline by the storage organs[18,19].

When '*CR* 127' and '*CR* 256' were tried in man (volunteers) a surprising effect was noted: approximately 1·5 h after taking 10–12 mg (equivalent to 0·125 mg/kg) epigastric pain was noticed, and this developed to severe aching and tenderness in all muscles of the body, but particularly those of the legs, arms, muscles of deglutition and superficial muscles of the scalp; tachycardia was noticed on climbing stairs and these effects persisted for 13 h (that is, to the time of retiring). No evidence of tranquillization was observed at this dose-level, but the volunteers were of course non-psychotic and for obvious reasons larger doses were not investigated. These effects in man resemble the extra-pyramidal reactions shown by certain tranquillizing drugs[20,21] (phenothiazines and reserpine).

The demonstration[22] that dopamine is found in high concentrations in the caudate- and entiform-nucleus has led to the suggestion that reserpine may produce extrapyramidal effects by depletion of this amine; it has also been suggested[20] that phenothiazines cause this effect by interference with dopamine, and Ernst[23] has ascribed hypokinetic rigid syndromes to O-methylation of dopamine. It is interesting that Martin *et al.*[24] have stated that β-diethylaminoethyl thymol ether (that is, '*CR* 127') specifically inhibits dopa-decarboxylase, hence it may be that '*CR* 127' and '*CR* 256' exert their action by interference with the biosynthesis of catechol amines. There is, however, evidence[25] that dopa-decarboxylase is identical with 5-hydroxytryptophan decarboxylase (inhibition of which by phenylalanine has been suggested[26] as a cause of mental disturbance in phenylketonurics).

Quaternary ammonium compounds derived from these basic ethers showed curare-like properties and caused flaccid paralysis with no evidence of initial stimulation. Most of the compounds caused a transient fall in blood pressure and were respiratory depressants. Many of the compounds were potent local anaesthetics. As might be expected, the rigid structural requirements elucidated for significant central nervous system-depressant activity in the tertiary bases were no longer important.

This work is part of an investigation of the relationships between structure and central nervous system-depressant activity in a simple model.

SYNTHESIS OF ORGANIC COMPOUNDS BY HIGH-ENERGY ELECTRONS

By Prof. J. ORÓ

Lawrence Radiation Laboratory, University of California, Berkeley, California, and Chemistry Department,
University of Houston, Houston, Texas

THE use of ionizing radiation for the synthesis of organic compounds under possible primitive earth conditions was initiated by Calvin *et al.*[1]. These investigators obtained formic acid and formaldehyde by irradiating aqueous solutions of carbon dioxide with 40-MeV helium ions. The reduction of carbon dioxide to formic acid and formaldehyde was confirmed using cobalt-60 γ-rays by Getoff *et al.*[2], who, in addition, observed also the presence of acetaldehyde among the reaction products. Since the foregoing initial observation was made, a number of experiments have been reported[3–7] which show the production of a few amino-acids and other organic molecules by the action of ionizing radiation on simple compounds, or mixtures of compounds, containing carbon, nitrogen, oxygen and hydrogen.

More recently, Palm and Calvin[8], using methane labelled with carbon-14 in aqueous ammonia mixtures and irradiating with 5-MeV electrons from a linear accelerator, observed the formation of glycine, alanine, aspartic acid, several hydrocarbons and a relatively large number of other unidentified compounds. Among these compounds purines and pyrimidines were suggested to be present[9,10].

Further experiments using ^{14}C-methane and 5-MeV electrons have been performed and are presented here. Some experiments were carried out with the irradiated mixture mainly in the gas phase, so that the results obtained may be compared with those obtained with electrical discharges under similar conditions[11]. An experiment was carried out with a mixture of ^{14}C-methane, ammonia and water in the solid phase. It was thought that such an experiment may give some insight on the possible products formed by ionizing radiation from the protosun acting on 'ices'[12] or hydrates[13] of simple compounds of carbon and nitrogen assumed to have been present in the primordial solar nebula. (Such interactions may also have occurred in protoplanetary bodies, and may be occurring at present in comets and other cosmic bodies of the solar system[14,15].)

The results have shown that the pattern of compounds formed by the irradiation of the aforementioned mixtures in the gas phase is similar to the pattern of compounds formed by the action of electrical discharges on analogous mixtures[11]. Secondly, it has also been observed that the irradiation in the solid phase of methane–ammonia–water mixtures leads to the formation of a reasonably large number of non-volatile organic compounds.

Irradiation technique and dosimetry. In general, the irradiation technique, particularly that used in the gas-phase experiments, was essentially that of Palm and Calvin[8]. High-energy electrons (5 MeV) were delivered from a linear accelerator (The linear accelerator was operated by W. Everette and D. Pounds, of the Lawrence Radiation Laboratory, who also carried out the dosimetry. Their help is gratefully acknowledged.) The absorbed dose was measured by means of a cobalt glass dosimeter. For this purpose a tube similar to the irradiation vessel was made (Fig. 1) and small pieces of cobalt glass were located inside the tube every 5 cm along its axis. The tube was partially evacuated, placed in front of the linear accelerator with its axis coinciding with that of the electron beam, and irradiated for a given time. The colour change of the cobalt glasses was measured by means of a spectrophotometer. The corresponding number of rads per microcoulomb was plotted against the distance of each piece of cobalt glass to the window of the linear accelerator. The results are shown in Fig. 2. It can be seen that the dose absorbed at about 25 cm (middle of the tube) is of the order of 1·5 × 10^4 rads per microcoulomb. In general, each irradiation was carried out for a period of 2 h. The current used during this time was 64,800 microcoulombs. Therefore, considering complete linearity, the dose absorbed was of the order 1 × 10^9 rads. It is of interest to note that this measured value agrees with the upper value calculated previously by Palm and Calvin[8]. For individual experiments the approximate values for the absorbed dose are given in Table 1.

Table 1. COMPOSITION OF GAS MIXTURES AND OTHER DATA OF THE EXPERIMENTS WITH HIGH-ENERGY ELECTRONS

	Exp. No.			
	RS–1	*RS*–2	*RS*–3	*RS*–4
Volume, irradiation tube (c.c.)	755	755	8·8	260
CH_4 pressure (cm Hg)	25	9	670	40
$^{14}CH_4$ activity (μc.)	—	370	100	300
$^{14}C_2H_6$ activity (μc.)	680	—	—	—
N_2 pressure (cm Hg)	25	24·5	—	—
H_2O (ml. liquid)	20	5	2	0·2
NH_4OH (moles/l.)	0·5	14	6	6
Average temperature (°C.)	25	80	20	−196
Time of irradiation (h)	2	2	0·4	2·5
Dose (1 × 10^9 rads)	1	0·97	0·12	1·3
Weight of residue (mg)	12	4·4	2	3·2
Activity of residue (μc.)	28	5·5	0·07	14·0
Activity of distillate (μc.)	26	1·2	0·10	3·6
Conversion of ^{14}C reactants to non-volatile products (per cent)	4·1	1·5	0·07	4·6
Conversion of ^{14}C reactants to volatile water-soluble products (per cent)	3·8	0·3	0·10	1·2

Gas-phase experiments. Not all the experiments were performed under the same conditions. The first and the second experiments (*RS*-1 and *RS*-2) were carried out with the hydrocarbons in the gas phase under slightly reduced pressure, and water and ammonia in the liquid and vapour phase. The vessel used in these two experiments was the same tube *B* described by Palm and Calvin[8].

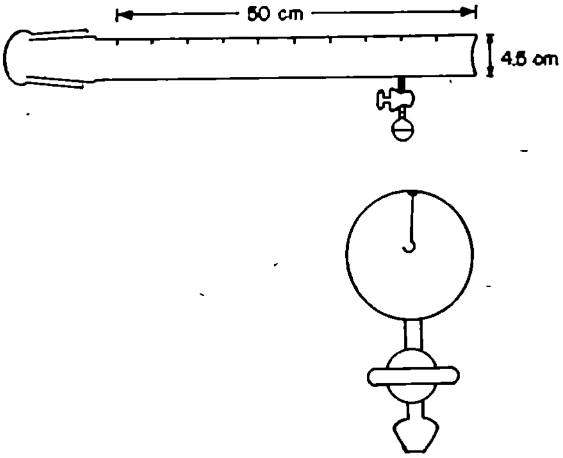

Fig. 1. Diagram of a 'Pyrex' glass tube used for dosimetry. Small rectangular pieces of cobalt glass were placed inside the tube at distances of 5 cm along the tube

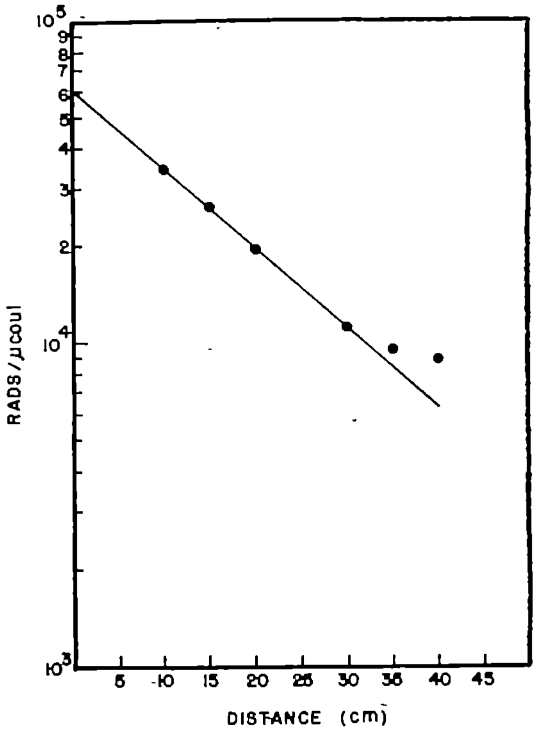

Fig. 2. Semilogarithmic plot of rads/microcoulomb against the distance of each piece of cobalt glass to the window of the linear accelerator

Only a minor modification was made: two permanent stopcocks were attached to the inlet and outlet of the tube.

After evacuation, the radioactive and non-radioactive hydrocarbons, and a solution of ammonium hydroxide were successively introduced into the vessel. The ammonium hydroxide solution was prepared using boiled distilled water, and care was exercised to avoid any bubbles of air going into the system. The tube was placed in front of the linear accelerator and irradiated. In experiment *RS*-2 the bottom well of the tube *B* was heated during irradiation to reflux the water and thus increase the partial pressure of the water vapour. In experiment *RS*-1 this was not done.

Solid-phase experiment. Experiment *RS*-4 was carried out in the apparatus shown in Fig. 3 with the reactants in the solid phase. The reactants were admitted into the horizontal tube at ambient temperature under slightly reduced pressure, and then liquid nitrogen was added into the adjacent Dewar flask. Immediate con-

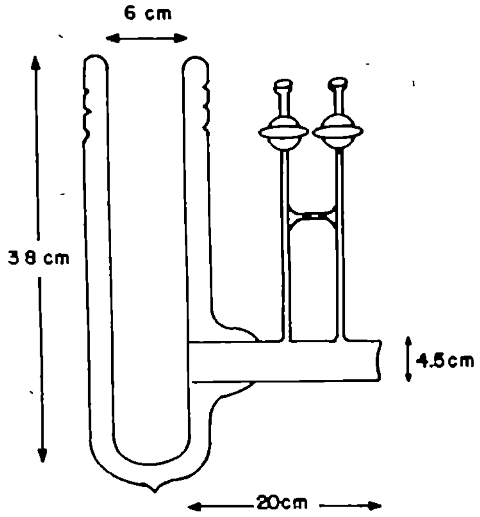

Fig. 3. 'Pyrex' glass vessel used in the solid-phase irradiation experiment. The horizontal tube contained the reactants which did condense in a solid layer on the left window as soon as the Dewar flask was filled with liquid nitrogen.

densation of water, ammonia and methane occurred on the inside of the window facing the liquid nitrogen. The resulting layer of white crystals, approximately 2 mm thick, was irradiated for about 2 h as in the case of the gas-phase experiments. The Dewar flask was always kept full of liquid nitrogen during the irradiation process, so that no volatilization or liquefaction of the solid layer occurred at any time. Visual observation of the integrity of this layer was afforded by a system of mirrors which reflected the image to the outside of the irradiation chamber.

Liquid-phase experiment. Experiment *RS*-3 was performed using a small tube, of 6·8 c.c. of volume, filled partially with water. The methane and ammonia were admitted while the tube was immersed in liquid nitrogen. The tube was then sealed and allowed to warm to room temperature. This resulted in a substantial positive pressure. In consequence, an appreciable portion of the methane was dissolved in water. This tube was irradiated for only 25 min and the current used during this time was 8,100 microcoulombs. The pressure measured after irradiation was of the order of 16 atmospheres.

Analysis of products. The gaseous and highly volatile products present in the gas phase of each experiment were not analysed. At the end of each run the contents in each tube were diluted with water and transferred quantitatively into a small tared flask. This solution was evaporated to dryness in a vacuum rotating evaporator. The water and other volatilized products were trapped in a tube immersed in liquid nitrogen. The flask containing the dry residue was weighed and the residue was dissolved in 0·2–0·4 ml. of 0·1 N hydrochloric acid. A small aliquot of the product from each experiment showing approximately 1×10^4 d.p.m. was analysed by two-dimensional paper chromatography and autoradiography. The chromatographic procedure followed was identical to that used in the previous experiments with electric discharges[11].

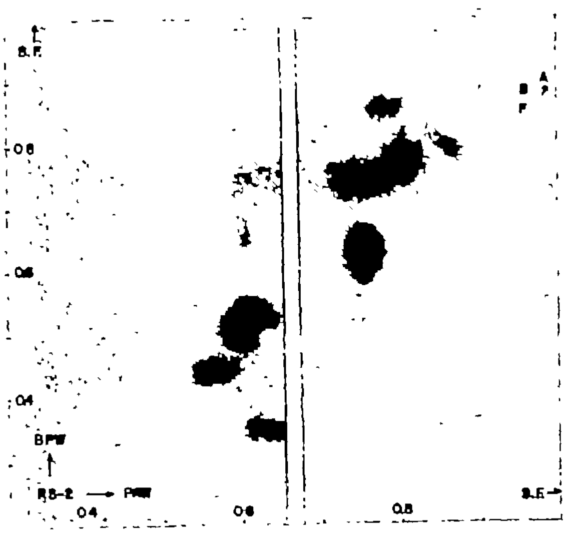

Fig. 4. Autoradiograph of a two-dimensional chromatogram of a gas-phase irradiation experiment (*RS*–2).

An autoradiograph of a two-dimensional chromatogram of experiment *RS*-2 (gas-phase irradiation) is shown in Fig. 4. By comparison with the autoradiograph of experiment *S*-5 (electric discharges[11]) it can be seen that the general distribution of compounds is similar. Since amino-acids, hydroxy acids, and their respective amides and nitriles seem to predominate in the experiments with electric discharges, the tentative conclusion is made that analogous compounds are formed by irradiation with electrons.

In particular, on the left side of the *RS*-2 autoradiograph there appears to be at least five compounds which show rates of migration essentially identical to those of five compounds on the left side of the *S*-5 autoradiograph. Of these five compounds, it is suggested that three more intense lower spots correspond to alanine, glycine and glycinamide. Spots corresponding to the latter compounds can also be observed in the chromatogram of *S*-7 (electric discharges[11]) which was sprayed with ninhydrin.

An analogous correlation can be observed by comparing the right side of *RS*-2 with the right side of *S*-5. At least three compounds appear to have identical R_F in the two chromatograms. This area of the chromatogram corresponds to the area of migration of some of the less polar amino-acids, such as the leucines, and also of some purines and pyrimidines such as adenine, thymine, uracil and cytosine[16].

The autoradiograph of the other gas-phase irradiation experiment (*RS*-1) was somewhat similar to that of *RS*-2. However, additional fast-moving components were also observed. Some of the latter compounds may be less polar or more lipophilic in nature than amino-acids or amino-acid amides.

The existence of a similarity between the products formed by irradiation with electrons and those formed by electrical discharges should not be surprising since both processes involve excitation and ionization phenomena by electrons. In fact, the products obtained in the decomposition of methane by electric glow discharges and low-energy electrons are almost identical and include hydrogen, ethane, ethylene, acetylene and other hydrocarbons[17]. The irradiation of methane by high-energy electrons is also known to produce hydrogen, ethane, ethylene, propane and butane[18].

An autoradiograph of a two-dimensional chromatogram of the products obtained from the solid-phase irradiation experiment (*RS*-4) is shown in Fig. 5. A careful comparison of this autoradiograph with that of *RS*-2 (Fig. 4) will reveal a number of spots with identical R_F. This correlation can be carried back to the autoradiographs of the experiments with electric discharges[11]. A comparison of the same autoradiograph with a two-dimensional chromatogram of standard purines and pyrimidines[16] revealed the presence of radioactive spots in the areas corresponding to purines and pyrimidines. No definite claim about the formation of these compounds can be made until they are identified by co-chromatography with authentic samples in additional solvent systems. (Adenine has been recently identified by C. Ponnamperuma and R. Lemmon[19].)

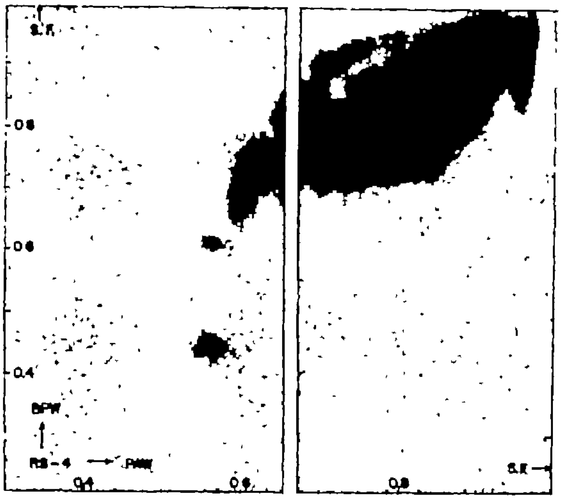

Fig. 5. Autoradiograph of a two-dimensional chromatogram of a solid-phase irradiation experiment (*RS*-4).

The increased number of radioactive spots in the zone of higher R_F's (Fig. 5) may be taken as an indication that the compounds formed in the solid-phase irradiation experiments are of a less polar character than those formed in the previously described fluid-phase experiments (electron irradiation or electric discharges). This is probably what should be expected from processes occurring in the solid phase, where hydrolytic and ammonolytic reactions must be very slow if not completely absent.

The autoradiograph of the irradiation experiment carried out in a predominantly liquid phase (*RS*-3) showed no detectable radioactive spots. Although only $3 \cdot 8 \times 10^4$ d.p.m. could be placed on the paper to carry out the two-dimensional chromatographic analysis, it would seem that if any compound was formed in significant amounts in this experiment it should have left a radioactive spot on the photographic film after five days of exposure. It can also be seen in Table 1 that the fixation of radioactive carbon into the non-volatile products in this experiment was between 1 and 2 orders of magnitude lower than in the other experiments. It is possible that under the conditions of this experiment most of the methane was oxidized to carbon dioxide.

Discussion

(1) Organic compounds are formed in the irradiation by high-energy electrons of mixtures of methane, ammonia and water not only when these reactants are in the gas phase but also when they are in the solid phase.

(2) The autoradiographic patterns of the compounds formed by high-energy electrons are similar to those obtained by electric discharges, although the products obtained in the solid-phase irradiation experiments appear to be of a less polar character. The compounds detected by comparing two-dimensional chromatograms include amino-acids, amino-acid amides, amines, and other molecules of biological significance. The positions of some radioactive spots on the chromatograms correspond closely to those of some purines and pyrimidines. Work is in progress for the identification of these compounds.

(3) On the basis of the results obtained here, and recognizing that the hydrides of carbon, nitrogen and oxygen (in the solid and gas phases) prevail in the universe, it is suggested that the radiation synthesis of organic and biochemical compounds is an important cosmic process. If an appreciable radiation flux prevailed during the early evolution of the primordial solar nebula[14] an extensive synthesis of these compounds probably took place in the protoplanets of the solar system. The synthesis may also occur presently, at lower rates, in the atmospheres of the Jovian planets and in cometary bodies during perihelion orbital travel.

I thank Prof. M. Calvin for providing the stimulus and laboratory facilities to carry out these experiments, and Dr. R. Lemmon for advice.

This work was sponsored in part by the U.S. Atomic Energy Commission and by a grant (*NsG* 257–62) from the National Aeronautics and Space Administration.

EFFECT OF ADENOSINE DIPHOSPHATE ON THE CONCENTRATION OF PLATELETS IN CIRCULATING BLOOD

By PROF. G. V. R. BORN and DR. M. J. CROSS

Department of Pharmacology, Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C.2

WHEN adenosine diphosphate (ADP) is added to blood plasma containing platelets they rapidly adhere to each other to form aggregates[1]; this effect is not brought about by any other naturally occurring nucleotide. In separated plasma the aggregation has been investigated quantitatively by a turbidimetric method[2]. With platelet-rich plasma of pigs and man, the rate and extent of aggregation depend on the concentration of added ADP, and its aggregating effect is inhibited by adenosine monophosphate (AMP) and, even more, by adenosine[2,4].

It has been suggested[3] that ADP is responsible for the initial adhesion of platelets to damaged vascular endothelium and to each other in the formation of hæmostatic plugs and of thrombi. If this were so, ADP might be expected to diminish the concentration of platelets circulating in the blood stream of living animals. This possibility has now been tested in experiments on cats.

When ADP was added *in vitro* to platelet-rich plasma of cats the platelets aggregated (Fig. 1), just as they do in plasma from man and from pigs. However, the plasma of cats differed from the plasmas of pig and man[4]. With

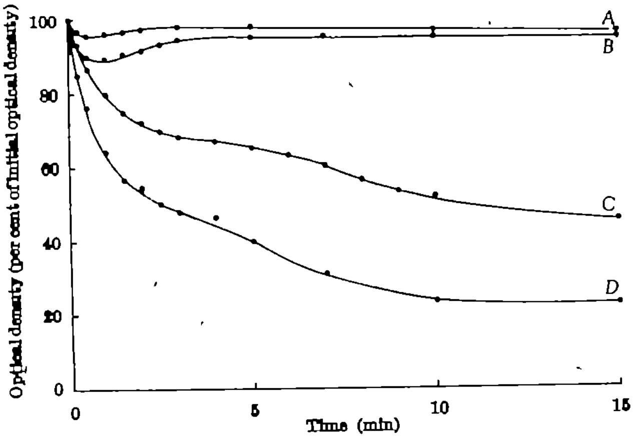

Fig. 1. Effect of adding ADP on the optical density of cat's plasma containing $1·91 \times 10^8$ platelets/ml. The plasma contained sodium citrate (3·0 mg/ml.) and was stirred at 1,000 r.p.m. ADP was added at 0 min to give the following concentrations: 2×10^{-7} M (curve *A*); $3·3 \times 10^{-7}$ M (curve *B*); 5×10^{-7} M (curve *C*), and $6·6 \times 10^{-7}$ M (curve *D*)

cats' plasma: (1) the concentrations of ADP which brought about aggregation were lower; (2) small changes in the concentration of added ADP had much larger effects on the rate and extent of aggregation (Fig. 1); (3) the aggregation produced by ADP was not inhibited by AMP or by adenosine; and (4) the effect of a second addition of ADP was no smaller than that of the first. Cats' platelets were, therefore, highly susceptible to the aggregating effect of ADP; moreover, its breakdown products did not inhibit the effect. This suggested that if there was an effect of ADP on circulating platelets it should be demonstrable in cats.

We infused ADP into the blood stream of healthy cats weighing 2·5–6·0 kg and determined the concentrations of circulating platelets. Each cat was anæsthetized with ethyl chloride followed by chloralose (40 mg/kg) injected through a cannula in the right external jugular vein. Heparin was injected intravenously at a concentration of 120 units/kg. More heparin and chloralose were injected at intervals during the experiment; neither affected the concentration of platelets. A cannula was tied into the trachea and another into the left common carotid artery from which the blood pressure was recorded with a mercury manometer recording on a kymograph. The left femoral vessels were exposed just below the inguinal ligament and a polythene cannula was tied into the first, very small, branch of the artery. The cannula was closed with a pair of artery forceps. For taking samples of blood, the forceps were released; about 0·1 ml of blood was allowed to flow out through the cannula to flush the dead space with fresh arterial blood; a sample of 0·1 ml of blood was withdrawn into a syringe containing 0·1 ml. of 4·5 per cent (w/v) ethylenediamine tetraacetate. The syringe was rapidly emptied into a plastic centrifuge tube containing 1·8 ml. of 4·5 per cent ethylenediamine tetraacetate which prevents aggregation of platelets. The platelets in the diluted blood were counted in duplicate by the method of Nygaard[5] as modified by Davidson and Tomlin[6].

In 19 cats the blood contained $0·9–3·2 \times 10^8$ platelets/ml., with a mean of 1·9. When a cat was left all day except for having blood samples taken from it the concentration of circulating platelets varied little (Fig. 2). Infusions were made through the cannula in the external jugular vein or through that in the femoral artery, at a rate of 0·2 ml./min. The concentration of circulating platelets was not altered significantly by infusing isotonic saline, in which the adenine compounds were dissolved.

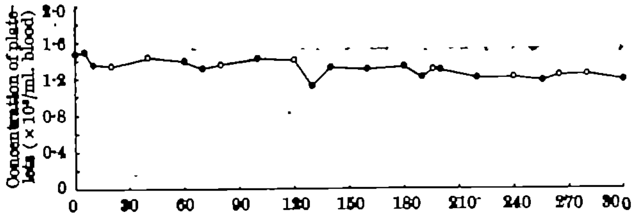

Fig. 2. Concentration of platelets in blood from the femoral artery of an anæsthetized cat weighing 3·0 kg

In four experiments, when ADP in concentrations of 1 and $2·5 \times 10^{-5}$ M was infused into the external jugular vein, the concentration of circulating platelets immediately decreased (Fig. 3). In two of these experiments the mean blood pressure did not change. In the other two the blood pressure fell briefly by 10 and 45 mm mercury respec-

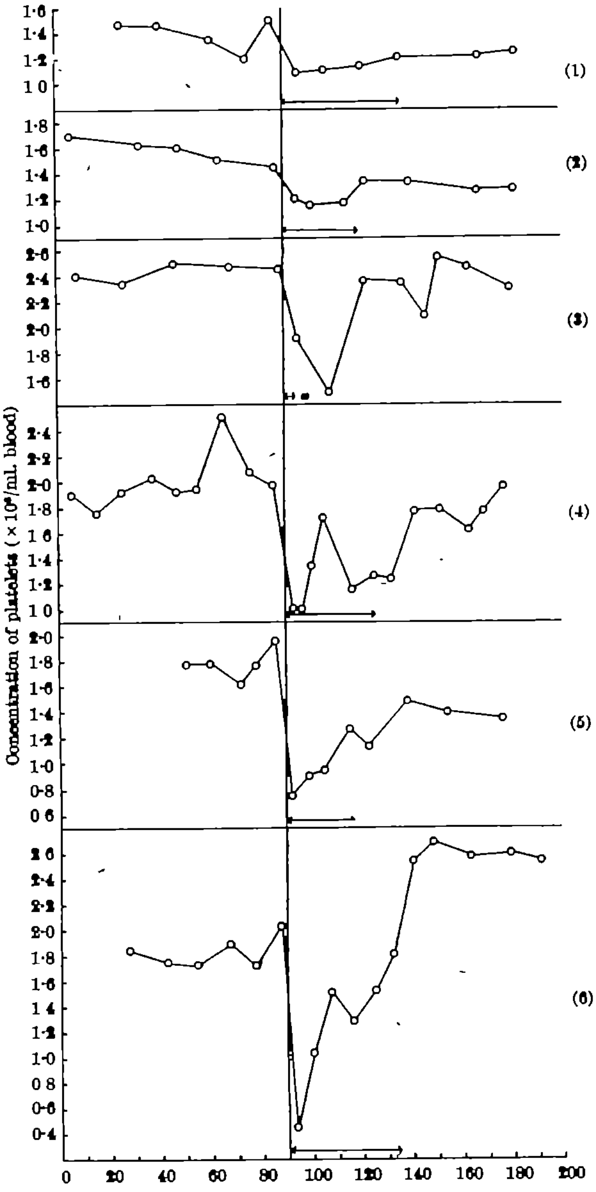

Fig. 3. Concentrations of circulating platelets in blood from the femoral artery of anæsthetized cats. Saline was infused into the external jugular vein from the beginning of each experiment; then ADP from the line at 90 min for times indicated ⟷; and then saline again. The rate of infusion was 0·2 ml./min

Exp. No.	Weight of cat (kg)	Concentration of infused ADP (M)
1	3·1	$1·0 \times 10^{-5}$
2	4·2	$5·0 \times 10^{-5}$

tively and then rose to what it had been before the infusion of ADP; at this time the platelet concentration was still reduced. When ADP was infused in lower concentrations the platelet concentration decreased slightly or not at all. In four experiments ADP was infused into the cannula in the femoral artery; the infusions were stopped when blood samples were taken. Again, the platelet count fell when the ADP concentration was 1×10^{-3} M but not when it was 5×10^{-3} M. In some experiments, samples of blood were also taken through a cannula in the uppermost branch of the accompanying femoral vein. Changes in the concentrations of platelets in the venous blood did not follow those in the arterial blood very closely, but large decreases in the arterial blood were accompanied by similar decreases in the venous blood.

When AMP was infused into the external jugular vein in concentrations of 1 and 5×10^{-3} M it had little or no effect on the platelet count (Fig. 4); the lower concentration caused no change in blood pressure, the higher a fall of 36 mm mercury. Adenosine was also infused at concentrations of 1 and 5×10^{-3} M. It had no effect on the blood pressure; its effects on the concentration of circulating platelets were less consistent (Fig. 4) than those of ADP and AMP but in no experiment was there a rapid fall in the platelet count.

The results show that when ADP was infused in high concentrations into the circulation of cats it brought about a rapid decrease in the concentration of platelets; neither AMP nor adenosine had this effect. The effect of ADP on the platelet count seemed to be independent of changes in blood pressure, for two reasons: first, in some experiments ADP reduced the platelet count without affecting the blood pressure; and secondly, AMP reduced the blood pressure without affecting the platelet count.

The diminution in the platelet count could have resulted from the formation of platelet aggregates which remained suspended in the circulating blood but were sedimented with the red cells when the blood samples were prepared for counting[5]. However, it is unlikely that all the aggregates, even the smallest, would have been removed in this way; and no platelet aggregates were seen during counting. Therefore, it seems that ADP brought about a real decrease in the concentration of circulating platelets.

The platelet count was decreased when ADP was infused at a rate of about 4×10^{-7} moles/min kg. From this and the cardiac output of cats[7] it can be calculated that the initial concentration of ADP in the blood which was sampled was about 4×10^{-6} M; this is about ten times the concentration of ADP which brought about aggregation *in vitro*. How the concentration of ADP changed as the infusion went on, because of breakdown, etc., is unknown.

When ADP was added repeatedly to human plasma its effectiveness in causing platelet aggregation progressively decreased. We have suggested[4] that this might be due to the inhibition of aggregation by breakdown products of ADP. This conclusion is supported by the results obtained *in vitro* with cats' plasma: a second addition of ADP was no less effective than the first; and the aggregating effect of ADP was not reduced by AMP or by adenosine, which are the most likely breakdown products.

The way in which ADP brings about the rapid decrease in the concentration of circulating platelets remain to be established. It may be that ADP makes platelets adhere to endothelium and form aggregates which are trapped in the smallest vessels.

We thank the Medical Research Council for a grant.

DIFFERENCES BETWEEN PENCILLINASES FROM GRAM-POSITIVE AND GRAM-NEGATIVE BACTERIA

By DR. J. T. SMITH and J. M. T. HAMILTON-MILLER
Department of Bacteriology, Guy's Hospital Medical School, London, S.E.1

UNTIL recently, studies on penicillinase have been devoted, almost completely, to the enzymes elaborated by *Staph. aureus* and the *Bacillus* group; furthermore, attention has remained directed largely at those aspects of the properties and production of penicillinases which provide models either for enzyme induction[1] or for the release of enzymes from bacterial cells[2,3]. No systematic enzymological study has been made of the properties of the penicillinases produced by other organisms, and indeed, reports of enzymological studies on even the well-

— Rates too slow to obtain accurate results. Results with *E. coli* 214 *O* are not shown since the activity of whole cell preparations was too low to measure precisely.

known penicillinases of *Staph. aureus* and *Bacillus* spp. are few[4–6]. With the advent of α-aminobenzylpenicillin ('Penbritin', ampicillin), which is relatively active against Gram-negative organisms[7], interest has been aroused in the penicillinases produced by such organisms. In a clinical trial[8] all penicillinase-producing coliform organisms were found to be resistant to ampicillin. The penicillinases from several strains isolated in this clinical trial have been found to differ in many important respects from others previously described. Some of these results have already been published[9–12], and it is intended here to present a summary of the enzymatic differences found between penicillinases produced by Gram-positive organisms and those obtained from eight coliform organisms.

The organisms were screened for penicillinase production first by the filter membrane method[13] and after tests for penicillin amidase[14] had proved negative, the enzymes were confirmed as β-lactamases by chromatographic identification of penicilloic acid[13,15] in suspensions of the various organisms incubated with penicillin *G*.

Location of penicillinase. Cell-free preparations of penicillinases were made as previously described[11], by disrupting organisms in an extrusion press and centrifuging at 3,000*g* for 20 min to remove whole cells and large debris. In all cases the enzymatic activity remained in the supernatant fraction after subsequent centrifugation of such disrupted preparations at 20,000*g* for 50 min, suggesting that the enzyme is in the soluble cytoplasm, in contrast to previous reports[16–19] concerning Gram-positive organisms, which indicate that penicillinases from these sources are associated with the cell wall fraction.

Effect of pH on enzymatic activity. Penicillinases obtained from a number of sources show an optimum activity at about pH 7 (ref. 20) for benzylpenicillin and this was the case for all the penicillinases obtained from Gram-negative organisms except for the enzyme produced by *Aerobacter cloacae* 53 (Table 1). This latter enzyme, however, is very unusual as it has been shown to possess essential sulphydryl groups[10]. The penicillinase of this organism was examined at pH 6·0, its optimum, and at pH 7·4—the value commonly used in the study of penicillinases.

Specificity patterns. Suspensions of whole or disrupted cells in M/40 phosphate-buffered saline or M/40 phosphate buffer at pH 7·4 (except where indicated) were incubated with a final concentration of 2 mg/ml. of various penicillins; samples were removed at intervals and assayed for penicillin by the hydroxylamine method as described by Knox and Smith[11]. Table 1 shows the results obtained with disrupted suspensions of the coliform organisms, together with the absolute rates of hydrolysis of benzylpenicillin, apparent activation energies and pH optima. Comparative figures are given for the penicillinases of *Staph. aureus E3* (ref. 21), *B. cereus NRRL* 569 (ref. 9) and *B. licheniformis*[12]. It is apparent that the penicillinases produced by Gram-negative organisms not only have specificity patterns different from those of penicillinases of Gram-positive organisms, but also that each species appears to have a specificity pattern peculiar to itself. For example, the *E. coli* strains hydrolyse only benzylpenicillin and phenoxymethylpenicillin appreciably; the *A. aerogenes* strains hydrolyse 6-aminopenicillanic acid rapidly; and *A. cloacae* hydrolyses 5-methyl-3-phenyl-4-isoxazolylpenicillin rapidly.

Permeability barrier. As reported previously[9,13] with two strains of coliform organisms, disruption of the cells resulted in a considerably increased penicillinase activity against certain substrates. Other strains have now been investigated and the same phenomenon has been found in every case. This suggests the presence of a permeability barrier between the enzyme and its substrate, presumably located in the cell membrane. The increases observed in penicillinase activity against various substrates on disruption of cell suspensions are shown in Table 2. In most cases it seems that the permeability barrier is selective, for example, with organisms 53, 415 and 418 6-aminopenicillanic acid is destroyed at a similar rate by disrupted or by intact cells; whereas with *A. cloacae* 53 at *p*H 6·0 disrupted cells destroyed benzylpenicillin 25 times as rapidly as intact cells. The presence of a permeability barrier in Gram-positive organisms has been shown either not to exist[2,22] or to be doubtful[9].

Antibacterial activity of penicillins. The eleven penicillins were tested by the tube dilution technique for their activity against all the coliform strains, *Staph. aureus E3* and *B. cereus NRRL* 569, using about 10^4-cells as inoculum. All these strains were resistant to at least 50 μg/ml. of all the penicillins tested, except the *E3* strain, which was sensitive to 1 μg/ml. of the isoxazolyl penicillins and 4 μg/ml. of methicillin, and strain 214*O*, which was sensitive to 10 μg/ml. of ampicillin. Furthermore, the most active penicillin against any strain was not necessarily that which most readily penetrates the permeability barrier, nor the most resistant to hydrolysis. However, with organism 418 a correlation between antibacterial activity and ease of penetration does exist[12]. A correlation between the inducing ability and antibacterial activity of penicillins has been suggested for certain Gram-positive bacteria[23,24].

Apparent activation energies. We have previously reported[11] on the difference in the apparent activation energies of penicillinases produced by different groups of organisms. It was shown that, based on the mean number of substrate molecules activated by each type of penicillinase, those from Gram-negative sources were 318 times more effective as catalytic agents than those from Gram-positive sources. The fact that the apparent activation energies of penicillinases from coliform organisms are so low suggests, on the hypothesis of Abraham and Newton[25], that the turn-over numbers of these penicillinases are even higher than those reported for the *B. cereus* and *B. subtilis* enzymes[26,27].

Inducibility. Penicillinases from the Gram-positive organisms have been repeatedly shown to be inducible, and relative inducing abilities have been studied in detail[21,23,28] for *Staph. aureus*. However, in no case has induction been demonstrated with any of the eight coliform strains, despite repeated attempts. In some cases[9,12] increased enzymatic activity after overnight incubation in high concentrations of various penicillins was observed, but only in intact cell preparations. It was later shown that this increased activity was due, not to an increased amount of enzyme production, but to damage to the permeability barrier. Similar findings have been made with the other Gram-negative bacteria reported here.

Absolute activity. The amount of penicillinase in Gram-negative bacteria varies considerably, whereas penicillinase-producing Gram-positive bacteria possess large amounts of enzyme only when induced. (Penicillinase-constitutive mutants of *B. cereus* and *Staph. aureus* have been obtained only as a result of special laboratory treatment[29]). The Gram-negative bacteria contain, generally speaking, low amounts of penicillinase except for *A. cloacae* 53 and *A. aerogenes* 366, which contain, respectively, almost as much as, or more, penicillinase than the highly induced *Staph. aureus E3*.

Discussion. The lack of precise enzymological investigations on penicillinases from different sources has led to the tacit assumption that they have the same properties and characteristics. The first clear indication that this was not the case came with the finding[1] that penicillinases from *B. cereus NRRL* 569 and *B. subtilis* 749 differed immunologically. The quantitative differences between penicillinases of different Gram-positive origin, although slight, appear to be quite distinct, for example: (*a*) the specificity patterns of penicillinases from *Staph. aureus*, *B. cereus* and *B. licheniformis*, although very similar in most respects[9,12,21] differ in regard to phenoxybenzyl penicillin, which is hydrolysed much more rapidly by staphylococcal penicillinase than by the others[9]; (*b*) the susceptibilities of the enzymes to inhibition by methicillin and the isoxazolyl penicillins differ[12,24]: staphylococcal penicillinase was not inhibited in conditions under which other penicillinases showed up to 80 per cent inhibition and it has been shown[30] that staphylococcal penicillinase requires a period of preincubation with the inhibitor before inhibition can be demonstrated. Despite these differences within this group of penicillinases, it is apparent that these enzymes show broadly similar properties and characteristics and form a homogeneous group within themselves.

However, major qualitative differences occur between penicillinases of Gram-positive origin and those derived from the eight Gram-negative organisms. As described here, the features which identify the penicillinases of the Gram-negative organisms are their specificity patterns, lack of inducibility, possession of a marked differential permeability barrier, difference in cellular location and significantly lower apparent activation energies[11]. The fact that there also exist quantitative differences, more marked than in the Gram-positive series, between the properties of penicillinases isolated from different Gram-negative sources[9,10,12] gives rise to the interesting speculation that each individual species of penicillinase-producing Gram-negative bacteria may produce a 'species-specific' penicillinase, the enzymological and physico-chemical properties of which cannot be predicted solely on the basis of comparison with such properties of other penicillinases from a different species.

We thank Beecham Research Laboratories for gifts of penicillins. We also thank Prof. R. Knox for advice and criticism.

ENZYMATIC DEBRANCHING OF GLYCOGEN

A New Pathway in Rabbit Muscle for the Enzymatic Debranching of Glycogen

THE breakdown of glycogen by rabbit-muscle phosphorylase is far from complete, owing to the inability of this exo-enzyme to sever or by-pass the α-1,6-branch linkages, and action normally ceases when less than 40 per cent of the glycogen has been converted into α-D-glucose-1-phosphate. There remains a macromolecular limit dextrin (φ-dextrin). Further phosphorolytic breakdown is possible only after hydrolysis of the branch linkages. Some 10 years ago G. T. Cori and Larner[1] reported the existence of a rabbit-muscle enzyme, amylo-1,6-glucosidase, which attacked φ-dextrin with the liberation of glucose and allowed further phosphorolysis to occur. The enzyme did not attack native glycogen[1,2]. They thought the glucose was derived from 1,6-bonded side-chains which had been attenuated to a single glucose unit by phosphorylase. The correctness of this hypothesis and of the postulated mode of release of glucose was, however, questioned by Walker and Whelan[3], who could detect no single 1,6-bonded glucose side-chains in amylopectin or glycogen φ-dextrins. The side-chains were four glucose units long and they suggested that a transferase enzyme was required to expose the single glucose residues for hydrolysis, the other three glucose units being transferred singly or severally to other parts of the molecule[3]. A transferase having some of the properties of the postulated enzyme was reported recently in rabbit muscle by Brown and Illingworth[4], and Verhue and Hers[5] found evidence of the co-existence of single-unit and four-unit side-chains in φ-dextrin. The debranching process in plants operates by a different mechanism[6]. Shortening of the chains by phosphorylase is not a prerequisite. The responsible catalyst, *R*-enzyme, hydrolyses the 1,6-linkages in the intact polysaccharide, setting free the member chains. During this action the iodine stain increases. This is ascribed[6] to the ability of the unbranched chains to complex with iodine more efficiently than chains combined in the dendritic macromolecule.

We now report a debranching process operated by a rabbit-muscle enzyme preparation that does not require prior phosphorolysis of the glycogen. A highly concentrated amylo-1,6-glucosidase preparation, kindly given to us by Prof. E. Bueding, was incubated with glycogen and amylopectin and a slow but eventually very pronounced increase in intensity of iodine stain occurred (Fig. 1). During the incubation with amylopectin, polysaccharide precipitated from solution, staining blue-purple with iodine, in contrast to the original red stain. These changes were accompanied by increases in the extent of β-amylolysis. Amylopectin, amylopectin β-limit dextrin and rabbit-liver glycogen, having initial degrees of β-amylolysis of 49, 0 and 44 per cent respectively, yielded 77, 54 and 72 per cent maltose with β-amylase after 24-h treatment with the glucosidase preparation. The iodine stain of amylopectin did not increase when ammonium molybdate was added to the digest. Molybdate also inhibits plant *R*-enzyme[7].

The effect now reported has previously been unnoticed probably because amylase frequently contaminates 1,6-glucosidase preparations[1,2] and causes the iodine stains of the polysaccharides to decrease. Indeed, of ten glucosidase preparations given to us by Dr. Bueding, only four were sufficiently free from amylase for increase in staining to occur.

In respect of increase in iodine stain, increase in degree of β-amylolysis and molybdate inhibition, the muscle-glucosidase preparation behaves very much like *R*-enzyme[6]. (There is the important difference that plant

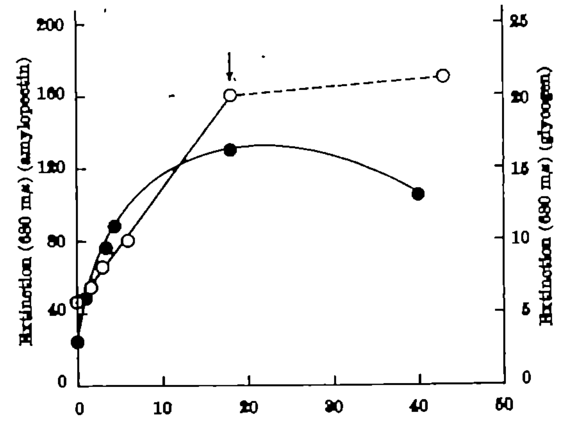

Fig. 1. Action of rabbit-muscle glucosidase on amylopectin (○) and rabbit-liver glycogen (●) at pH 7·2 and 30°. The amylopectin was waxy-maize starch. At the point indicated by an arrow precipitation of polysaccharide was noted and the iodine-stained solution at this time and at 43 h contained suspended polysaccharide. The extinction coefficient was therefore lower than if the polysaccharide had been dissolved

R-enzyme does not debranch glycogen of normal unit chain-length (about 12)[8]. Only glycogen of abnormally high chain-length, comparable with that of amylopectin (20 or more), is attacked by plant *R*-enzyme.[9]) It is, however, possible that the debranching process is mediated by the same combined actions of a transglucosylase and amylo-1,6-glucosidase which we have already postulated occurs with φ-dextrin[3]. It is a logical extension of our earlier hypothesis that the native polysaccharides should also be debranched by these two enzymes. The transferase action that exposes single glucose residues for hydrolysis by glucosidase will lengthen some of the polymer chains and increase the intensity of the iodine stain, and the removal of the 1,6-linked glucose residues by glucosidase will increase the degree of β-amylolysis. The limit of transferase–glucosidase action on glycogen would be reached by its conversion into glucose and the linear polysaccharide amylose. Indeed, the precipitation of polysaccharide from amylopectin during the action of the muscle enzyme preparation suggests the formation of amylose, with its pronounced tendency to retrograde from solution. When plant *R*-enzyme acted on amylopectin the total increase in intensity of iodine stain was only half that observed with the muscle system, and the polysaccharide did not precipitate[8,9]. This comparison strengthens the view that the muscle preparation causes chain-lengthening rather than simple debranching. Further support for the transferase–glucosidase system comes from a paper-chromatographic examination of polysaccharides treated with muscle system, but conclusive proof must wait on the further purification of the enzymes involved, particularly with respect to their freedom from amylase.

The observation of an increase in iodine stain when the glucosidase preparation acts on amylopectin and glycogen recalls the recent report by C. F. Cori *et al.*[10] that such increases occur when crystalline muscle phosphorylase is incubated with these substrates in presence of a trace of inorganic phosphate or α-glucose-1-phosphate. This was ascribed[10] to a phosphorolytic disproportionation of the member chains, not to a debranching action. Our enzyme preparations are free from phosphorylase *a*, since the iodine stain still increases in presence of an excess of phosphate sufficient to permit the full degree of phosphorolysis, and consequent diminution of iodine stain, if active phosphorylase were present.

We were informed by Dr. D. H. Brown that he and his colleagues have made similar observations of increase in iodine stain on incubation of glycogen with muscle glucosidase and their results are published in the following communication.

We thank the Medical Research Council for supporting this work.

Combined Action of Oligo-1,4→1,4-glucantransferase and Amylo-1,6-glucosidase in Debranching Glycogen

THE development of a procedure for the purification of rabbit muscle amylo-1,6-glucosidase to a specific activity of approximately 80,000 U./mg protein[1] facilitated a study of the action of this enzyme preparation on various polysaccharides. The fact that the specific activity was 10–15 times that of earlier preparations[2] was reflected in the rapidity with which very small amounts of this protein acted together with phosphorylase *a* to catalyse the total degradation of glycogen. Thus, 1·0 µg of such a glucosidase preparation and 7·0 µg of phosphorylase *a* caused 100 per cent degradation of 1·5 mg of glycogen in *p*H 6·7 phosphate buffer at 30° within 1 h. As expected, small amounts of the glucosidase preparation also acted directly and rapidly on a limit dextrin of glycogen prepared by prior phosphorylase treatment to yield free glucose (Fig. 1). Since several other enzymes are known to form glucose from polysaccharides, the various glucosidase fractions obtained during purification were assayed for their ability to form glucose from maltose and from glycogen. It was found that the highly purified glucosidase never formed any glucose from maltose; however, an action on glycogen was always demonstrable. Table 1 shows a comparison of the extent of glucose formation by a small amount of a glucosidase preparation with a specific activity of 42,000 U./mg protein acting on various polysaccharides. In view of the fact that the glycogen sample (M. L.) had been isolated from the liver of a patient with Type III glycogen storage disease (absence of amylo-1,6-glucosidase) and was known to have short outer chains (17 per cent degraded by phosphorylase), it was not surprising that it yielded considerably more glucose than the normal human glycogen sample. The possibility was considered that the glucose arising from the latter glycogen sample as well as the much smaller quantity from amylopectin might have had its origin in some exposed glucose stubs as branch points on the outer chains of the native polysaccharides. A similar explanation was offered by Larner who found the liberation of 0·3 per cent glucose by 200 units of glucosidase acting on glycogen for up to 2 h (ref. 3). It was not possible to decide this point with certainty from these findings alone. However, when an attempt was made to measure the total amount of glucose which could be removed from the human pectoralis glycogen by exhaustive treatment with large amounts of a glucosidase preparation, the results of Fig. 2 were obtained. Here, it can be seen that glucose is produced in rather large amount and without any apparent endpoint either in time or with increasing enzyme concentration. Glucose formation was so extensive that an explanation in terms of preformed, exposed glucose branch points was extremely unlikely.

Table 1. ACTION OF A PROTEIN FRACTION CONTAINING AMYLO-1,6-GLUCOSIDASE ON SOME POLYSACCHARIDES

Polysaccharide	Glucose formed in 5 h (per cent)
Glycogen, human pectoralis muscle	0·41
Glycogen, human liver (M.L.)	1·65
Corn amylopectin	0·17

Protein concentration, 4·6 µg/ml. corresponding to 193 units. Polysaccharide, 6 mg/ml. Glycylglycine buffer, 0·003 M, *p*H 6·8, 30°.

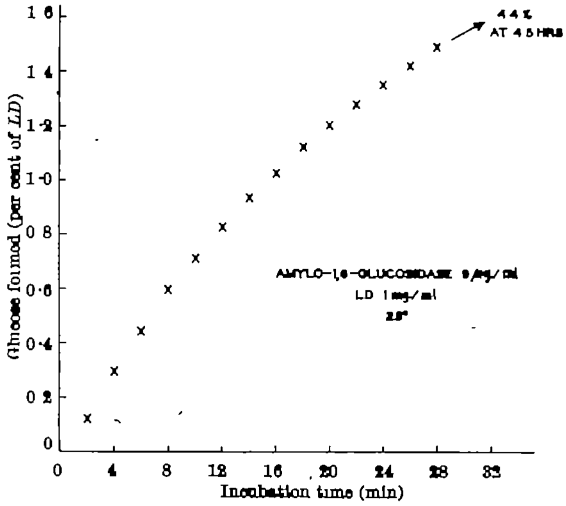

Fig. 1. Action of amylo-1,6-glucosidase on a phosphorylase limit dextrin. The reaction mixture (in a Beckman spectrophotometer cuvette) contained limit dextrin as indicated, 50 µmoles *tris* buffer, 3 µmoles mercaptoethanol, 0·5 µmole ethylenediamine tetraacetic acid, 10 µmoles $MgCl_2$, 2 µmoles ATP, 0·4 µmole NADP, yeast hexokinase and glucose-6-phosphate dehydrogenase (Boehringer) in excess, and amylo-1,6-glucosidase (sp. act., 42,000 U./mg protein) *p*H 7·2, 1·0 ml. The formation of glucose was followed by the increase in absorption at 340 mµ

The reaction of glucosidase preparations with glycogen was found to be accompanied also by large increases in iodine colour, often after a lag relative to glucose formation (Fig. 3). This finding served to show that α-amylase

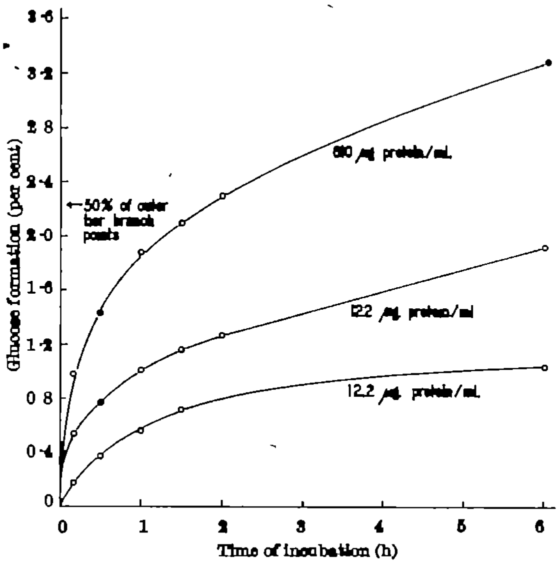

Fig. 2. Formation of glucose from glycogen as a function of time at various concentrations of a protein fraction containing amylo-1,6-glucosidase (sp. act., 41,000 U./mg protein). The reaction mixtures (0·50 ml.) contained 1·8 mg glycogen, 10 µmoles glycylglycine, and enzyme as indicated, *p*H 6·6. Aliquots (0·05 ml.) were removed at intervals and assayed micro-enzymatically for glucose

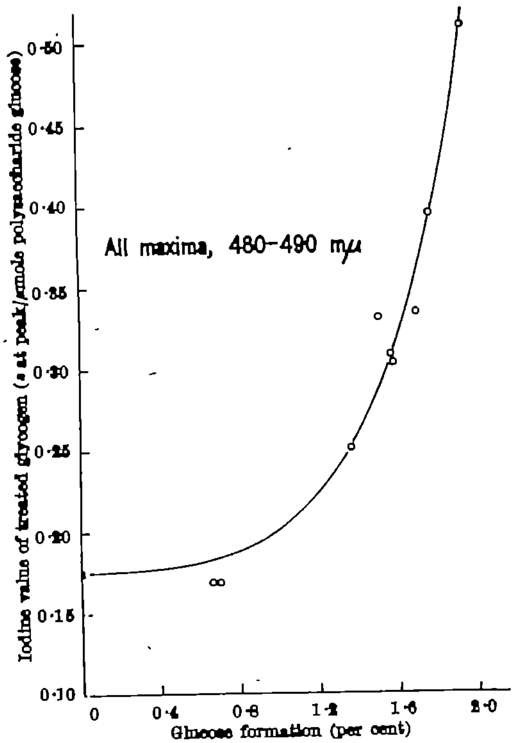

Fig. 3. Change in chromogenicity of the iodine complex of glycogen as a result of pretreatment with various amylo-1,6-glucosidase fractions. The extent of enzyme action is expressed in terms of the glucose formed. Aliquots containing about 0·2 mg of glycogen were diluted to 0·9 ml. with water and 0·1 ml. of 0·2 per cent iodine–0·4 per cent potassium iodide was added with thorough mixing. In each case extinction values were determined between 450 mμ and 550 mμ in the Beckman *DU* spectrophotometer

was not a contaminant of any of the highly purified fractions and so could not have been responsible for any part of the observed formation of glucose. Absence of action of the enzyme system on maltose showed that there was no detectable contamination by the glucose-forming enzyme studied by Stetten[4] and found to be a transglucosylase.

Since Illingworth *et al.* reported[5] that phosphorylase itself in the presence of traces of inorganic phosphate or glucose-1-phosphate can catalyse a rapid redistribution of some of the outer glucose units of glycogen and amylopectin so that the iodine colour of the polysaccharide shows a large increase, it was important to establish that the highly purified amylo-1,6-glucosidase preparations were free of phosphorylase. By direct analysis phosphorylase *a* was found to constitute less than 0·1 per cent of the total protein of a preparation in which the specific activity of amylo-1,6-glucosidase was 80,000 u./mg. In addition to using this preparation containing such an extremely small amount of phosphorylase *a*, the test solution of glycogen was electrodialysed to remove any trace of phosphate ion. These precautions when taken were without effect on the capacity of the glucosidase preparation to increase the iodine colour of glycogen. Hence, it must be concluded that this reaction is separate from the increase of similar magnitude which phosphorylase brings about. The latter will be reported in detail in a subsequent communication.

Evidence that the action of the glucosidase preparation on glycogen was actually accompanied by a partial debranching of the molecule was obtained by structure determinations of the polysaccharide remaining after measured amounts of free glucose had been produced. In six such experiments the quantity of glucosidase and the time of its action were varied in order to produce up to 1·6 per cent glucose formation. After boiling the solutions to stop enzyme action, phosphorylase *a* free of amylo-1,6-glucosidase was added together with excess inorganic phosphate to one aliquot and degradation of the outer chains of the glycogen was measured at various times by micro-enzymatic determination of glucose-1-phosphate. The final degradation observed is plotted in Fig. 4*a* against the amount of glucose which had been produced by prior glucosidase action. The results clearly show that the molecule has longer outer chains as a result of its pretreatment by the glucosidase preparation. The increase in iodine colour shown in Fig. 3 is another expression of this fact.

Another aliquot of the glycogen solution after glucosidase treatment was subjected to total enzymatic degradation by the combined action in phosphate buffer of phosphorylase and added amylo-1,6-glucosidase. The amount of free glucose formed thereby was calculated from the total present after degradation (determined micro-enzymatically) and that present at zero time due to the prior glucosidase action. In this way the end-group percentage of the treated glycogen was found, and the results are plotted in Fig. 4*b* against the measured prior glucose formation. In general, it is seen that a reduction in the number of branch points accompanies glucosidase action. The precision of these results is less than the measurement of outer chain-length by phosphorylase (Fig. 4*a*).

In order to investigate whether any part of the glucose formed by the glucosidase preparations had its origin in 1,4-linked units, a phosphorylase limit dextrin of the human pectoralis glycogen was enlarged with ^{14}C-glucose-1-phosphate by the synthetic action of phosphorylase. The extent of enlargement was 28·6 per cent, corresponding to the average addition of 2·4 ^{14}C-glucose units to each outer chain. The specific activity of the added glucose residues was 2,120 c.p.m. per μmole. This radioactive glycogen was treated for 23 h at 30° with 2·6 μg

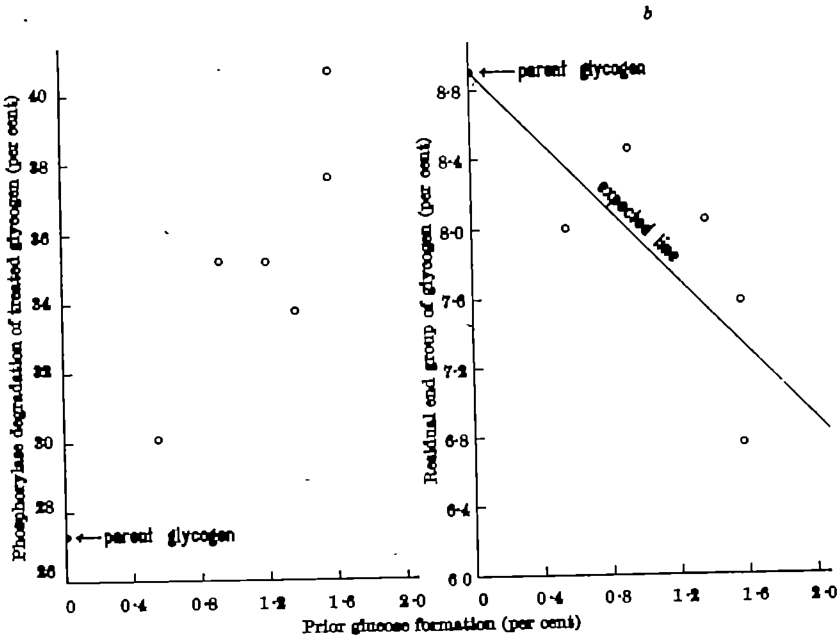

Fig. 4. *a*, Determination of the outer chain-length of various glycogen samples as a function of the extent of preceding action by amylo-1,6-glucosidase fractions; *b*, determination of the end-group percentage of various glycogen samples as a function of the extent of preceding action by amylo-1,6-glucosidase fractions

of glucosidase (sp. act., 70,000 U./mg), and in another experiment, with 28·5 μg of glucosidase (sp. act., 6,300 U./mg). In these two experiments the units of glucosidase activity added were the same, although the enzymes differed greatly in their purity. It is interesting that the amount of glucose produced during incubation was nearly the same in each experiment, 1·57 and 1·77 per cent. A measured amount of carrier glucose was added, the glycogen was precipitated by alcohol, and buffer salts removed by passage over a short column of a mixed bed resin ('Amberlite *MB*-3'). Recovery of glucose was complete. The solutions were subjected to paper chromatography (Whatman No. 1) in a butanol–pyridine–water solvent (3 : 2 : 1·5) and the glucose zones eluted (90 per cent recovery). The glucose was analysed microenzymatically and its radioactivity measured in a low background counter (Nuclear). From the known dilution with carrier it was possible to calculate that the glucose formed by glucosidase action in 23 h of incubation had a specific activity in one experiment of 27 c.p.m. per μmole and in the other of 33 c.p.m. per μmole. Thus, it could have contained no more than 1·5 per cent of molecules derived from 1,4-linkages. An enzyme with glucamylase action on the outer chains of glycogen such as that found in rat muscle by Torres and Olavarria[6] seems to play no part in the phenomenon studied here.

An explanation for the changes in the structure of glycogen (and amylopectin) which highly purified amylo-1,6-glucosidase preparations are able to bring about became available after definitive experiments were devised to show that the enzyme preparation in fact contains an oligo-1,4 → 1,4-glucantransferase which acts to transfer maltotriosyl and maltosyl (but not glucosyl) residues in α-1,4-linkage from donor to acceptor chains[7]. Possibly longer chains of glucose units may also be transferred. Walker and Whelan had suggested earlier[8] that a transferase with some of the properties of the enzyme described by Brown and Illingworth[7] would be found to play a part in glycogen metabolism. From a study of the structure of a phosphorylase limit dextrin they concluded that movement of glucose residues from outer side-chains to other parts of the molecule is necessary before action of amylo-1,6-glucosidase on a limit dextrin is possible.

In the reactions described here, glycogen gradually becomes debranched as amylo-1,6-glucosidase removes the α-1,6-linked glucose residue whenever such a unit becomes exposed by prior action of the oligotransferase. The longer outer chains of the partially debranched glycogen are, of course, more chromogenic when tested with iodine. It is not excluded that a small part of the glucose liberated has its origin in glucose stubs which are already exposed in the native polysaccharides as they are isolated. It should be emphasized, as shown in Fig. 2, that the debranching of glycogen by the non-phosphorolytic pathway described herein is slow and requires rather large amounts of the highly purified glucosidase in which oligo-1,4 → 1,4-glucantransferase is a minor contaminant. A determination of the speed at which the debranching action would proceed if the latter enzyme could be added in excess awaits the success of experiments to purify the transferase itself.

CULTURE OF STRAIN *L* CELLS IN SUSPENSION: REPLACEMENT OF POLYMER BY TRACES OF TRYPSIN IN A DEFINED MEDIUM

By DR. R. SINCLAIR, R. A. REID and DR. P. MITCHELL

Chemical Biology Unit, Department of Zoology, University of Edinburgh

METHODS for the culture of tissue cells *en masse* have been studied in a number of laboratories[1-5] with the view of opening up to the student of tissue cells the valuable cytostat and washed suspension techniques familiar to the microbiologist. All the methods described so far, however, fall short of their microbiological counterparts in that they require media containing serum protein or some other polymer, such as methyl cellulose, to support normal rates of dispersed cell growth[6,7]; and it has often been reported that the cells nevertheless tend to clump and undergo necrosis in the clumps[1,4,8-10]. We have recently had some success in overcoming these technical difficulties, and as our findings appear to be both simple and useful, we are reporting them briefly here in a preliminary form.

We have used the defined medium *MB*752/1 described by Waymouth[11], modified[12] by the addition of 0·0032 mM ferrous sulphate, 0·25 mM α-ketoglutarate, by the increase of glutamine to 3·4 mM, and by maintaining an atmosphere of 5 per cent (v/v) carbon dioxide in air in all culture vessels. It was confirmed that although strain *L* mouse cells grow well (mean generation time about 48 h) from mechanically dispersed ('scraped') roller tube inocula in unshaken 'Pyrex' vessels, identical cultures decline, or grow very slowly when gently reciprocated or stirred. Attention was thus directed to the mechanism by which movement inhibits the growth of cultures in defined polymer-free medium.

The effects of different speeds of simple harmonic reciprocation (stroke-length 4 cm) were examined in 50-ml. conical flasks, at 37°, beginning with 4 ml. scraped cell suspensions ranging in population from 0·2 to 1·0 × 10^6 cells per ml. At reciprocation rates below 30 cycles/min, the cells adhered to the bottom of the flask in a uniform monolayer, and growth was not significantly different from stationary control cultures. Rates of 60–80 cycles/min caused many of the cells to aggregate at a 'high water mark' on the sides of the flask. This aggregation could not be prevented by siliconizing the glass, or by the addition of 0·1 per cent methyl cellulose to the medium. Microscopical examination after 24 h reciprocation at 60–80 cycles/min showed that the cells in the interior of the aggregates were undergoing necrosis, but cells free in suspension were apparently healthy, although the latter were occasionally seen to be associated with folded membranous debris, containing nuclei. Cell counts made after dispersing the clumps with 0·25 per cent crude trypsin indicated that the live cell population remained almost stationary over a few days. Higher reciprocation rates resulted in the formation of increased amounts of membranous debris, and the cell number declined rapidly. At 150 cycles/min, for example, the total cell count was reduced to less than 30 per cent of the initial count after only 15 min.

These, and related experiments, suggested two main mechanisms of inhibition of growth: (*a*) aggregation, causing locally unfavourable nutritional and physical conditions; (*b*) cell disruption, due to cell-to-cell, cell-to-interface, and cell-to-vessel adhesion, followed by extension of the adhering cell surfaces, forming membranous debris which later autolyses slowly. We therefore sought to minimize the lethal effects of the motion of the medium by reducing the adhesive properties of the cell surfaces.

It was observed that cells which had been treated briefly with trypsin were much less readily destroyed by high rates of reciprocation. Scraped cell suspensions were exposed to 10 µg crystalline trypsin per ml. for 15 min at 37°, washed, re-suspended in fresh medium and reciprocated at 130 cycles/min for 15 min. Cell counts were made before and after reciprocation at 130 cycles/min, and at daily intervals for the next four days, during which a shaking rate of 65 cycles/min was maintained. Total cell number is recorded in Fig. 1, curve *A*, for the culture after trypsinization, and curve *B* for a corresponding control culture, not trypsinized. It is significant that cell aggregates appeared in the trypsin-treated culture only after the third day.

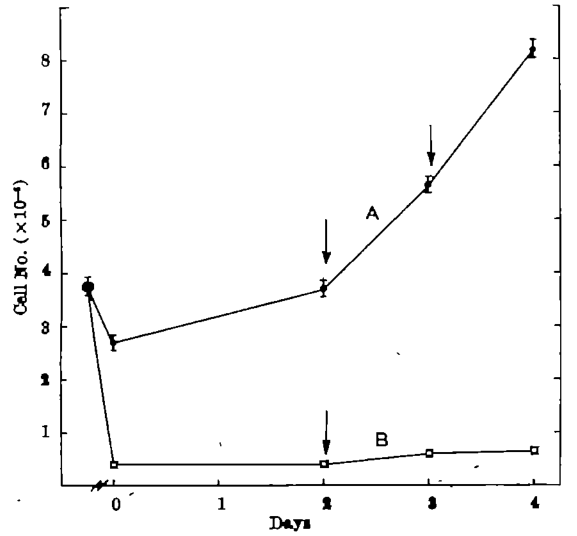

Fig. 1. Total cell number each day (with standard deviation) in culture of trypsinized cells (curve *A*) and in control culture (curve *B*), after reciprocating at 130 cycles/min for 15 min, and afterwards at 65 cycles/min. Fresh medium (2·0 ml.) was added to the starting volume of 4·0 ml at the points indicated by the arrows

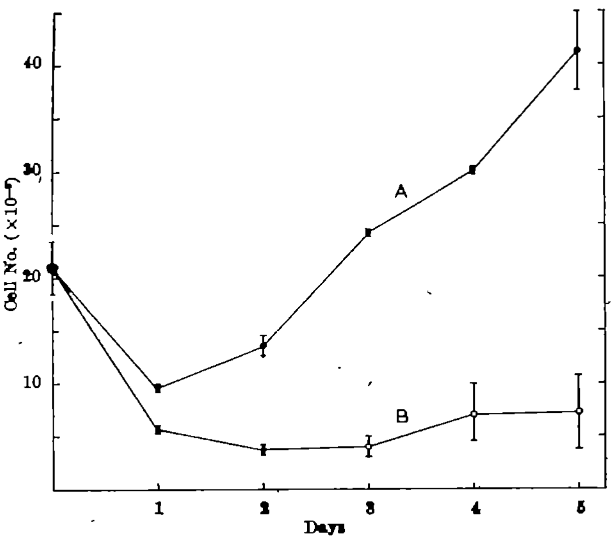

Fig. 2. Total cell number each day in trypsin-treated culture (curve *A*) and in control culture (curve *B*) reciprocated at 65 cycles/min. One-fourth volume of fresh medium and 0·2 ml. 0·005 per cent trypsin were added daily to the starting volume of 50 ml.

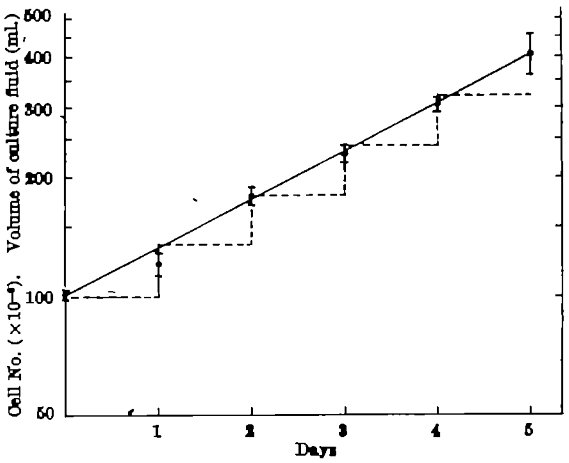

Fig. 3. Cell growth in spinner flask (200 r.p.m.) in defined medium plus trypsin. The concentration of crystalline trypsin was daily made up to 10 µg/l. of culture fluid. Volume of culture fluid (– – – –)

The excellent protective effect of trypsin in this type of experiment led us to examine the effect of maintaining low concentrations of crystalline trypsin in the culture medium at the intermediate reciprocation rate of 65 cycles/min. Fig. 2 shows the results of a typical experiment in which 0·2 ml. 0·005 per cent crystalline trypsin in basal salt solution was added to 50 ml. scraped cell suspension initially, and at each daily addition of one-fourth volume of fresh medium. The control culture (curve *B*) received an equivalent volume of basal salt solution without trypsin.

As already indicated here, reciprocating motion is especially liable to cause cell aggregation by sequestering the cells at 'high water marks'. Therefore, we have adopted the more conventional spinner culture technique, using a silicon-rubber covered follower impelled at 200 r.p.m. by a magnet attached to a clock motor. Long-necked, flat-bottomed flasks have been found ideal in shape for this method of stirring. The follower is in contact with the floor of the flask, but despite this, little evidence of cell damage is observed. The growth curve shown in Fig. 3 was obtained by the daily addition of one-third volume of fresh medium followed by 0·1 ml. 0·001 per cent crystalline trypsin in basal salt solution per 100 ml. cell suspension. Similar growth experiments have shown that crystalline trypsin does not exert an appreciable cytostatic or cytocidal effect up to a concentration of 0·2 mg/l.

A simple continuous culture system has now been established. Fresh medium containing 50 µg crystalline trypsin/l. is filtered directly into a refrigerated reservoir which is connected to the growth flask through a drawn-out capillary tube. Medium is allowed to flow in at a rate which trebles the starting volume of cell suspension (for example, 0·5 l. in a 10-l. flask) after four days, when two volumes are siphoned off. One such unit, yielding about 6×10^8 cells at each collection, has been operated for thirteen weeks. We are now developing this type of arrangement on more sophisticated cytostat principles.

The use of trypsin in such small amounts (10–50 µg/l.) is, of course, possible only in protein-free media. The trypsin appears to function by breaking down an extracellular material by which the cells adhere to surfaces and to each other, and it is a characteristic feature of suspended growth in trypsin-containing media that, as in normal cultures of micro-organisms, the cells mostly exist singly or in pairs. We are at present investigating what crystalline trypsin does to the cell surfaces, and whether other enzymes, such as neuraminidase, may also assist growth in suspension.

We thank the Nuffield Foundation for grants in aid of this work.

HISTOGENESIS OF THE CEREBRAL CORTEX

By M. BERRY and PROF. J. T. EAYRS

Department of Anatomy, University of Birmingham

IT is generally accepted that stratification in the mammalian neocortex is established as a result of three cellular migrations in the wall of the telencephalon which, occurring in the rat on the 16th, 19th and 21st days of gestation, give rise respectively to layers II and III, layer IV and layers V and VI (ref. 1). A recent examination of silver and Golgi–Cox preparations showing the effects of X-irradiation on the developing nervous system has suggested, however, that the manner in which cortical lamination arises may be more complex than has been inferred from the Nissl-stained material previously examined.

In the developing nervous system the elements which are particularly susceptible to the effects of ionizing radiations are mitotic and differentiating neuroblasts[2] and it would accordingly be expected that X-irradiation during the period of general cortical differentiation would destroy the germinal and mantle layers but would leave cells in the marginal layer largely unaffected. This prediction has, in fact, been borne out by examination of the effects of X-irradiation (200 r.) given to the fœtal rat on either the 17th or 19th day of gestation. In this species 12, 24, 36, 48 h and, in some cases, 9 days after irradiation both the mantle and germinal layers are extensively and seemingly irreparably damaged while the majority of cells lying in the marginal layer near the pial surface are apparently normal (Fig. 1*A* and *B*). These cortical remnants are found to give rise later in life (30 days of age *post partum*) to a cerebral cortex composed of three layers only (Fig. 1*C* and *D*), tentatively identified on the basis of histological appearances as layers I, V and VI. However, the cortex of rats in which X-irradiation has been delayed until the 21st and 22nd days of gestation (and in which destruction of the mantle layer is less severe) includes, in addition, a thin band of disorganized cells lying superficially and deemed to represent layers II, III and IV (ref. 3). On the basis of this interpretation it would seem that, in spite of the total destruction of those elements classically destined to give rise to the infra-granular layers, the development of these layers is considerably less impaired than is that of the granular and supragranular. One possible explanation of this phenomenon is that the pyramidal cells which develop in the cortex of X-irradiated animals may, at least in part, be hyperplastic pyramids derived from layers III and IV which have differentiated abnormally in an atypical environment. The findings could equally be explained, however, in terms of a pattern of cellular migration similar to that seen in the developing cerebellar cortex[4]. Thus some of the first cells which

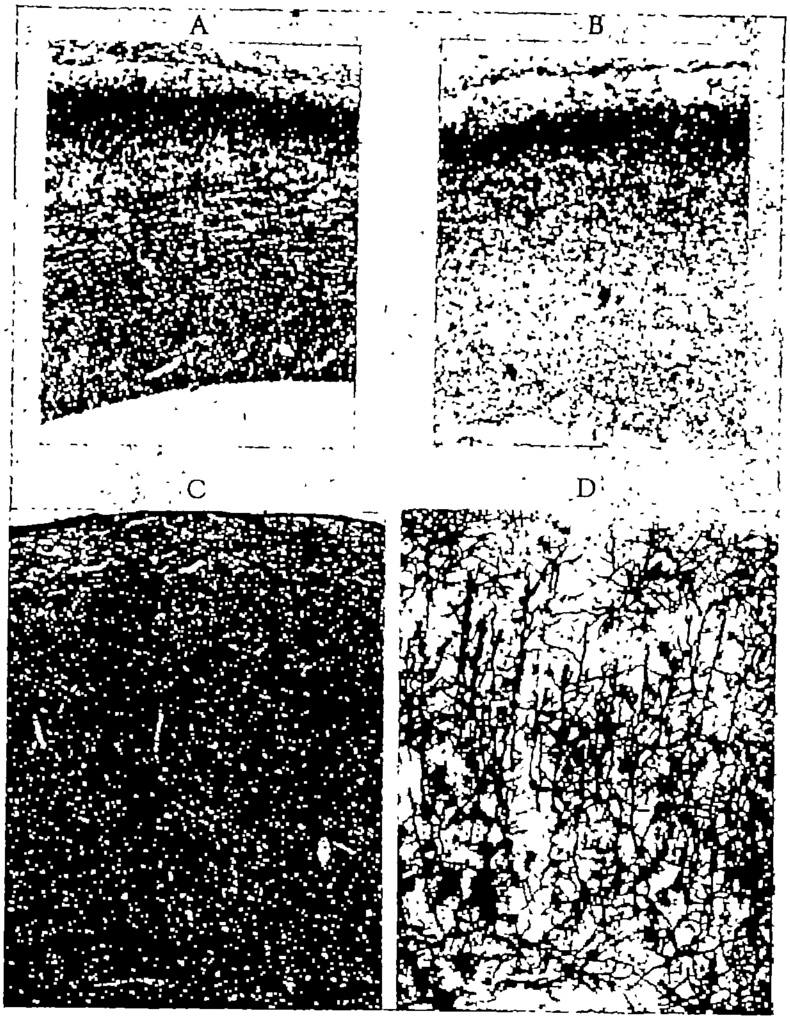

Fig. 1. Cerebral cortex of rat

A, normal, nineteenth day of gestation (methylene blue, × *c.* 83); *B*, *C* and *D*, X-irradiated (200 r.) on nineteenth day of gestation; *B*, 36 h after irradiation (methylene blue, × *c.* 83); *C*, 33 days after irradiation (silver impregnation, × *c.* 60); *D*, as *C* (Golgi–Cox, × *c.* 60) migrate into the marginal layer to occupy a position juxtaposed to the zonal layer may be destined to form layers V and VI, the granular and supragranular layers arising as a result of subsequent migrations which are vulnerable to X-irradiation between the 17th and 19th day of gestation. This schema implies that the normal six-layered cortex is established by an inward migration of cells, ultimately constituting the developing layers V and VI, intermingled with an outward migration of cells destined to form layers II, III and IV.

With this possibility in mind, an attempt has been made to identify the large pyramidal cells in the cortex of the X-irradiated animals at 30 days *post partum* by both qualitative and quantitative examination of silver and Golgi–Cox preparations. The shape of some cells in the irradiated cortex is abnormal (Fig. 1C); but if these are excluded from quantitative analyses the results indicate that morphological characteristics such as the cross-sectional area of the perikarya, the number and length of basal dendrites and the number and position of branching points along the length of these dendrites closely resemble those of the normal pyramidal cells of layer V*b* and bear little resemblance to data relating to the pyramids of layers III and IV in the normal animal. The view that the pyramidal cells present in the X-irradiated cortex are the counterparts of those of the normal lamina ganglionaris receives further support from examination of the developing three-layered archipallium in which the effects of irradiation are found to follow a course similar to that seen in the neocortex. On the 17th and 19th days of gestation the subicular area is not present, and the cells lying superficially in both the neocortex and hippocampus form, in coronal sections, a continuous band around the medial aspect of the lateral ventricle; yet Ammon's pyramids, regarded as homologous with the pyramidal cells of layer V*b* (ref. 5), can be seen in the hippocampus of the irradiated rat aged 30 days and, although disorganized and hypoplastic, form a zone of cells which, in the absence of a corpus callosum, is continuous with that occupied by the neocortical pyramids.

These findings, which imply that cells destined to form the phylogenetically older infra-granular layers appear before those giving rise to the more recently acquired superficial laminae, would seem to suggest a more compatible relationship between ontogeny and phylogeny than that indicated by the earlier interpretations. It is still not possible, however, to infer from such indirect evidence as is so far available that events occurring in the irradiated cortex also take place during the normal course of development, and studies, now in progress, of the behaviour of tritiated neuroblasts may yield more direct information concerning cellular movements during cortical differentiation.

RAPID CHANGES IN TRANSPIRATION IN PLANTS

By Dr. HENRY RUFELT
Institute of Plant Physiology, University of Uppsala

It has been repeatedly shown that excision of a leaf from a plant causes a rapid change in the transpiration rate from the leaf. The change may be an increase or a decrease[1]. It has also been found that an addition of an osmotically active substance to the root medium or an increase in the salt content of a nutrient solution surrounding the root system causes an immediate increase in the transpiration rate[2,3] and in the former case also in the stomatal width as measured with a porometer[4]. The addition of various chemicals such as ethyl alcohol, diethyl ether and some respiration inhibitors also causes a rapid increase in transpiration[3].

The increase obtained after an excision of a leaf in air (the Ivanoff effect) was interpreted by Ivanoff[5] as caused by a sudden release of the water stress in the conducting elements, which means that it is caused by an increase in the water supply to the leaf. This interpretation was adopted by workers using the corona hygrometer[1] and was strongly supported by the experiments of Allerup and Nielsen[6]. The increase in transpiration obtained after addition of mannitol to the root medium was interpreted by me to be caused by an increase in the water permeability of the roots[3]. Thus, also in this case the rush of water might be an Ivanoff effect caused by a release of the water stress in the plant. The mechanism suggested can be characterized as hydroactively induced.

The alternative explanation was first suggested by Darwin and Pertz[7]. They assume that the stomatal opening is caused by a loss in turgor of the epidermal cells surrounding the stomata, mainly the companion cells. This would mean that the opening is caused by a decrease in the water supply to the leaf instead of the increase assumed by Ivanoff.

An inherent requirement of the hypothesis is that the epidermis cells dry out faster than the guard cells. The movement can be characterized as mechanically induced. Later on the guard cells lose water too and a hydroactive closure of the stomata occurs. This explanation was the only one which was referred to by Slatyer[8]. During investigations of the water relations of various plants in the laboratory as well as under field conditions several results have been obtained which are in favour of the theory of Ivanoff.

During work on the transpiration of forest trees under field conditions, a series of excision experiments on leaves and shoots of various species was performed. Rapid changes normally followed the excision. However, this immediate effect was sometimes a decrease and sometimes an increase, and in some cases no immediate change at all was found. Aspen mostly gave very considerable increases, while all conifers tested (pine, spruce, larch) gave decreases. Birch behaved as an intermediate, as this tree was found to be able to give increases, decreases or no changes at all. I assume that the direction of the change is determined by the amount of water available in the leaf together with the intensity of the transpiration.

Extremely high increases were obtained in the following way in the laboratory. Excised leaves were placed with their petioles in water and were allowed to increase their turgidity in darkness. Then they were illuminated, and when the transpiration had attained a constant value they were taken from the water. Even in these circumstances coniferous twigs gave no increases. I assume that the lack of Ivanoff effect is due to the fact that the water transport in the coniferous stem takes place via tracheids and not in vessels and thus the water column is less movable. Wood of conifers has a very low water conductivity[9].

Aspen leaves were found to give extremely high Ivanoff effects. Fig. 1 shows an experiment with an aspen leaf

Table 1 Relative Turgidity (RT) of Leaf and Petiole of Aspen Leaves before and during the Increase in Transpiration caused by Lifting the Leaf out of Water

(The determinations were performed by M. and P. Jarvis at this Institute.)

Sample		RT	
T_1	Leaves	99 5	99 3
		100 0	
		98 5	
	Petioles	97·0	97·2
		97·3	
T_2	Leaves	97·3	97·2
		96 7	
		97 7	
	Petioles	94 0	93 7
		93·4	

where the petiole was taken from and brought in contact with the water repeatedly. It is apparent that the Ivanoff effect is greater and starts earlier at the higher light intensity. Furthermore, the increase caused by the removal of water commences faster than the decrease caused by the restoration of water. This result can be explained on the basis of the Ivanoff theory, while no mechanical effects from the surrounding cells can be traced. The changes in relative turgidity of leaf and petiole were determined. Detached leaves were put in water and were illuminated for 15 min Then samples (T_1) were taken. Then the petioles were lifted and left in air for 6 min and new samples were taken (T_2). It was found (Table 1) that: (1) the relative turgidity (RT) decreased more rapidly in the petioles than in the leaves; (2) the RT was lower in the second sample where the stomata, according to the transpiration record, were more open.

Wheat plants were placed as is shown in Fig. 2. The transpiration from the leaves enclosed in the cuvette (c) was recorded and the leaves were illuminated until the transpiration had attained a constant value. Then sodium chloride was added to the vessel A to give a concentration of 1 M. This treatment can only cause an increase in the water transport to the immersed leaf which may in turn bring about a decrease in water supply to the transpiring leaves but cannot possibly cause an increase. The effect on the transpiration was a decrease (Fig. 3, curve I). According to the mechanical theory already referred to, the decrease should be preceded by a transient increase, but no such increase was found. After the transpiration had decreased to the low value the immersed leaf was cut off; this was followed by a return to the higher transpiration rate. When it had re-attained a constant value, sodium chloride was finally added to the root medium in vessel B, which was made 1 M. The effect on transpiration is shown by curve II. The increase obtained in this case means that the salt addition to the roots has an effect peculiar to this organ. So far as I am aware nothing contradicts the assumption that an increase in permeability of the roots is elicited.

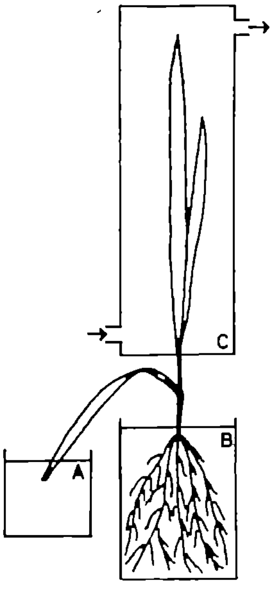

Fig. 2

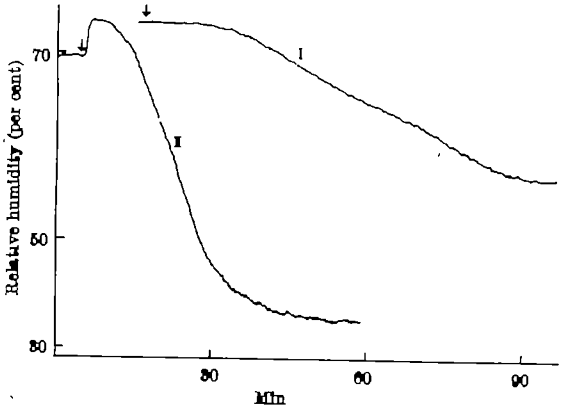

Fig. 3. Corona hygrometer record of the transpiration from wheat leaves arranged as is shown in Fig. 2. Further explanation in the text. The additions of sodium chloride are marked by an arrow

It seems to me that these experiments are interesting from another point of view. The fact that no mechanical effects could be found would imply that the water-stream from the roots to the guard cells passes the companion cells without changing the volume of these to a measurable extent. However, changes in the water supply to the leaves immediately affect the water content of the guard cells. This is possible if Strugger's[10] idea that the water transport occurs in the cell walls is accepted (see also ref. 11). A second necessary condition is that the guard cells take up water faster than the other epidermal cells, that is, a supposition which is quite opposite to that of Darwin and Pertz[7]. Experiments by Stålfelt[12] indicate that the guard cells change their water content very fast. A logical consequence of these considerations would be that hydroactive control of stomatal width is not mediated by the water-content of the leaf but by the water content of the cell walls. In this connexion the RT determinations of Table 1 are illustrative. Even if the RT decreases after the excision of the leaf which means that the leaf water deficits has increased, the stomata become more open. It seems necessary to distinguish between leaf water deficit and cell wall water deficit.

ELECTRON-TRANSPORT SYSTEM IN PHOTOSYNTHESIS OF GREEN PLANTS ANALYSED BY SENSITIVE FLASH PHOTOMETRY

By Prof. H. T. WITT, Dr. A. MÜLLER* and B. RUMBERG
Max-Volmer Institut, Physikalisch-chemisches Institut der Technischen, Universität, Berlin

THE observation of Emerson *et al.*[1] showed that light absorbed in the far red limit of the absorption spectra of green algae at ~700 mμ, that is, in a long wave-length chlorophyll *a*, shows a poor yield of photosynthesis but is enhanced to a much greater efficiency when it is supplemented by shorter wave-length light absorbed by chlorophyll *b* (peak at ~650 mμ). He concluded from this effect that two different photochemical reactions may be involved in photosynthesis, one sensitized by a long wave-length chlorophyll *a* and the other by chlorophyll *b*-650. Govindjee *et al.*[2] have shown that, in addition to light absorption by chlorophyll *b*-650, absorption in a chlorophyll *a* with a peak at 670 mμ can enhance the light-reaction sensitized by a long wave-length chlorophyll *a*. Correcting Emerson they concluded that two chlorophyll *a* sensitize the postulated two light-reactions. Blinks[3] and Myers and French[4] have extended the measurements of Emerson by different methods. The Emerson effect occurs also in non-green plants such as the brown, red and blue algae, etc.

Different hypotheses have been postulated to explain how a co-operation of two light-reactions may occur. Franck[5] developed a theory based on *n*–π and π–π-triplet-states. Hill *et al.*[6] proposed a hypothetical scheme, suggesting that cytochrome *b* and *f* may be involved. Brody[7] discussed the participation of monomere and dimere chlorophylls. French and Fork[8] suggested a two-pigment mechanism based on work of changes in oxygen.

Further indications for two light-reactions were obtained by other methods.

Kautsky[9] suggested from fluorescence measurements that coupling of two light-reactions occur. Allen *et al.*[10] obtained indications for two light-reactions from paramagnetic resonance signals. Losada *et al.*[11] derived a two-light-reaction mechanism from oxygen and TPN measurements in combination with poisons.

There was no experimental evidence: (1) on the chemistry of all the substances which are involved in the mechanism, except plastoquinone[12]; (2) on the nature of the light-reactions; (3) on the mechanism how the substances are correlated with each other; or (4) on the kinetics of the partial reaction itself.

Direct evidence about substances which are in action during the excitation of plants by light came from measurements of absorption changes. Duysens[13] discovered with a static method cytochrome oxidation particularly in red algae. In green plants he observed unidentified absorption changes at 420, 475 and 515 mμ. Kok[14] discovered the one-electron-oxidation of a pigment *P*700, with a redox-potential 0·43 V and with absorption changes at 703 mμ and suggests that this pigment is a chlorophyll *a*. We measured: (1) the π–π*-triplet-state in the bulk of chlorophyll *a* and chlorophyll *b* respectively (symbolized as $Chla_0$ and $Chlb_0$ (ref. 21); (2) a metastable state of a special chlorophyll *a* ($Chla_I$) which is not a π–π*-triplet-state[20]; (3) the oxidation of cytochromes (Cyt) in normal green plants[22,24,26]; (4) the reduction of plastoquinone (*Q*) (ref. 25); (5) the reduction of a substance *X*, which is a special plastoquinone[18,22,23,29] sensitized by a chlorophyll *a* ($Chla_{II}$); (6) pronounced absorption changes in photoactive chloroplasts at 433 mμ which are exactly correlated with the changes at 703 mμ and which verify the suggestion that *P*700 is a chlorophyll *a* symbolized

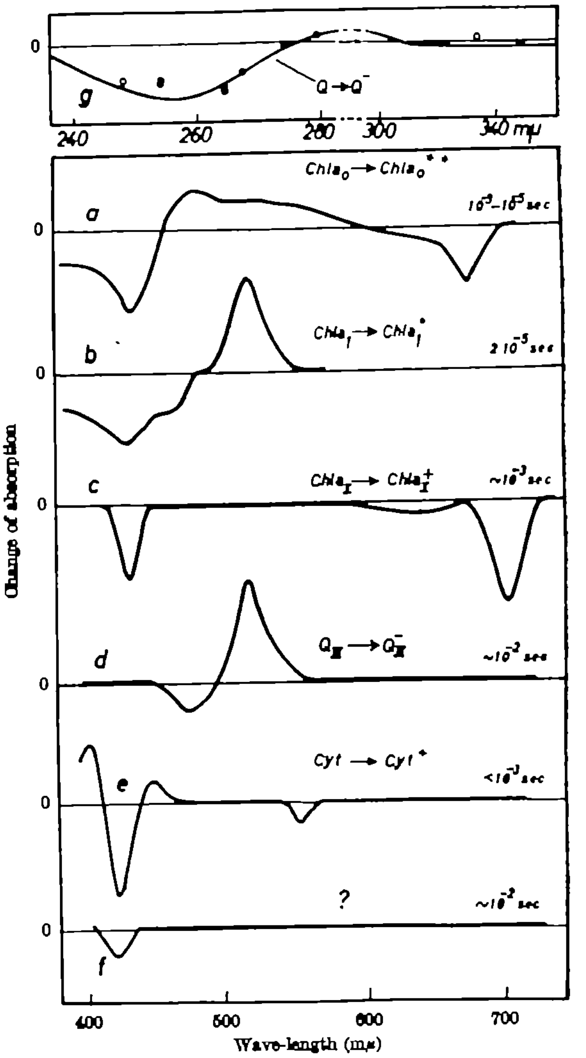

Fig. 1. Separated difference spectra caused by flashing light in chlorella and chloroplasts of spinach. (*a*) Caused by the π–π*-triplet state in the bulk of chlorophyll *a* ($Chla_0$). A corresponding spectrum was also obtained for chlorophyll *b*. The life time depends on the oxygen content and on the viscosity in the suspension (refs. 21 and 25). (*b*) Caused by a probably metastable state of a chlorophyll *a* ($Chla_I$) (refs. 20 and 28). (*c*) Caused by photo-oxidation of a chlorophyll *a* ($Chla_I$) in photoactive chloroplasts (refs. 24 and 26). (*d*) Caused by oxidation of cytochrome Cyt-*f* (refs. 22, 24 and 26). The difference spectrum can be obtained when the reduction of Cyt^+ is delayed. This can be done in different ways (ref. 26). The depicted spectrum was obtained especially by uncoupling Cyt from Q_{II} in fresh chloroplasts with added dichlorophenol indophenol. (*e*) Caused indirectly in surrounding pigments by photo-oxidation of plastoquinone (Q_{II}). Formerly Q_{II} was symbolized by *X* (refs. 17–19, 22, 23, 28 and 29). (*f*) Caused by an unknown reaction (ref. 26). (*g*) Caused directly by plastoquinones (Q_I and Q_{II}). The *in vitro* spectrum of plastoquinone is shown as a solid curve (refs. 25 and 29)

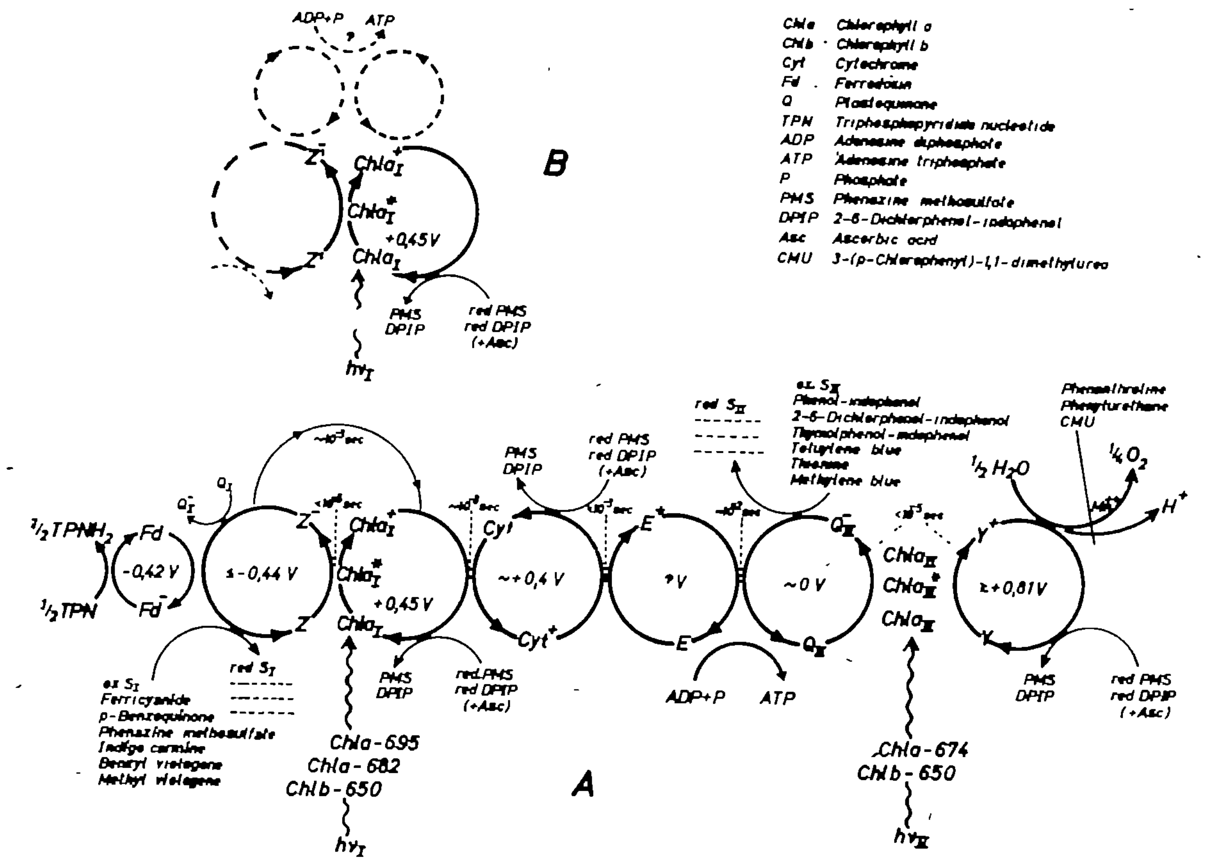

Fig. 2. Reaction scheme of the electron-transport system in photosynthesis derived from analysis of short time absorption changes measured by sensitive flash photometry

therefore here as $\mathrm{Chla}_{\mathrm{I}}$ (refs. 24 and 26); (7) the existence of $\mathrm{Chla}_{\mathrm{I}}$-oxidation in different systems *A* and *B* (ref. 26); (8) an unidentified difference spectrum with a maximum only at 420 mμ (refs. 26 and 28).

Using the two-colour effect of Emerson in combination with measurements of absorption changes, it was possible to demonstrate directly the existence of two light reactions coupled in series. This was done independently by Kok[31], Duysens[32] and Witt *et al.*[33]. Kok[31] showed that 700-light causes an oxidation of *P* 700, and shorter wave-length its reduction by an unknown product. Duysens[32] demonstrated in red algae that red light causes cytochrome oxidation and shorter wave-length its reduction again by an unknown product. We demonstrated in green plants that 700 mμ-light causes cytochrome oxidation while shorter wave-length causes the reduction of a substance *X* (identified as plastoquinone) which reduces the oxidized cytochrome[33,34].

Our measurements of absorption changes were done with the method of very sensitive flash photometry[15]. Photosynthesis was excited by single as well as periodically weak flashes (~ 1 W sec) with a duration variable between 3×10^{-6} sec and 1 sec. The detectors could measure transmission changes of 5×10^{-3} within 3×10^{-6} sec. In this way 7 different types of absorption changes between 10^{-5} sec and 1 sec could be analysed[24]. From the difference spectra depicted in Fig. 1 the participation of the afore-mentioned substances was derived. Besides this analysis, the changes in absorption have been investigated since 1954 also in relation to numerous physical and chemical parameters[15-30]. In this way numerous results on the properties of the substances, its kinetics and its relation to each other were obtained. With this information a rather detailed reaction scheme of photosynthesis was developed, including a two-light-reaction mechanism[22-24]. In this article an extended scheme is presented in which newer results have also been considered (Fig. 2).

It can be seen from scheme (*A*) that TPN or substances such as ox.S_{I} are reduced by transfer of electrons originating from water through at least eight reaction cycles. The electron-transfer between $\mathrm{Chla}_{\mathrm{I}}$ and *Z*, and the transfer between *Y* and Q_{II} (both endergonic in the dark, energy gaps ≥ 0·85 eV, ≳ 20 kcal) are made possible by two light absorptions $h\nu_{\mathrm{I}}$ and $h\nu_{\mathrm{II}}$. A simplified energy diagram of Fig. 2 is shown in Fig. 3.

In light-reaction $h\nu_{\mathrm{I}}$, $\mathrm{Chla}_{\mathrm{I}}$ is oxidized, giving up its electron in the excited state $\mathrm{Chla}_{\mathrm{I}}{}^{*}$ to the substance *Z*. $\mathrm{Chla}_{\mathrm{I}}$-oxidation is accompanied by pronounced absorption decreases at 433 mμ and 703 mμ (refs. 33, 24 and 26) which are characteristic for light reaction $h\nu_{\mathrm{I}}$ (Fig. 1c). Decreases of absorption changes just within the two absorption bands of chlorophyll *a* indicate that a chlorophyll *a* ($\mathrm{Chla}_{\mathrm{I}}$) is in action. The decreases indicate, furthermore, an oxidation because of a corresponding dependency on

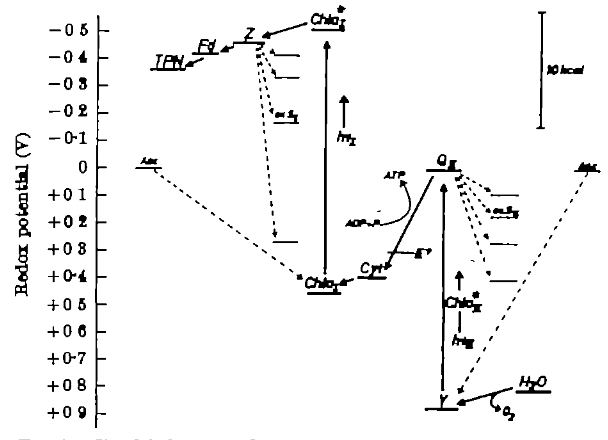

Fig. 3. Simplified energy diagram of the reaction scheme in Fig. 2

Table 1

Properties	Light-reaction $h\nu_{\text{I}}$	Light-reaction $h\nu_{\text{II}}$
Absorption	Chla$_{\text{I}}$: 433, 703 mμ	$Q_{\text{II}}(e)$: 475, 515 mμ*
Concentration	[Chla$_{\text{I}}$] ≈ 10^{-3} [chlorophyll]	[Q_{II}] ≈ 10^{-3} [chlorophyll]
Extinction	ε(703) ≈ 10^{5} M/l cm	ε(475) ≈ 10^{5} M/l cm
Redox-potential Donor	+ 0·45 V (Chla$_{\text{I}}$)	≳ + 0·81 V (Y)
Acceptor	< − 0·44 V (Z)	~ ± 0 V (Q_{II})
Supplied by	(Chlb-650) Chla-682, Chla-695	Chlb-650, Chla-675
Limit of excitation	~ 730 mμ	~ 705 mμ
Reaction constant	2 × 10^{7} L/m.sec (Chla$_{\text{I}}^{+}$ with red. PMS at pH = 8)	2·7 × 10^{6} L/m.sec (Q_{II}^{-} with DPIP at pH = 6·5)
Activation energy	4 kcal (Chla$_{\text{I}}^{+}$ with red. PMS)	7·4 kcal (Q_{II}^{-} with DPIP)
pH-range	4–11	5–8
Temperature of inactivation (5 min)	~ 65° C	~ 50° C

added ferro/ferricyanide[33]. From such measurements the redox-potential of Chla$_{\text{I}}$ could be calculated as + 0·43 V (ref. 33). Our measurements gave a slightly higher value (+ 0·45 V) (ref. 24). Different evidence that Chla$_{\text{I}}$ is oxidized in light was provided by the fact that added reduced phenazine methosulphate (red. PMS) or reduced dichlorophenol indophenol (red. DPIP) (both with ascorbic acid in excess) can be directly coupled to the light product[24,26] (reaction constant and energy of activation; Table 1). This coupling can be demonstrated by the strong acceleration (factor 100 and more) of the decay time of the absorption changes of Fig. 1c with increasing concentrations of red. PMS or red. DPIP (Fig. 4). The coupling between Chla$_{\text{I}}^{+}$ and red. PMS or red. DPIP is possible when light-reaction $h\nu_{\text{II}}$ is inactivated (by ageing chloroplasts[24] or heating to 50° C (ref. 22) or extraction of Q_{II} (ref. 22)). The production of Chla$_{\text{I}}^{+}$ within 10^{-5} sec and the trapping of Chla^{+} at − 150° C gave evidence that this oxidation is a primary act[24]. The Chla$_{\text{I}}$ reaction is stable in the pH range 4–11 and up to ~ 65° C. Z^{-} reduces substances ox.S_{I} as ferricyanide, benzoquinone, phenazine methosulphate, indigo-carmine, benzyl viologene, methyl viologene and TPN-reductase. This is demonstrated in Fig. 5 (see later). From ox.S_{I} the redox-potential of Z was estimated as ≲ − 0·44 V.

When no ox.S_{I} is added to the chloroplasts a back-flow of electrons from Z^{-} to Chla$_{\text{I}}^{+}$ occurs in ~ 10^{-3} sec (ref. 26) (Fig. 2). This is demonstrated in more detail also in Fig. 5 (see later).

A ferricyanide reactive plastoquinone Q_{I} (absorption changes at 260 mμ, Fig. 1g) is probably associated with Z (ref. 25).

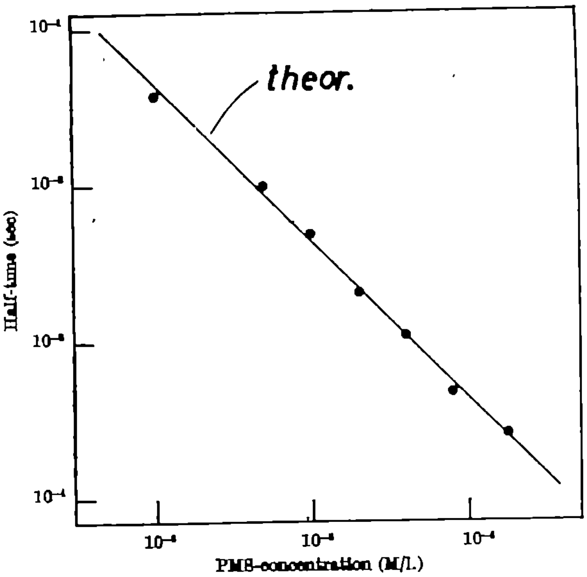

Fig. 4. Half-time of the absorption changes at 705 mμ in aged chloroplasts related to the concentration of red. PMS (with 3 × 10^{-3} M/l. ascorbic acid in excess). 20 C, pH = 8

The changes at 433 and 703 mμ show a biphasic behaviour in relation to various conditions[26]. From this the oxidation of Chla$_{\text{I}}$ in two different systems A and B could be derived. The redox-reaction in system B occurs probably only in a cyclic e-flow which may be accompanied by phosphorylation. One example for the biphasic behaviour of Chla$_{\text{I}}$ was given in ref. 26 and is also included in the discussion of Fig. 5. From this follows the ratio of Chla$_{\text{I}}$ (in A) : Chla$_{\text{I}}$ (in B) = 1.

In light-reaction $h\nu_{\text{II}}$, Chla$_{\text{II}}$ transfers in its excited state an electron from Y to plastoquinone Q_{II}: $Q_{\text{II}}\,\text{Chla}_{\text{II}}{}^{*}Y \rightarrow Q_{\text{II}}{}^{-}\text{Chla}_{\text{II}}Y^{+}$ (ref. 29). The reduction of Q_{II} (formerly symbolized with X) causes pronounced short-timed absorption changes at 475 (decrease) and 515 mμ (increase) in surrounding pigments (Fig. 1d). That these changes are caused by Q_{II} was shown by extraction experiments and redox-potential measurements[22,23,29].

Absorption changes caused directly by Q_{II} were observed at 260 mμ (Fig. 1g) (ref. 25). In the meantime, it was shown that the kinetics of the changes at 260 mμ correspond to those at 475 and 515 mμ under different conditions so far as investigated[19]. The suggestion that Q_{II} is engaged in a light-reaction follows from the very fast appearance of the changes (< 10^{-5} sec) and the temperature independence of its magnitude at all light intensities[17]. That in light a reduction of Q_{II} occurs was verified by the fact that added oxidized substances ox.S_{II} as dichlor-thymol- and phenol-indophenol, toluylene blue, thionine and methylene blue can be directly coupled to the light product[19] (reaction constant and activation energy see Table 1). This coupling can be demonstrated by the strong acceleration (factor 200 and more) of the decay time of the absorption changes at 515 mμ with increasing concentrations of ox.S_{II}. From ox.S_{II} the redox-potential of Q_{II} (formerly X) was estimated as ~ 0 V (ref. 19). Since ox.S_{II} is a Hill reagent and that with its reduction a simultaneous stoichiometric production of oxygen from water takes place, it follows that Y^{+} oxidizes directly or indirectly water[22]. Therefore, the redox-potential of Y is ≳ + 0·81 V. The Q_{II} reaction is stable in the pH range between 5 and 8 and up to + 50° C (ref. 17). The co-operation of Mn^{++} in water oxidation was shown by Kessler[34].

Action spectra[30] of the isolated light-reaction $h\nu_{\text{I}}$ and $h\nu_{\text{II}}$ respectively show that light absorbed in the bulk of the different chlorophylls is transmitted to the two reaction centres in the following way. Chla-682, Chla-695 and probably also Chlb-650 excite Chla$_{\text{I}}$ per energy-migration. Chlb-650 and Chla-674 excite Chla$_{\text{II}}$. The far red limit for $h\nu_{\text{I}}$-excitation is at ~ 730 mμ, the limit for $h\nu_{\text{II}}$-excitation at ~ 705 mμ (refs. 22 and 30). This is in good agreement with the Emerson effect. Hence, using far red light (~ 720 mμ), the light-reaction $h\nu_{\text{I}}$ is almost solely excited[22,30].

The Chla-674 is very probably the fluorescing pigment *in vivo* (fluorescence peak at ~ 685 mμ). Therefore, quenching the reaction of Q_{II} should increase the fluorescence and vice versa. A corresponding relationship was shown by the simultaneous measurements of the absorption changes of Q_{II} (at 515 mμ) and the fluorescence at different conditions[18].

The product of light-reaction $h\nu_{\text{II}}$, Chla$_{\text{I}}^{+}$, reduces via intermediates the product of light-reaction $h\nu_{\text{II}}$, Q_{II}^{-} (refs. 24 and 26). By comparing the absorption changes caused by Q_{II} with those of Chla$_{\text{I}}^{+}$ (in A) under different conditions it was possible to demonstrate the *quantitative* kinetic relation between the light-reactions $h\nu_{\text{I}}$ and $h\nu_{\text{II}}$ (ref. 26).

Intermediates between Chla$_{\text{I}}^{+}$ and Q_{II}^{-} are cytochrome Cyt and the unknown substance E. Light-induced cytochrome reactions have never been observed in normal green plants. The difference spectrum (Fig. 1e) which indicates participation of cytochrome-oxidation is only observable when the reduction of Cyt^{+} is strongly delayed or prevented (exciting only $h\nu_{\rm I}$, cooling to $-150°$ C, uncoupling from $Q_{\rm II}$ by red. DPIP, ageing, etc.)[24]. From this it was concluded that under normal conditions the reduction time of Cyt$^+$ is faster ($< 10^{-3}$ sec) than the oxidation time of Cyt ($\sim 10^{-5}$ sec). That the observed cytochrome is probably Cyt-*f* (redox-potential $+ 0{\cdot}37$ V *in vitro*[45]) is supported by the redox-potential measurement *in vivo*[23] ($\sim + 0{\cdot}4$ V). That Cyt is one reaction partner of $\mathrm{Chla_I}$ follows from three observations: (*a*) the oxidation time of Cyt corresponds (within the limits of accuracy) to the reduction time of $\mathrm{Chla_I}^+$ ($\sim 10^{-5}$ sec) (ref. 24); (*b*) both accumulate in the oxidized form when only light-reaction $h\nu_{\rm I}$ is excited (at $\sim$ 720 mμ) and both are reduced by exciting $h\nu_{\rm II}$ (at $<$ 700 mμ) (refs. 22, 24 and 26); (*c*) $\mathrm{Chla_I}^+$ and Cyt$^+$ are both trapped at $-150°$ C (ref. 24).

(Lundegårdh[35] states that he measured in *Chlorella* a "light-induced" cytochrome-*f* oxidation. Due to his measurements the lifetime of Cyt$^+$ must be of the order of 10 sec. Neither Chance *et al.*[34] nor we could confirm his results. Chance suggests that he measured an oxygenation of a previously anaerobic *Chlorella* and not a light-induced cytochrome oxidation (see special note on this point in ref. 36). Duysens[13] suggests that the absorption changes at 420 mμ may be caused by cytochrome. But the separation of the difference spectrum which belongs to 420 mμ (Fig. 1*f*) shows that the changes are not caused by cytochrome. Chance[34] suggests that the failure to detect light-induced absorption changes of cytochrome in green plants might be caused—especially in the blue—by the strong absorption of carotenoids and chlorophylls, so he used a mutant with only 1/500 the total carotenoids of normal cells and 1/10 the chlorophyll, and observed small cytochrome-*f* oxidation but only under aerobic conditions. Since our measurements were done in normal cells with high pigment concentrations and since we saw pronounced difference spectra of cytochrome (when Cyt$^+$-reduction was delayed) the pigments cannot be the reason for masking different spectra. Perhaps the abnormal conditions in the mutant delay Cyt$^+$-reduction which leads to accumulation of Cyt$^+$.)

The kinetics show that Cyt$^+$ is reduced by $Q_{\rm II}^-$ at least via E (ref. 26). E is not a cytochrome since corresponding absorption changes of 10^{-5} sec do not exist.

The energy released in the back-reaction between Cyt$^+$ and E or between E^+ and $Q_{\rm II}^-$ ($\sim 0{\cdot}4$ eV, $\sim$ 10 kcal) can be used for a phosphorylation[22,24].

From the quantitative measurements of reduced ox.$S_{\rm II}$ per flash the concentration of $Q_{\rm II}$ was estimated as $\sim 10^{-3}$ of the bulk of chlorophyll[19]. From the magnitude of the absorption changes of $\mathrm{Chla_I}$ and Cyt the same concentration also follows for these substances.

The reaction times, indicated in the scheme, follow directly from the kinetic of the absorption changes.

According to system A, eight quanta are needed for the production of one oxygen and two $\mathrm{TPNH_2}$.

The whole process can be separated into 7 partial reactions[27,28]. The flow of electrons from water to $Q_{\rm II}$ via Y and $\mathrm{Chla_{II}}$ can be blocked by addition of CMU, phenanthroline and phenylurethane (no more changes at 475 and 515 mμ, Fig. 1*d*). In this event, instead of water, at least added red. DPIP and red. PMS (with ascorbic in excess) can supply electrons to Y^+ (changes at 475 and 515 mμ reappear in full[24]). $Q_{\rm II}\mathrm{Chla_{II}}Y$ can be inactivated by ageing[24], heating up to 50° C (ref. 22) or extraction of $Q_{\rm II}$ by petroleum ether[33] (no more changes at 475 and 515 mμ, Fig. 1*d*). In this case added red. PMS or red. DPIP can provide Cyt$^+$ with electrons[24,26] (Fig. 2). With concentrations of PMS (or DPIP) $\gtrsim 10^{-5}$ M/l. (*p*H = 8, ascorbic acid in excess) Cyt is by-passed[26] (no more changes of cytochrome, Fig. 1*e*), and red. PMS reacts directly with $\mathrm{Chla_I}^+$ (only changes at 433 and 703 mμ, Fig. 1*c*). This is indicated by the linear decrease of the half-time of $\mathrm{Chla_I}^+$ with increasing concentrations of red. PMS. In these circumstances, light reaction $h\nu_{\rm I}$ is isolated[24]. (This reaction (ox.$S_{\rm I} \leftarrow Z \overset{h\nu_{\rm I}}{\leftarrow} \mathrm{Chla_I} \leftarrow$ red. PMS) must be responsible for the system that operated when Vernon, Kamen and Zaugg[46] used aged chloroplasts with red. substances which are capable of reducing TPN in the light.

At 20° C the reaction of Z–$\mathrm{Chla_{II}}$ can be suppressed by permanent oxidation of $\mathrm{Chla_I}$ with ferricyanide ($> 10^{-3}$ M/l.) (no more changes at 433 and 703 mμ, (Fig. 1*c*). In this case addition of ox.$S_{\rm II}$ (for example, DPIP) can directly accept the electron from $Q_{\rm II}^-$ (only changes at 475 and 515 mμ, Fig. 1*d*). In these circumstances, light reaction $h\nu_{\rm II}$ is isolated[27,28]. This reaction:

$$\mathrm{ox.}S_{\rm II} \leftarrow Q_{\rm II}\,\overset{\leftarrow h\nu_{\rm II} -}{\mathrm{Chla_{II}}}\,Y \leftarrow \mathrm{H_2O}$$

must be responsible for the system which was described by Losada *et al.*[10] (oxygen-producing chloroplasts with ferricyanide and DPIP). In contrast with their interpretation we conclude from our optical measurements that the essential function of ferricyanide is the chemical oxidation of the $\mathrm{Chla_I}$ in A and B.

When the chlorophylls in the bulk are separated or both light-reactions are inactivated by heating to 65° C, the migration of energy to the reaction centres $\mathrm{Chla_I}$ and $\mathrm{Chla_{II}}$ is interrupted. In this case the light energy should stay in the π–π^*-triplet states of the molecules in the bulk (Fig. 1*a*). This has been directly proved[31].

The chlorophyll *a* reaction causing the very fast changes[29] (difference spectrum in Fig. 1*b*) is as yet not included in the scheme. It might be that this reaction is in relation with the reaction of $\mathrm{Chla_{II}}$.

Since Hill[38] made the discovery that isolated chloroplasts can oxidize water and can reduce added substances during illumination, extensive work was done on the reducing and also oxidizing capacity of illuminated chloroplasts. For the highest reduction power, for example, a potential of $-0{\cdot}44$ V was estimated[39]. With the upset of the reaction scheme it now becomes clear that at least 8 sites are possible for a reduction or oxidation reaction and the question arises at what site the different substances are reduced or oxidized respectively. On this point we already gave detailed information (Fig. 2) which was derived from the behaviour of the different types of absorption changes.

On the reaction capacity of Z, we have published only a short note[24]. There are two ways of measuring which substances react with Z^-, although Z is not accompanied by absorption changes in the visible range (Fig. 5, top).

(1) By exciting photosynthesis with flashing light at t_1 the $\mathrm{Chla_I}$ (A) and $\mathrm{Chla_I}$ (B) at level α are immediately oxidized to level δ. Afterwards, $\mathrm{Chla_I}^+$ (A) is reduced by Cyt in $\sim 10^{-5}$ sec and $\mathrm{Chla_I}^+$ (B) via the cyclic way also in $\sim 10^{-5}$ sec back to level α. The corresponding absorption changes are shown in Fig. 5 (middle, first picture). Exciting only light-reaction $h\nu_{\rm I}$ with soft permanent far red background light ($\sim$720 mμ) at t_2, $\mathrm{Chla_I}$ (A) as well as Cyt and E should accumulate in its oxidized form (level β) since no $Q_{\rm II}^-$'s are produced for its reduction. ($\mathrm{Chla_I}^+$ (B) cannot accumulate because of the cyclic *e*-flow in B.) A supplementary flash with $h\nu_{\rm I}$ and $h\nu_{\rm II}$ lights ($<$ 700 mμ) at t_3 oxidizes $\mathrm{Chla_I}$ (B) and the level δ is reached. Simultaneously the same flash produces $Q_{\rm II}^-$. Afterwards, $\mathrm{Chla_I}^+$ (B) is reduced in $\sim 10^{-5}$ sec via the cyclic way. Because $\mathrm{Chla_I}$ (A), Cyt and E are oxidized the $\mathrm{Chla_I}^+$ (A) is reduced only so fast as $Q_{\rm II}^-$ can react with E^+, that is, in $\sim 10^{-2}$ sec. So the time course depicted in Fig. 5*b* should be characteristic for $\mathrm{Chla_I}^+$ accumulation in system A. Nevertheless the experiment in Fig. 5 (middle. second picture), shows no accumulation. The reason may be that $\mathrm{Chla_I}^+$ (A) can also be reduced by a cyclic back flow of electrons from Z^- to $\mathrm{Chla_I}^+$ (A). If this is so. trapping of the electrons of Z^- should prevent the back flow. Indeed, with addition of oxidized indigo-carmine absorption, changes occur which are characteristic

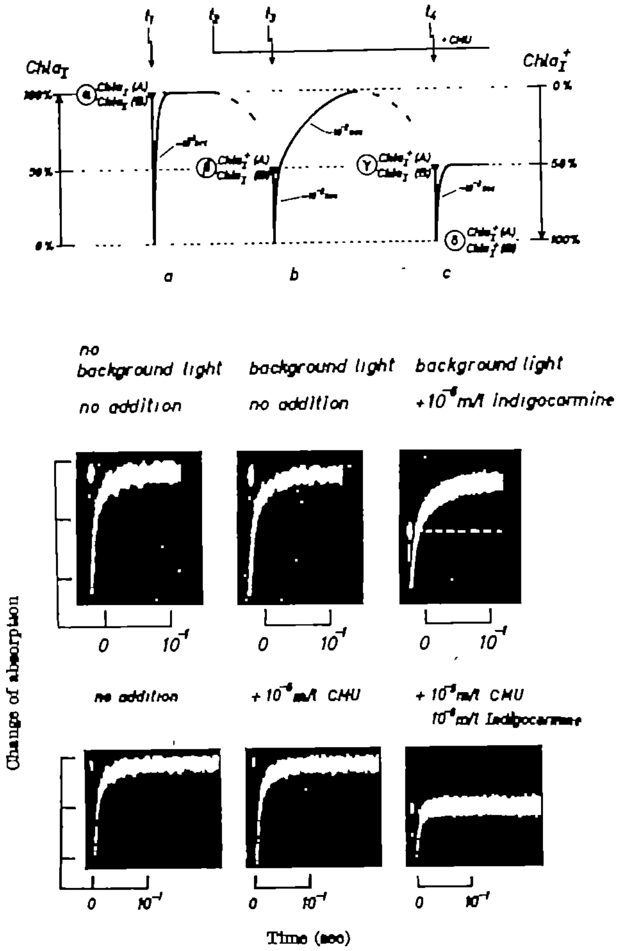

Fig. 5. Top: Scheme of the expected kinetics of Chla under different conditions. Middle and bottom. Absorption changes of Chla at 703 mμ in chloroplasts (spinach) caused by blue flashing light under different conditions. 20 C, *p*H = 7. The flash was turned on at $t = 0$. Flash duration = 10^{-5} sec. For details see text

for accumulation of Chla$_{I}^{+}$ (*A*) (Fig. 5, middle, third picture).

(2) Another consequence from the scheme is the following. With addition of CMU the electron inflow from water is totally blocked. Then Chla$_{I}^{+}$ (*A*) should be permanently oxidized at level γ. A flash can only oxidize Chla$_{I}$ (*B*) to level δ which is afterwards reduced via the cyclic way in $\sim 10^{-2}$ sec to level γ. So disappearance of the absorption changes which are caused by Chla$_{I}$ (*A*), that means half reduction of the magnitude of the changes at 433 and 703 mμ (Fig. 5c), is characteristic for the blocking of system *A* by CMU. Nevertheless, the experiment in Fig. 5 (bottom, second picture) shows that with CMU the changes are not influenced at all. Again, the cyclic back-flow may be the reason. Indeed, by trapping the electrons from Z^- by oxidized indigo-carmine the changes caused by Chla$_{I}$ (*A*) disappear, indicating that system *A* is now totally blocked (Fig. 5, bottom, third picture).

By these two tests it is possible to decide directly which oxidized substances ox.S_I can react with Z^-. So far as investigated, ferricyanide, benzoquinone, phenazine methosulphate, indigo-carmine, benzyl viologene and methyl viologene react with Z^-. Henriques[40], in our laboratory, tested that not TPN but TPN-reductase[41] traps also the electrons from Z^- in the same way as indigo-carmine, etc. The reaction of ox.S_I with Z^- is specific in so far as all substances surnamed under ox.S_I cannot react with Q_{II}^-. This was shown by the observation that ox.S_I does not influence at all the absorption changes of Q_{II}^-. From these results the following conclusions can be drawn:

(1) Because methyl viologene can be reduced by Z^- the redox potential of Z^-/Z is ≤ -0.44 V. Then the redox potential of the excited Chla$_{I}^{*}$ must be ≤ -0.44 V.

(2) Because TPN-reductase is reduced by Z^-, TPN-reductase must contain a redox system. This is a confirmation of the result of Arnon *et al.*[42], who have recently shown in a different way that TPN-reductase contains a redox system, ferredoxin. Ferredoxin was discovered by Mortenson *et al.*[43]. The difference spectrum not identified in Fig. 1*f* may be caused by ferredoxin.

(3) Ferredoxin is not identical with the electron acceptor of Chla$_{I}$ (*A*), since also without ferredoxin the oxidation of Chla$_{I}$ occurs (furthermore, absorption changes at 433 and 703 mμ, Fig. 1c).

Ferredoxin reduces directly or indirectly TPN, probably with the help of the enzyme component of TPN-reductase. With TPNH$_2$ and with ATP carbon dioxide can be reduced to sugar via the Calvin cycle[44].

LETTERS TO THE EDITOR

GEOPHYSICS

Growth of the Earth's Core

To his recent communication[1], proposing that the cause of convection in the mantle is chemical, Dr. Stacey added a note in proof attacking the idea used by me[2,3] of a gradual growth of the Earth's core to give a tentative explanation of continental drift. He makes the objection that the settling of the Earth's core from an undifferentiated Earth, formed by the accretion of iron and silicate bodies like the meteorites, would release an amount of energy greater by an order of magnitude than that which would have been conducted through the Earth's surface since 3,000 million years ago, when I suggest separation began, supposing the geothermal gradient had always its present value. I do not think Stacey's objection is valid. I have a detailed paper in preparation giving an account of the thermal history of the Earth, assuming that convection in the mantle is possible: naturally this differs radically from the thermal history of the Earth previously presented by those[4] who have only assumed conduction in the mantle.

It is possible here only to make the following points:

(1) If the Earth was formed by the accretion process, and if the heat generated at the surface of the developing planet by impacts is radiated off into space, then the initial temperature of the Earth would have varied from 0° C at the surface to about 800° C at the centre, owing to the adiabatic gradient. It is possible, if the planet accumulated sufficiently fast, for some of this energy to be trapped within the Earth and it is of course possible to suppose that the short-lived radioactive isotopes, for example, aluminium-26, might also contribute initial heat, but again this assumes a very rapid collection of matter. There seems no strong reason to postulate much initial heat.

(2) If the radioactivity of the silicates composing the Earth's mantle is that of chondritic meteorites, which now generate $1{\cdot}6\times10^{-7}$ joules/g/year, and the radioactivity of the iron core is negligible as is the case for iron meteorites, the temperature of the Earth would have risen by only 1,800° C in the last 4,500 m.y., even if no heat escapes. Also H. C. Urey (private communication) believes that this is probably an over-estimate, as the chondritic meteorites may be over-rich in potassium. One may therefore deduce that on this theory there has had to be another source of heat in the Earth's interior, for the lowest estimate ever made of the temperature at the core mantle interface is in excess of 3,000° C and probably is much greater.

The gravitational energy released in the process of forming the dense core may reasonably be identified as the likely source. Urey[6] calculates the heat generated as being between $1{\cdot}67 \times 10^{31}$ joules and $2{\cdot}19 \times 10^{31}$ joules assuming that no changes in temperature have occurred. About a tenth of this heat has been lost through the surface; perhaps a twentieth has gone to melt the core, supposing the latent heat is 100 calories/g (mass of core is 2×10^{27} g). Also, the increase in gravitational energy in the expansion of the Earth consequent on the Earth's temperature rising through, say, 4,000° C is considerable. Assuming the volume coefficient of expansion to be 3×10^{-5}, an increase in volume of 12 per cent is to be expected. This requires the gravitational energy to increase by 2 per cent. As the total gravitational energy of the Earth is about 2×10^{32} joules, half the energy released by separation of the iron core has been accounted for.

The remaining energy, between 7 × and 12×10^{30} joules, is available for heating up the Earth to its present temperatures. The mass of the Earth is 6×10^{27} g, so that the increase in temperature lies between 1,000° C and 2,000° C, of the order of that required.

The fallacy in Dr. Stacey's argument lies in the fact that it is tempting to believe that a system of convection currents will carry away exactly the heat generated, but the proviso must be added that the heat sink is adequate. But it is quite clear, from the present-day values, that the heat conducted through the crust is insufficient, and if the Earth's initial temperature were low it could scarcely be otherwise. The convection currents will, of course, distribute the heat generated uniformly through the 'fluid' part of the mantle and the general temperature of this will rise. The thermal gradient through the crust will therefore increase with time.

Photometric Observations from the Southern Hemisphere of 5577*A* Emission from the Aurora on October 28, 1961

IN a recent communication[1] Silverman reports unusual fluctuations in 5577*A* airglow emission intensity on October 28–29, 1961, at Sacramento Peak (geomagnetic latitude 41·6° N.). Silverman gives a curve, consisting of readings taken at 10-min intervals for the period 0200–1100 h U.T. on October 29, 1961. The peak intensity for that night is almost 450 and the minimum about 50, the units being unstated. It is of interest to compare these results with some recorded around 1200 U.T. October 28, from a similar experiment at Lauder, New Zealand (170° E., 45° S. geographic; 50° S. geomagnetic).

The Lauder photometer points continuously to the zenith and views an angle of 0·5°. The instrument was designed to search for rapid fluctuations in the airglow and uses a photon pulse-counting technique; the wavelength is selected with a dielectric filter having a half-width of 70*A*. It came into operation early in September 1961 and recorded 5577*A* emission until December 1961—the same period as that reported by Silverman.

On the night of October 28, 1961, a bright aurora was observed at Lauder. This aurora, which consisted of an active rayed arc, was the brightest observed here during the whole of 1961. The sky was clear in the zenith, and during the period 1135–1235 U.T. the curve reproduced in Fig. 1 was recorded by the photometer. Until 1141 the recorded intensity was at the normal airglow-level, although the aurora in the south had been bright for an hour or more. The rays rose higher in the sky until at 1144 they reached the zenith and the photometer went full scale with the recorder at normal sensitivity. (At 1147 the recorder sensitivity was reduced by one half, at which setting it remained for the rest of the night.) The rays stayed in the zenith for only 3 or 4 min and then retreated to the south. By 1230 the auroral display had quietened to no more than a glow. The moon rose at 1208, and after 1235 the photometer record was contaminated by moonlit cloud. For the period 0900–1200 *Kp* was 5, rising to 6 for the period 1200–1500 U.T.

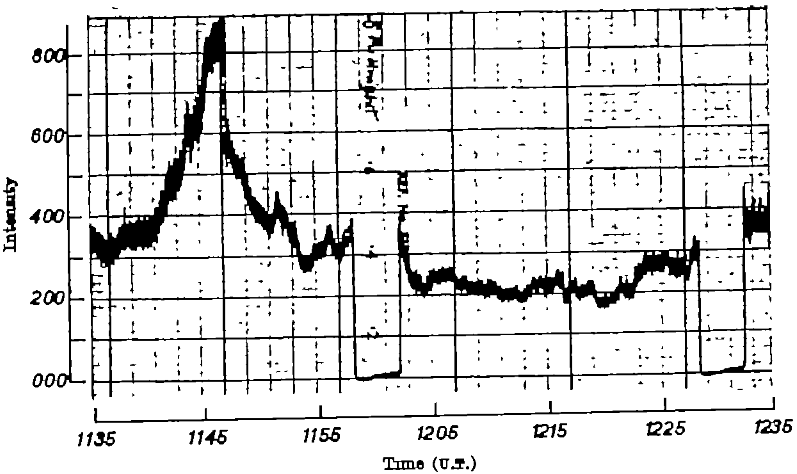

Fig. 1. Photometer trace for the period 1135–1235 U.T. of 5577 Å emission observed from Lauder. The 4-min decreases centred at 1200 and 1230 are due to the shutter closing for a reading of the photomultiplier dark current. The intensity scale is in rayleighs for the record until 1147 and should be doubled for the record after this time; contamination by moonlight becomes serious from approximately 1220

Silverman's record covers the period 0200–1100 U.T. on October 29. During this period K_P was 6, 5, 6 and 4. He does not state whether an aurora was visible, but elsewhere Gartlein[2] reports that a "large aurora" which began early in the morning of October 28 and continued until daylight was observed in North America. On the following night, which is covered by Silverman's record, glows were reported.

An all-sky camera is run in conjunction with the Lauder photometer. The photograph for the period 1132–1137 U.T. is reproduced in Fig. 2. During the nights when the photometer was operating, seven auroræ bright enough to be visible to the naked eye were recorded by the all-sky camera; but the photometer recorded a definite increase associated with an aurora only on October 28. This is evidence that this night was indeed unusually active.

Silverman recorded an intensity variation on October 29 of two to one in a period less than 36 sec. As mentioned earlier, the Lauder photometer was specifically designed to look for very rapid variations in airglow. Due to the short time-constant of about 1/100 sec, the photometer registers statistical variations of about 15 per cent: I have been unable to detect any short-period fluctuations in airglow during the period September–December 1961. If the short-term fluctuations do exist their amplitude must be less than 15 per cent of the mean level. The only major fluctuation observed during more than three months of operation was on October 28, when a visible aurora was in the field of the instrument.

The last 2 h of the Sacramento Peak record corresponds to the first 2 h of the night's run at Lauder for October 29; but the sky at Lauder was almost completely overcast for this night, so no comparison can be made.

The evidence shows that on October 28, 1961, commencing about 1100 U.T., considerable auroral activity was observed in both hemispheres. It appears that the large fluctuations recorded at Sacramento Peak were a manifestation of this widespread auroral activity rather than simple airglow variations. As Silverman makes no mention of an aurora being visible it is concluded that the activity at Sacramento Peak was sub-visual. It would be interesting to know the nature of the Sacramento Peak record for the last hour of the previous night, when the aurora at Lauder was most intense.

PHYSICS

Neutron Numbers 98, 108 and 116

In a discussion of neutron capture processes and theories of element origin, Malkiél[1] has suggested that the neutron numbers 98, 108 and 116 may be favoured. Malkiél mentions that mass data also appear to support the "special character" of $N = 116$. It may be recalled that these numbers are not predicted as significant by the shell model of the nucleus.

The possibility that $N = 98$ and $N = 116$ might be significant had in fact already been briefly noted by me[2] in a systematic study of the relative abundances (per cent proportions) of the isotopes of the elements. It is the purpose here to consider further the probability that these neutron numbers are favoured using as evidence a systematic study of the principal (most abundant) isotopes of the elements. It is assumed that the principal isotopes are particularly significant.

Fig. 1 is an N–Z, Z diagram of the principal isotopes of the stable elements plus those of uranium and thorium. The diagram is based on my work elsewhere (Fig. 19, ref. 2; and Figs. 3 and 4, ref. 3). A few points have been placed in brackets. These are not the true principal isotopes but are not regarded as seriously exceptional as their proportions are very slightly less than those of the principal isotopes[3]. On the basis of diagrams similar to Fig. 1 and other evidence, I have proposed[3] a 3-fold division of nuclei:

(1) N (and Z) < 20 (${}^4_2$He region)
(2) $N > 20 < 50$ (transition region)
(3) $N > 50$ (${}^6_2$He region)

and have suggested the possibility that ^{4}He ($2p + 2n$) and ^{6}He ($2p + 4n$) be considered as cluster components of nuclei. Let us now consider the region $N > 50 < 82$. ^{6}He

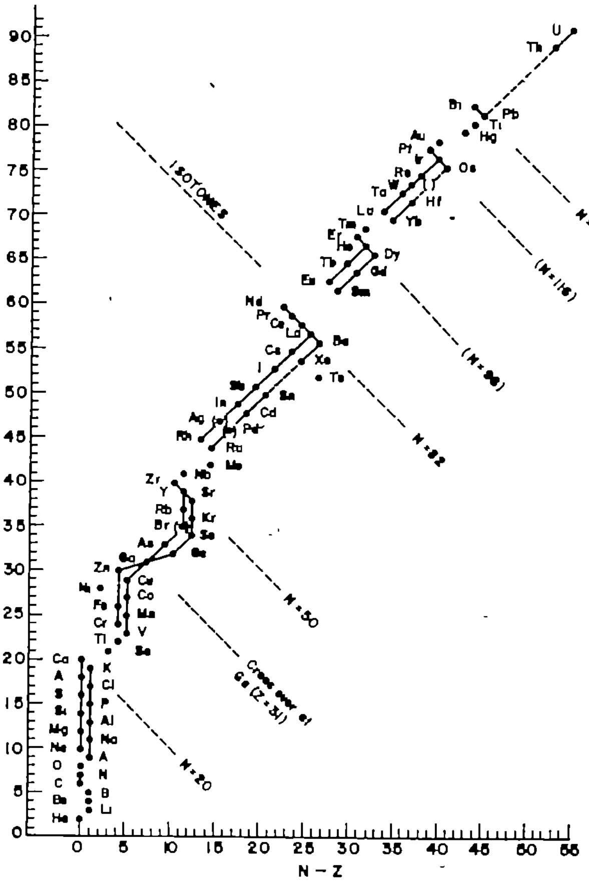

Fig. 1. $N-Z$, Z diagram for the principal isotopes of the elements; adapted from ref. 3. ○, Even Z; ●, odd Z

sequences are apparent and terminate at highly favoured $N = 82$. Such sequences are apparent also in the region $N > 82$, but these sequences are displaced with respect to those for $N < 82$. Similar discontinuities and displacements, but on a smaller scale, occur at $N = 98$ and $N = 116$; these numbers have been placed in parentheses in Fig. 1.

The well-developed discontinuities and displacements at $N = 82$ and the related discontinuity-developments at $N = Z = 20$ and $N = 50$ indicate that the systematics of stable isotopes clearly reflect the effects of the well-known highly favoured neutron numbers 20, 50 and 82. Accordingly, if such principal isotope systematics are sensitive in this respect, it is not unreasonable to assume that the discontinuity-displacements at $N = 98$ and $N = 116$ indicate that these neutron numbers are also favoured, corresponding perhaps to sub-shells or to cluster groups.

Period and Amplitude in Atmospheric Gravity Waves from Nuclear Explosions

Fig. 1 is a log-log plot of the peak-to-peak pressure Δp of the first full cycle of the waves against the period τ measured from the first to the second overpressure peak. The points shown refer to waves with a well-defined first cycle and are taken from microbarographic records, made in Stockholm[1], of nuclear explosions in the vicinity of Novaya Zemlya. The instrument response is essentially flat for lengths of periods between 0·5 and 300 sec. All points correspond to explosions seismically recorded by Båth[2] in Uppsala during 1961 and 1962. The site of the explosions from Stockholm are in the range of 1,900–2,300 km.

The straight line in Fig. 1 approximates the apparent interdependence of pressure and period as:

$$\Delta p = 3{\cdot}5 \times 10^{-3} \times \tau^2$$

when Δp is in dyne cm^{-2} and τ in sec.

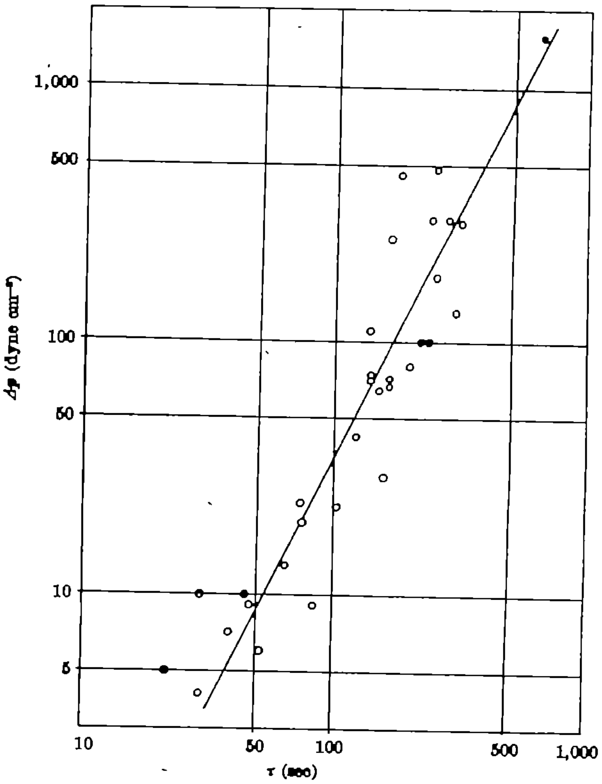

Fig. 1. Pressure and period of atmospheric gravity waves from nuclear explosions

Donn and Ewing[3] have mentioned that they could not find any significant correlation between explosion yield and record appearance in records obtained before 1961: they attributed this to the then inadequate instrumentation. In view of the proportionality of Δp to yield W used in the theoretical investigations of atmospheric gravity waves by Scorer[4], by Hunt, Palmer and Penney[5], and by Weston[6], our results indicate a proportionality between W and τ^2.

Connexion between Local and Global Physics

If relativistic quantum mechanics can be founded on the 'principle of triality' as I have claimed elsewhere[1,2] then this ought to be reflected in the global structure of physics. Locally, triality means the invariance of a form trilinear in phase functions and two kinds of wave functions. Globally the latter are replaced by the expectation values of phase functions and globally defined fields. So the question becomes, what kind of triality is possible in the relativistic phase space E_8, considered as a quasi-classical object?

It was shown by Cartan and Schouten[3] that the elliptic space S_7 admits a triality which is unique. That is, in addition to possessing two kinds of absolute (Clifford) parallelism[4], these together with the points of the space form a triality. Here I show that this observation throws entirely new light on possible cosmological models.

All models so far considered[5] have the structure of a group space $H_n = G/K$. That is, a group G, connecting the observations of different observers, and a maximally compact subgroup K of symmetry for each observer. If $G = D_2$ the Lorentz group, and $K = B_1$ the rotation group of 3-space, then the model is determined up to an arbitrary gauge function which determines the equation of motion of a test particle. This can be chosen to give either general relativity (geodesics) or kinematic relativity (velocity–distance relation). As is well known, neither of these is satisfactory owing to the impossibility of reconciling the dynamic and kinematic requirements.

The reason for the impasse is two-fold. First, the group of dynamical transformations is potentially greater than kinematics and is only reduced to the latter by the assumption (E) that it is a group of extended point transformations; that is, momentum $p^\alpha = m_0\, dx^\alpha/ds$ with proper mass m_0 an absolute constant.

In a sense this assumption is already dropped in the steady-state theory in which proper mass is not conserved, but the only formulation of this theory[6] does not differ essentially from the introduction of a 'cosmological term' into the energy-momentum tensor, an admittedly *ad hoc* procedure. A satisfactory theory would have to relate such a term to locally observed fields as indeed others[7,8] have recognized.

The second restrictive assumption (H) lies in the fact that for a group space H_n, the number of parameters $r = n$ the number of dimensions. But the essential property of the H_n, namely, the existence of absolute parallelism, is according to the Cartan–Schouten result also possessed by just one other space, S_7. The group $G = B_3$ here acts in such a way that $r = 3n$.

Consider an affine space V_8 in the phase variables $x^\alpha = (p,x)$ with linear connexion:

$$\delta v^\alpha = dv^\alpha + \Gamma^\alpha_{\beta\gamma}\, dx^\gamma \qquad (1)$$

and of constant curvature:

$$R_{\alpha\beta} = \lambda g_{\alpha\beta} \qquad (2)$$

If the connexion is split:

$$\overset{\pm}{\Gamma}{}^\alpha_{\beta\gamma} = \overset{0}{\Gamma}{}^\alpha_{\beta\gamma} \pm S^\alpha_{\beta\gamma} \qquad (3)$$

into a metric and a totally antisymmetric part, then the pair of parallelisms given by equation (3) is absolute if:

$$S^\alpha_{\beta\gamma} S^\delta_{\alpha\epsilon} S^\beta_{\delta\eta} = \pm R_{\gamma\delta} S^\delta_{\epsilon\eta} \qquad (4)$$

The positive sign corresponds to assumption (H), while the negative, only possible for $n = 7$ in homogeneous co-ordinates with:

$$g_{\alpha\beta}\, x^\alpha x^\beta = M^2 \qquad (5)$$

gives triality between the connexions (3) and the points of S_7.

In this case $G = B_3$ is the holonomy group of V_8 which leaves invariant the Riemannian curvature:

$$R = R_{\alpha\beta\gamma\delta}\, v_1^\alpha v_2^\beta v_1^\gamma v_2^\delta \qquad (6)$$

associated with the directions v_1, v_2. Since:

$$S^\delta_{\gamma\alpha} S^\gamma_{\delta\beta} = \lambda g_{\alpha\beta} \qquad (7)$$

the structure of V_8 is entirely determined by the trivector field $S_{\alpha\beta\gamma} = g_{\alpha\delta} S^\delta_{\beta\gamma}$ depending on 21 parameters.

To see the physical significance of the foregoing, consider the two possible interpretations of S_3 in existing theory; namely, as on Einstein static[4] space S_3^4 in four homogeneous co-ordinates x^i (excluding time) or the velocity space S_3^4 of special relativity in the four-velocity co-ordinates $v^\alpha = dx^\alpha/ds$. Writing y as a quaternion representing either co-ordinates, we have[4]:

$$\frac{dy}{d\tau} = PyQ = A\,B\,y\bar{B} \qquad (8)$$

as an equation of motion due to a bivector field the polar and axial parts of which are the quaternions ABB, $AB\bar{B}$. Thus, for S_3, this is the electro magnetic field $F = (E, H)$, where (8) is the equation of ponderomotive force (without radiation terms):

$$\frac{dv}{ds} = e/m\,(v_4 E + v \times H) \qquad (9)$$

Thus, F is an acceleration-creating field. Analogously one might expect a velocity-creating field G in S_3^4, but because the norms $N(y) = N(A) = N(B) = 1$ this cannot be proper mass-creating. For that one has to go to S_7, where the weaker condition (5) allows mass creation off the light cone in time-like regions.

In S_7, (8) still holds with $z = (y,y')$ being interpreted as an octonion with the additional hypercomplex unit e, and non-associative multiplication:

$$(A + A'e)(B + B'e) = AB - \bar{B}'A' + (B'A + A'\bar{B})e \qquad (10)$$

If, now, G is regarded as weakly coupled to its sources with relative strength N^{-1}, (10) shows that cross-terms will appear with relative strength $N^{-\frac{1}{2}}$ which can be interpreted as nett charge creation. We thus have a type of model, which is not static, in which stationarity is maintained by electromagnetic forces.

Equation (8), and by triality its cyclic permutations, also hold in the local quantum theory with the skew fields P, Q, replaced by 8-component spinors. (This analogy for S_3 has been known for some time[9].) As noted previously[1], the group here is F_4, which, since it is of rank one higher than B_3, must describe an additional invariant, namely, a scale factor given by a short range field. Thus it seems likely that the number N will be given by the representation theory[10] of F_4.

Note added in proof. The same geometrical interpretation[11] of the sources of a skew field can be given to G as for F; the essential point is that congruences of parallels in elliptic geometry are not simply connected.

METALLURGY

Electrolytic Detachment of Anodic Oxide Films on Aluminium Alloys

THE common technique for removing anodic oxide film from aluminium alloys is by dissolution of the metal substrate or attack along the metal–oxide interface using a bromine–methanol solution[1,2], or a mercuric chloride solution[3]. Both these procedures are slower, offer more risk of contamination of the oxide and yield smaller pieces of intact film than the electrolytic detachment technique developed by Lacombe and Beaujard[4].

In spite of its advantages the electrolytic detachment technique has not been widely used. This is due in part to its use of a potentially explosive mixture of perchloric acid and acetic anhydride, the necessity for filing panel edges before treatment, and a treatment period of up to 5 min. The substitution of a solution with lower perchloric acid concentration and with methanol replacing acetic anhydride has been suggested[5] to reduce the explosive hazard.

A further examination of the electrolytic detachment technique has shown that unsealed sulphuric acid anodic films can be detached in pieces up to 4 in. × 2·25 in. in size by anodic treatment for periods of less than 5 sec. Filing of the edges is not required. The solution used requires only normal care in preparation and use to avoid any hazard. The air-dried anodized panel is immersed in a perchloric acid (70 per cent)–methanol (abs.) solution with a composition of 1 : 5 parts by volume held at 21° C. The panel is made anodic by sudden application of voltage (50–65 V) for a period of from 1–4 sec during which the current rises steadily to a density of 6–12 amp/in.^{2}. The cathode is an aluminium sheet bent to fit around the panel. After the current flow is discontinued, the panel is immediately removed and rinsed for 1 min in warm water, then rinsed in cold water for 30 min.

In many cases full detachment of the film from the five surfaces of the panel occurred during the electrolytic treatment. In other cases, the film had to be removed by gentle insertion of a thin blade between the film and the metal or by tapping the air-dried film to shake off smaller portions of the film.

This new technique has been used successfully to remove oxide films from a wide range of commercial aluminium alloys. The optimum voltage required and the time needed for the current density to rise to the most effective value varied slightly with alloy. Films ranging from 7 to 60μ have been readily removed. Thinner films were more difficult to retain in large pieces than the thicker coatings. Oxide films prepared in electrolytes other than sulphuric acid and including sulphosalicylic acid–sulphuric acid type solution were detached but with somewhat less success. Cathodic treatment[6] has been tried but proved much less effective.

The colour and opacity of the detached films varied greatly with the condition of the metal surface, alloy, film thickness and electrolyte. Films from superpurity sheet were colourless and transparent, those from aluminium–5 silicon alloy were dark grey and opaque while films from certain alloys were tinted due to the effects of specific alloying constituents.

The two surfaces of the detached films differed slightly in that the electrolyte side surface took up colour from dye solution in normal quick fashion, while the metal side surface became coloured at a much lower rate. However, the colour produced by prolonged dyeing did not differ on the two sides. Agreement between the coating weight per unit area measured on the detached film and that obtained by chemical dissolution of the oxide on the metal was excellent, well within the possible experimental error. Most of the films after electrolytic detachment curled slightly, producing a concave effect on the metal side. This appeared due to the film having been formed under compression in the anodizing procedure, and to differences in the degree of compression at the two surfaces.

Anodic oxide films detached by the bromine–methanol method were compared with coatings removed by the electrolytic technique. The former film took up no colour on the metal side surface in sharp contrast with the normal colouring that ensued on its other surface. The mechanism of the detachment of the oxide films by this electrolytic technique is not clear but is believed due to the sudden evolution of large amounts of oxygen (possibly contaminated to a slight degree with reaction products of the perchloric acid and methanol). The accompanying pronounced local electrical heating effect is also a factor. The average current density is 1,000 amp or more per square foot while the actual value in the pores of the anodic film will be very much greater. Gas evolution occurs probably at the base of the pores adjacent to the barrier layer. This contributes to the penetration of the barrier film, which permits electrolyte flow to the metal substrate which becomes polished. The film ruptures laterally, either before or after penetration, at the metal-barrier layer interface or close to it.

Sealing of the anodic film, even for a very short period, interferes with its removal by the electrolytic technique described. However, sealed films have been removed with partial success in a solution with the acid reduced to 4·5 per cent, methanol to 77·5 per cent and water added to 18 per cent. Pieces detached were much smaller than detached unsealed films. It was necessary to file the edges of the panel before treatment and to slightly increase the voltage and the time of treatment.

I thank W. N. Stassen for help with the experimental work.

Delayed Failure in a Hydrogenated Face-centred Cubic Alloy of Nickel

RECENTLY[1] it has been suggested that interstitial hydrogen in a face-centred cubic lattice will produce embrittlement and cause delayed failure under the appropriate conditions. Basically, the required conditions are that sufficient flow must occur to produce dislocation pile-ups and that the interstitial, under the influence of stress, must diffuse to the region of the piled-up array. In both the body-centred cubic and face-centred cubic lattices, dislocations have been observed to pile-up at an obstacle[2,3].

It has been postulated that stress-induced diffusion of hydrogen to the region of the dislocation array will result in the formation of a crack when a critical concentration has accumulated. The leading dislocations in the array will then coalesce to form a crack which propagates almost instantaneously and eventually is stopped by plastic flow; whereupon this process is repeated. Since the segregation of the solute is a time-dependent diffusion-controlled process, crack propagation is expected to be discontinuous in the appropriate temperature range. Presumably, substitutional atoms could produce a similar effect but the behaviour is particularly apparent with interstitials.

The delayed failure of the face-centred cubic structure which has generally been believed to be resistant to hydrogen embrittlement was examined in a high-strength alloy with the nominal composition, 66 nickel–30 copper–3 aluminium. Fig. 1 illustrates the results of static fatigue tests at various temperatures for the hydrogenated 'monel' alloy. Delayed failure was observed in the range 350°–500° F over a relatively wide range of stress (~80,000 lb./in.^{2}). The curve is typical of those observed for hydrogen in steel[1]. There is an upper limit of stress, a range of delayed failure, and a lower critical stress. Because of the lower mobility of hydrogen in the face-centred cubic lattice[4] the delayed failure phenomenon was observed at temperatures well above ambient. The creep characteristics at these temperatures rule out the association of this behaviour with conventional creep damage often observed in this type alloy.

Resistance measurements (Fig. 2) delineated the crack kinetics. There did not appear to be an initial incubation time. The absence of an induction period prior to crack initiation is attributed to a non-uniform distribution of hydrogen. The way in which the cracks grow, a series of initiations with virtually instantaneous propagation, is

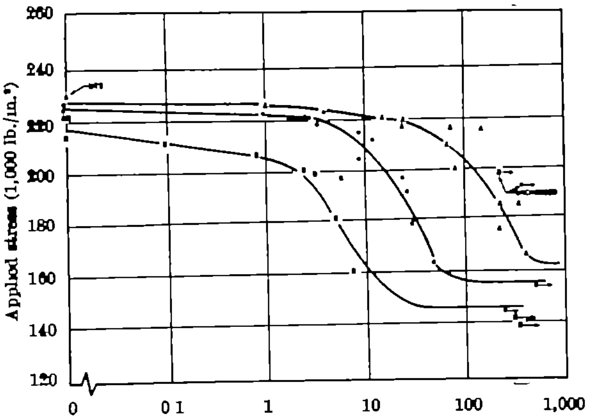

Fig. 1. Static fatigue curves for hydrogenated 66 nickel–30 copper–3 aluminium alloy. Sharp notch specimens. 185,000 lb./in.² strength-level. Test temperatures. △, 350° F; ○, 400° F; ■, 500° F

analogous to that observed with brittle delayed failure in steel[6]. It follows that the geometric details of crystal structure cannot be significant elements in a basic mechanism.

The typical strain rate sensitivity associated with hydrogen embrittlement was also obtained for this alloy. At room temperature and to 400° F or above, a pronounced decrease in ductility was observed as the strain rate was decreased. The ductility of the uncharged material was virtually unaffected by the large change in strain rate.

X-ray diffraction studies as well as mechanical tests were conducted in order to explore more fully the behaviour of hydrogen in this 'monel' alloy. The introduction of hydrogen into this alloy did not result in the formation of a second phase such as a hydride. Large increases in lattice parameter were observed in the hydrogenated material, illustrating that interstitial hydrogen caused a dilation of the lattice. This observation strongly suggests the concept of a hydrogen-dislocation interaction in face-centred cubic materials and lends further support to the same concept previously applied to body-centred cubic materials where the diffraction data are somewhat less conclusive.

Ageing at 212° F demonstrated the reversibility of this process. The lattice parameter was restored to the uncharged value when hydrogen was removed from solid solution. There was some line broadening which did not completely disappear. This phenomenon, which did not apparently influence the mechanical behaviour, was tentatively attributed to non-uniform plastic deformation resulting from hydrogenation.

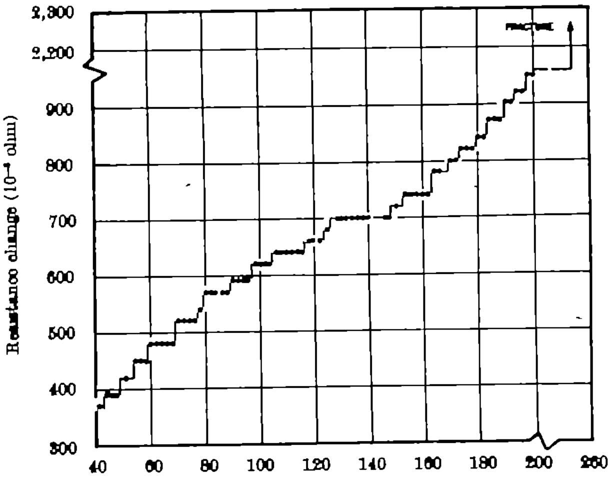

Fig. 2. Resistance increase as a function of time for hydrogenated 66 nickel–30 copper–3 aluminium in the stress-range of delayed failure. Test temperature: 400° F; applied stress, 221,000 lb./in.²

The influence of hydrogen on the stacking fault energy of face-centred cubic alloys has considerable interest in its relation to the basic mechanism of embrittlement. Interstitial hydrogen is expected to decrease the energy of a stacking fault[4]. The expanded fault implied by this change in energy can result in embrittlement by affecting the deformation processes and/or the cohesive strength. The investigation now in progress will attempt to provide evidence for this behaviour.

BIOPHYSICS

Effect of Radio-frequency Fields on the Zeta-potential of a Colloidal Suspension

Reports from this laboratory[1–4], afterwards confirmed elsewhere[5], have shown non-thermal effects of radio-frequency on living organisms and non-living material. To preclude heat in these experiments, the radio-frequency was pulsed with pulse widths in the μsec range, and the duty cycle usually was less than 1 per cent. In these conditions any rise in temperature could be controlled so as to be virtually undetectable.

The manifold non-thermal biological changes were puzzling because the energy input on an $h\nu$ basis, at these frequencies (1–100 Mc/s), are orders of magnitude below that necessary to break the weakest chemical bond.

Because of the complexity of the biological materials and the difficulty of quantifying changes, it was decided to investigate a simpler system. For this purpose polystyrene latex was used. This material, obtained from Dr. John Vanderhof at Dow Chemical Corporation, is monodisperse and of known particle size. If these particles are placed in a radio-frequency field, the well-known pearl chain formation[6–8] may be observed under the microscope. However, as was pointed out previously[8], there appears to be a frequency optimum for alignment. This should not be the case if the dielectric constant of the particles and the medium does not vary with frequency over the range explored.

Since these particles have a high zeta-potential (about 50 mV in distilled water) which is responsible for the potential energy of repulsion between them, it was suspected that during pearl chain formation the zeta-potential might in some way be reduced. If this were the case, significantly greater reduction should occur at the frequency of optimal alignment.

Initially radio-frequency was applied at right angles across a micro-electrophoresis cell, and it was shown that the zeta-potential decreased as a function of applied radio-frequency voltage. However, the indication of a permanent change on the colloid induced by the radio-frequency led us to abandon this approach and undertake the following.

A suspension of polystyrene particles (1·305μ diam.) was dialysed against 10^{14} volumes of distilled water and

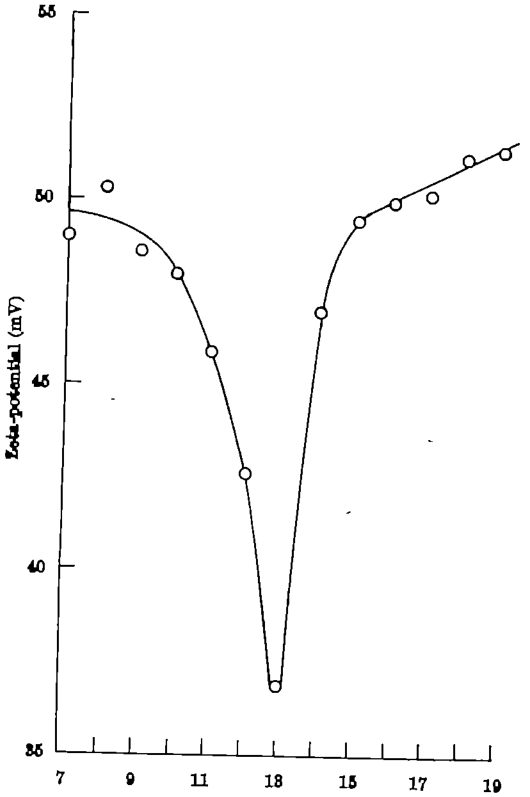

Fig. 1. Frequency dependency of change in zeta-potential. Control value of zeta-potential = 51·2 mV; applied voltage, 500 V, peak to peak/cm; pulse width, 10 μsec; pulse repetition frequency, 500; time in radio-frequency field, 1 min

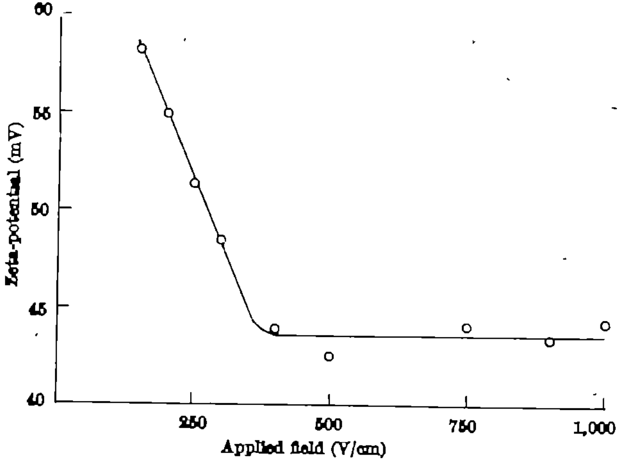

Fig. 2. Voltage dependency of change in zeta-potential at 13 Mc/s. Control = 58·7 mV; pulse width, 10 μsec; pulse repetition frequency, 500; time in radio-frequency field, 1 min

diluted with more distilled water to 10^7 particles/ml. The suspension was placed in a rectangular 2 × 2 × 5-cm cuvette. Two of the vertical sides were of sheet platinum serving as electrodes, and the other sides and base were made of polystyrene sheet.

A generator capable of delivering pulsed radio-frequency, variable over the range of 5–50 Mc/s, was connected to the platinum plates. The radio-frequency was applied in 10 μsec pulses at 500 pulses/sec for 1 min. The suspension was then removed and the zeta-potential measured in a microelectrophoresis apparatus 10 min later.

Fig. 1 illustrates the effect of varying frequency at a constant voltage on zeta-potential.

It can be seen that the maximum reduction in zeta-potential occurs at 13 Mc/s—the frequency at which optimal pearl chain formation occurs with 1·305μ spheres.

Fig. 2 shows the change of zeta-potential at 13 Mc/s as a function of applied voltage.

Such a decrease of zeta-potential might be explained by: (1) adsorption on the surface of either ions or molecules; (2) an increase in ionic strength of the medium; (3) the removal of surface charge groupings (in this case either $—COO^-$ or $—SO_3^-$); or (4) the re-association of dissociated surface charge groups. It is difficult to visualize how applied radio-frequency fields could influence any of the foregoing, especially on a permanent basis.

Phase Shifts in the Human Retina

Brindley[1] has shown that in the human eye a part only of the attenuation responsible for flicker fusion phenomenon is localized in the receptor cells.

When previously De Lange's[2] experimental attenuation characteristics were fitted to a simple diffusion model[3] of retinal transfer characteristics the quantum efficiency of the process came out too low[3,4]. At that time, no experiments capable of yielding phase-shift characteristics for cross-checking could be[4] or had been taken. To understand why the diffusion model as applied was unable to produce an acceptable value of the quantum efficiency only a guess could be offered[4], which is now largely borne out by Brindley's[1] work.

The model[3,4] essentially yields expressions for the amplitude- and phase-shift characteristics, for the responses to a pulse and to a step as well as for the quantum efficiency, containing two parameters, namely, the time constant τ for the diffusion inside the receptor cell of photo-chemical decomposition products and the decay constant ρ, describing (pseudo-) monomolecular fading away of these products. The ranges in which on the ground of physiological data these parameters can be expected to fall have been discussed earlier[4].

From the original fit[3,4] to De Lange's[2] data the results $\tau = 0·4$ sec and $\rho = 25$ sec^{-1} were obtained, which in themselves seemed reasonable enough. The quantum efficiency Q for the diffusion process alone—equalling $(\cosh \sqrt{2\rho\tau})^{-1}$ and so being strongly dependent on parameter values—came out at 0·025, which is perhaps some 10 times too low.

Now that Brindley[1] has obtained phase-shift data on the receptor process it might be of some interest to compare these with the predictions of the diffusion model[3,4]. Unfortunately, phase-shifts below 40 c/s are not reported. The probable course of the phase-shift curve from 0 to 40 c/s must be discussed first.

Since the transit time of the system for optical stimulation is finite and for electrical stimulation essentially zero, the curve has to indicate zero phase-shift at zero frequency, if it is agreed that it is necessary to have the electrical pulse coinciding with the top of the optically excited wave at a certain site—and from there onwards—in order to obtain maximum flicker. In passing, it should be noted, however, that in view of the form of De Lange's[2] curves at elevated brightnesses it might be more advantageous for flicker perception in the region 1–6 c/s to

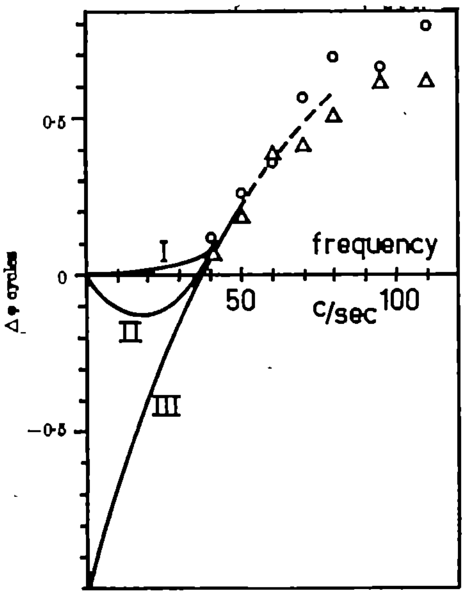

Fig. 1. Plot of Brindley's phase-shift data. ○, Cornea anode; △, cornea cathode

double the frequency by having the electrical pulses arrive at this site exactly in between optically activated wave tops; since such a mechanism could scarcely affect phase-shifts at frequencies of more than 40 c/sec it need not be considered in extrapolating Brindley's data.

A course like curve I in Fig. 1 would appear rather unnatural; such a sharp bending of a phase characteristic around 35 c/s would certainly involve a sharp top in the amplitude characteristic, which is not to be found in De Lange's[2] experimental results. Again, a course like curve II (Fig. 1) involving negative phase angles (light pulse after current pulse) would appear to have no rational meaning. I therefore believe that a reasonable extrapolation should follow a course like curve III (Fig. 1), involving a translation of the origin over one full cycle, such that Brindley's data at 40 c/s are to be read 1·12 and 1·07 cycles respectively.

In general, this full cycle can easily be overlooked in an experiment of this kind; the difficulty of the shortness of transit times encountered by Brindley[1] is thus avoided.

In Fig. 2, some of the phase-shift curves as predicted by the diffusion model[3,4] have been plotted; as shown, Brindley's data when corrected can be fitted to all curves for reasonable quantum efficiencies Q by choosing $\tau = 0{\cdot}19 \pm 0{\cdot}03$ sec, which is about half my former[3,4] value. The curves are too insensitive against Q to permit an appraisal of it on these grounds.

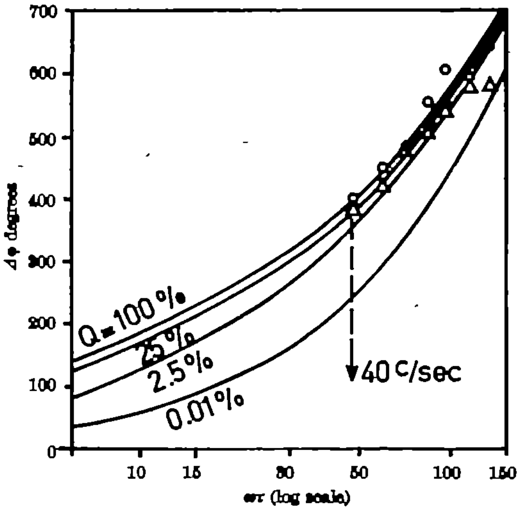

Fig. 2. Brindley's experimental points, corrected as discussed in text, can be fitted to phase-shift curves calculated for the diffusion model by choosing $\tau = 0{\cdot}19$ sec. The quantum efficiency Q cannot be appraised on these grounds

A new comparison of De Lange's[2] attenuation curves with replotted, calculated[3,4] amplitude characteristics (Fig. 3) taking $\tau = 0{\cdot}19$ sec and normalizing the experimental points on the reasonable attenuation value of 1·2–1·3 at 1·5 c/s will allow any quantum efficiency up to some 20 per cent. The existence of Brindley's[1] nervous attenuating mechanism is now clearly shown by the vertical deviation between experimental and calculated curves.

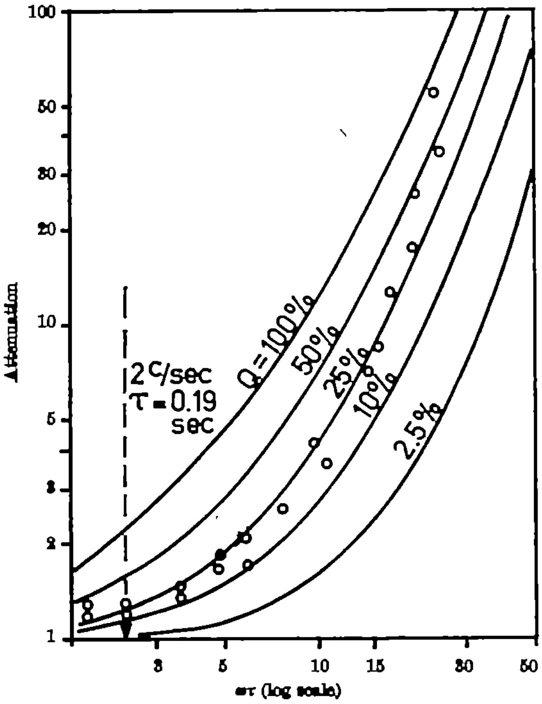

Fig. 3. Amplitude characteristics for the diffusion model for several values of the quantum efficiency Q have been plotted; if the value $\tau = 0{\cdot}19$ sec, as determined for Brindley's observer in Fig. 2, is assumed valid for De Lange's observers, that author's measurements will lie as shown. The existence of an extra nervous attenuating mechanism is apparent; Q could have any value up to some 20 per cent

Of course, the numerical values obtained for parameters τ and Q should be considered tentative for three main reasons, namely, that Brindley's[1] measurements are made with pulsed, in contradistinction to modulated, lights and currents at very elevated brightness, that De Lange's[2] measurements used here apply to one particular test field configuration (2° ⊖) and brightness (0·375 troland) only and that the model of one-dimensional diffusion used[3,4] is certainly much simplified as compared with physiological configurations. Moreover, the complete comparison given here depends on the reasonability of the addition of a full cycle to Brindley's data, which should be checked experimentally, and on the validity of the same value of τ for Brindley's and De Lange's observers.

It would appear, however, that models based on diffusion and recombination of photochemical decomposition products inside the receptor cells of the human retina can easily comprise a large body of experimental data by reasonable adjustment of few parameters.

CHEMISTRY

Use of Xenon Adsorption for Measurements of Surface Area

MEASUREMENTS of surface area with xenon adsorption have not been used extensively despite the obvious advantage that very low dead space corrections are obtained at liquid nitrogen temperature. The reluctance to use xenon for surface area measurements seems to be due to the past difficulty of obtaining it in a pure state. Xenon with impurities totalling less than 100 p.p.m. by volume is now commercially available, and there should be no reason why the xenon Brunauer–Emmett–Teller (B.E.T.) method should not enjoy wider application.

In this laboratory, xenon adsorption at 77·3° K has been used for determining surface areas and roughness factors of nickel and nickel oxide-coated specimens. The geometrical areas of the specimen ranged from 20 to 100 cm^2 and roughness factors were 1·7–3·2. The areas were too small for accurate estimation by krypton adsorption, especially in view of the large dead space required by the configuration of the specimens (rectangular flat sheets). While relative values of surface area may be obtained irrespective of the cross-sectional area chosen for the adsorbate molecule, the determination of roughness factors requires an accurate estimate of the effective cross-sectional area (σ_{Xe}) of the xenon molecule. The literature, until recently, yielded no information concerning comparative monolayer volume (V_m) for xenon and other adsorbates of known molecular area.

Singleton and Halsey[1] give relative V_m values for nitrogen and xenon on carbon black, silver iodide, and anatase, but the measurements were made at different temperatures. The σ_{Xe} values at 148° K calculated from the data of Singleton and Halsey are 18·2 Å^2 for silver iodide, 20·2 Å^2 for carbon black, and 27·3 Å^2 for anatase. Anderson and Baker[2] comment on the observed xenon monolayer coverage on anatase and conclude that the packing is dependent on the arrangement of adsorption sites at the surface. They adopt a model in which the xenon atoms occupy preferred sites on the (001) plane, which is assumed to predominate because it is a natural cleavage plane. Due to the size of the xenon atom, adjacent sites cannot be occupied, and the xenon atoms form an array in which the effective coverage per atom is calculated to be 28·3 Å^2. Using this concept of crystallographical adsorption sites, Anderson and Baker compute average σ_{Xe} values of 23·0 and 19·5 Å^2 on polycrystalline tungsten and nickel surfaces, respectively. Pritchard[3] has recently compared V_m values for krypton and xenon on an evaporated copper film. The V_m value for krypton was determined by the B.E.T. method at 77° K and for xenon by a surface potential method at 90° K. The experiment led to a value for σ_{Xe} equal to 24 Å^2, taking 19·5 Å^2 for σ_{Xe}. The observed ratio of σ_{Xe}/σ_{Kr} is in nearly perfect agreement with the relative coverages calculated from the lattice constants of solid xenon and krypton.

Ponec and Knor[4] recently published comparative V_m data for krypton and xenon on evaporated nickel films. At 78° K the observed ratio of σ_{Xe}/σ_{Kr} was 0·92, showing that the molecular area was less for xenon than for krypton. The authors allude to the possibility of binding forces related to chemisorption playing a significant part in the case of xenon.

The lack of agreement in published molecular coverage data and uncertainty concerning the manner of packing in adsorbed films prompted our investigation of krypton and xenon adsorption on representative surfaces at the same temperature and over the same range of relative pressures (P/P_0). Krypton isotherm measurements have been carried out at 77·3° K on nickel powder, oxidized nickel powder, and glass wool. Specific surface areas and V_m values were obtained by the B.E.T. method. Smaller samples of the same materials were used for xenon isotherm measurements from which V_m values and σ_{Xe}/σ_{Kr} ratios were calculated.

The krypton B.E.T. method used was essentially that described first by Beebe, Beckwith and Honig[5]. Sample sizes were selected to yield total surfaces in the range from 2,000 to 4,000 cm^2. The vapour pressure of solid krypton was used for P_0 rather than the extrapolated liquid vapour pressure. (Justification for the use of the true vapour pressure can be found in ref. 6.) Specific surface areas calculated for this P_0 value are approximately 5–10 per cent lower than if the extrapolated liquid vapour pressure were used.

For the xenon adsorption measurements, an apparatus similar to that of Wooten and Brown[7] was used. Samples were used which had total surface areas in the range 200–

Table 1. Relative Monolayer Volumes for Krypton and Xenon

Sample material	Specific surface area (cm²/g)	V_m, ml./g Krypton	Xenon	σ_{Xe}/σ_{Kr}	σ_{Xe} (Å²)
Ni powder I	2,530	0·0482	0·0362	1·33	25·9
Ni powder II	950	0·0182	0·0142	1·28	25·0
Glass wool	1,590	0·0304	0·0226	1·35	26·3
Ni powder I (oxidized)	1,730	0·0331	0·0262	1·26	24·6
Ni powder II (oxidized)	1,090	0·0207	0·0171	1·21	23·6

400 cm². Corrections were applied for the internal area of the glass sample holder and connecting tube, assuming a unit roughness factor for glass. Thermal transpiration corrections were applied, and P_0 was taken as the solid xenon pressure, which was calculated from the data of Podgurski and Davis[8]. Values of P_s were in the range 1·95–2·03 × 10^{-3} torr.

Monolayer volumes for krypton and xenon in ml. (S.T.P.)/g of adsorbent are given in Table 1. The V_m values are taken from the B.E.T. plots for krypton and xenon vapour shown in Figs. 1 and 2, respectively. Specific surface areas were calculated from the krypton data assuming 19·5 Å² for σ_{Kr}. The mean value of σ_{Xe}/σ_{Kr}, 1·29, is in fair agreement with the ratio found by Pritchard[3] (namely, 1·23) but does not agree with the findings of Ponec and Knor[4].

The nickel powders used were commercial materials of high, but unspecified, purity. They were used without any surface treatment and hence, even after outgassing, undoubtedly had the normal thin oxide film characteristic of an active metal. Nickel I was a 200 mesh (Tyler standard) powder containing a considerable amount of fines, while nickel II was a 150–300 mesh material. The oxidized powders were prepared by igniting nickel I and II until a black oxide film coated all particles. The gain in weight in each case was about 10 per cent of the theoretical weight gain for complete conversion to nickel oxide. Oxidation caused a slight gain in specific surface area of the Nickel II, whereas Nickel I lost area, due probably to sintering and agglomeration of the finer particles. The glass wool used was a commercial borosilicate material which had been degreased in benzene prior to outgassing in the adsorption apparatus.

All the B.E.T. plots for nickel and nickel oxide exhibit a curvature convex to the abscissa. The curvature is slight up to a relative pressure (P/P_s) equal to about 0·2, and slopes were obtained by taking the best straight line up to this value. The B.E.T. plots for both krypton and xenon on glass do not have perceptible curvature up to relative pressures of at least 0·35.

An independent measure of σ_{Xe} was made by determining xenon adsorption isotherms on samples of glass tubes and rods for which the total apparent geometrical area of the samples plus the internal area of the glass sample container could be readily measured. The roughness factor for the glass surface was assumed to be unity, in agreement with several workers who have presented experimental data to show that the roughness factor of glass and fused silica is very close to unity.

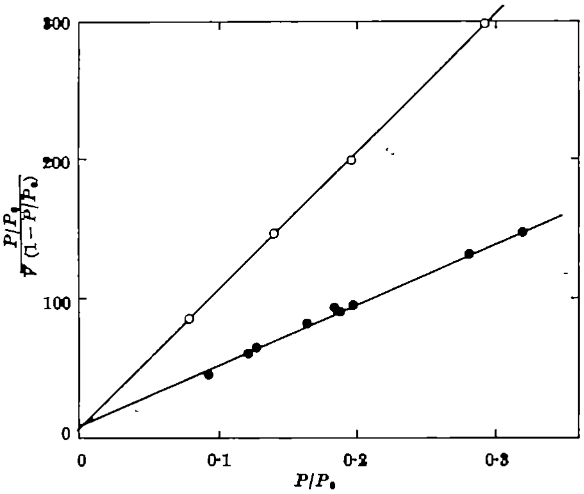

Fig. 3. Xenon B.E.T. plots on glass. ⊙, Glass tube, 72 cm² area; ●, glass rods, 166 cm² area

Table 2. Monolayer Volume and Molecular Area for Xenon on Glass Surfaces

Sample material	Geometrical area (cm²)	V_m (ml./g)	σ_{Xe} (Å²)
Glass tubing	72	0·00099	27·0
Glass rods	166	0·00226	27·1

The B.E.T. plots for the two experiments are given in Fig. 3; the corresponding computed V_m and σ_{Xe} values are shown in Table 2. Because the roughness factor of glass cannot be less than unity, the calculated σ_{Xe} values should be considered minimum values, and yet they are higher than any of the results given in Table 1. These results indicate the possibility that, with the given ratio of σ_{Xe}/σ_{Kr}, the accepted molecular area of 19·5 Å² for σ_{Kr} may be too low. Indeed, it appears from the literature that this value has been derived by averaging the various results obtained by comparison with nitrogen adsorption, and using the extrapolated liquid krypton vapour pressure data to estimate P_0. Values obtained by using the true solid vapour pressure require a higher σ_{Kr} value to bring the relative nitrogen and krypton coverages into agreement.

This work was partially supported by a contract from the Diamond Ordnance Fuze Laboratories as a part of the Energy Conversion Project sponsored by the Advanced Research Projects Agency, Department of Defense.

A Bouncing Liquid Stream

I wish to report an unexpected effect observed when a thin stream of a solution of polyisobutylene in 'Decalin' is poured into solution in an open dish.

The solution was poured from a height of about 25 cm in a stream approximately 1 mm diameter into solution contained in an evaporating dish of diameter 10 cm. The ciné still photographs in Fig. 1 consist of every fifth frame from a 16-mm film shot at 64 frames/sec. The whole sequence shown therefore occurred in slightly less than 1 sec.

In Fig. 2 a key to the various features in the photographs is given.

As the stream enters the liquid the condition in the first frame of Fig. 1 is quickly established. A small 'heap' of liquid is formed at the point of entry. As pouring proceeds a small stream of liquid appears to emerge from the heap with a trajectory approximately parallel to the liquid surface (frame 2). The trajectory of this secondary stream gradually steepens and usually changes in azimuth (frames 3, 4, 5, 6 and 7) and at the same time the heap disappears. The secondary stream then begins to die away and disappears (frames 8, 9, 10 and 11). The heap of liquid grows again (frame 12) and the whole sequence is repeated. The secondary stream is approximately the

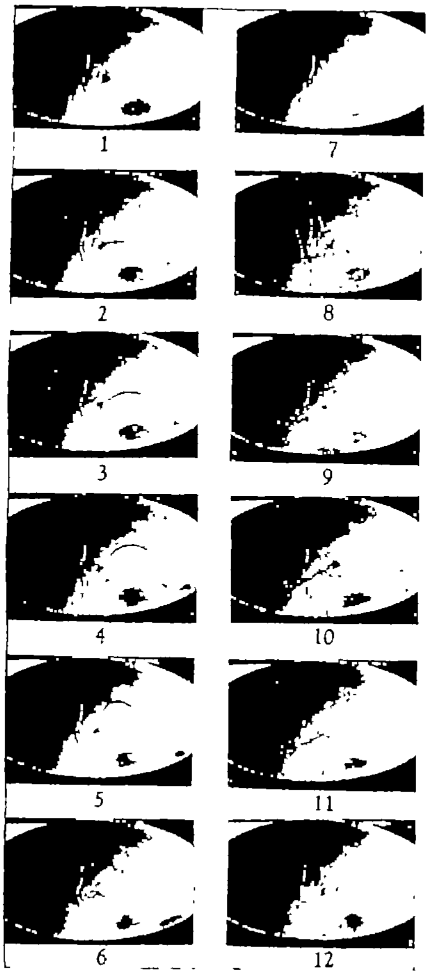

Fig. 1

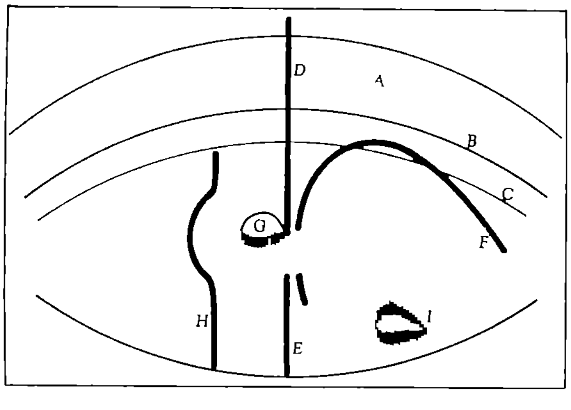

Fig. 2. *A*, wall of the evaporating dish; *B*, edge of the surface of the solution in the dish; *C*, reflexion of the rim of the dish in the liquid surface; *D*, liquid stream entering the dish; *E*, reflexion of the stream in the surface; *F*, bouncing liquid stream; *G*, 'heap' formed where the stream enters the liquid; *H*, reflexion, in the surface, of the stand used to hold the flask from which the liquid is being poured; *I*, shadow, on the bottom of the dish, of the 'heap' *G*

same diameter as the primary stream and its trajectory has a base of about 2 cm when the stream is fully developed.

I can offer no explanation for this behaviour, but it may be relevant to note that solutions of the type described are markedly non-Newtonian and visco-elastic, as shown by the work of Brodnyan, Gaskins and Philippoff[1]. It is tempting to speculate that when the 'heap' reaches a critical condition the primary stream effectively bounces off it, forming the secondary stream. The supply of liquid to the heap is thus cut off, and it therefore sinks into the main liquid surface, changing its shape and thus, perhaps, the trajectory of the secondary stream. When the heap has disappeared, 'normal' behaviour is resumed. The heap reforms and the cycle is repeated.

The phenomenon was first observed as the result of a chance observation, and no systematic investigation of the conditions necessary for its occurrence has been undertaken.

The particular solution used consisted of 5·8 g of *L*100 grade 'Vistanex' (Esso Petroleum Co., Ltd.) in 100 c.c. of 'Decalin'. The solution viscosity, measured in a concentric cylinder viscometer, was approximately 3·3 poise at a shear rate of 10 sec^{-1} and at 25° C.

Uranium (VI) – Chromotropic Acid Chelate

DISODIUM-1:8-dihydroxy naphthalene-3:6-disulphonate (trivial name chromotropic acid–sodium salt) yields coloured lakes with various cations[1]. Investigations of chelates of chromotropic acid with iron (III)[2] and titanium (IV)[3,4] have already been made. Sommer *et al.* have extensively examined chelates of titanium with chromotropic acid and various polyphenols[5–7] and have discussed the structure of the metal chelates. The use of chromotropic acid in the colorimetric determination of uranium[8,9] has also been reported.

Here, the composition and stability of the uranyl ion–chromotropic acid chelate have been examined by spectrophotometry.

Solutions of disodium-1:8-dihydroxy naphthalene-3:6-sulphonate were prepared and standardized by determining the sulphur content. Solutions of uranyl sulphate (B.D.H. AnalaR) were prepared by dissolving the salt in double distilled water, free from carbon dioxide. All solutions used were freshly prepared to avoid the effects of hydrolysis of the metal salt.

The spectrophotometric examination was made with a Unicam *SP* 500 spectrophotometer, with matched glass cells 10 mm thick. Measurements were made at 25° C and the *p*H of the solutions adjusted to 4·5 ± 0·2. *p*H measurements were carried out with a mains-operated Leeds and Northrup *p*H indicator with a glass–calomel electrode system.

Examination by the method of Vosburgh and Cooper[10] showed that the complex species in mixtures containing varying proportions of the reactants is identical, having a λ_{max} at 435 mμ.

To examine the stoichiometry of the components the method of continuous variations was used, the total volume in each case being kept constant at 50 ml. The absorbances were measured at two different wave-lengths of 435 and 445 mμ. The plot between the differences in absorbance of the mixtures and that which would have been shown by the chelating agent alone, if no chelation occurred against the composition of the mixture, showed a composition of 1:1 for the chelate. Some typical observations are plotted in Fig. 1.

In the legend (Fig. 1) *c* represents the concentration of uranyl sulphate and *c′* the concentration of disodium-1:8-dihydroxy naphthalene-3:6-sulphonate, that is, $p = c'/c$.

The λ_{max} of 1:1 mixtures of uranyl sulphate and chromotropic acid lies at 435 mμ when the *p*H of the solutions are between 3·2 and 8·25.

The apparent stability constant of the uranyl–disodium-1:8-dihydroxy naphthalene-3:6-sulphonate, as calculated

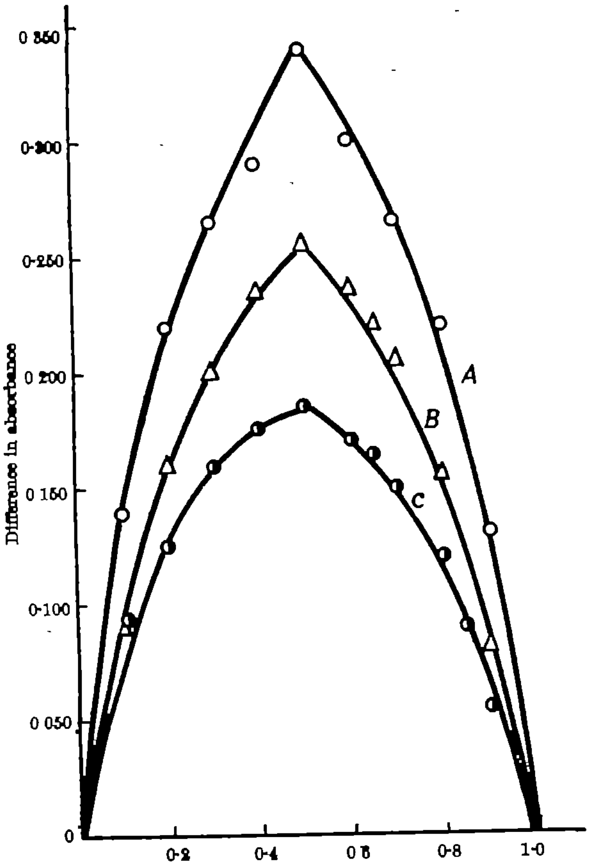

Fig. 1. Determination of the composition from absorption spectra studies at 435 mμ (equimolecular solutions). Curve *A*, $c = 2·0 \times 10^{-4}$ M, $p = 1$; curve *B*, $c = 1·33 \times 10^{-4}$ M, $p = 1$; curve *C*, $c = 1·0 \times 10^{-4}$ M, $p = 1$

from absorbance data using the method of Dey *et al.*[11], is 7·14 ± 0·11 at 25° C. The free energy of formation $\Delta F°$ of the chelate corresponds to −9·85 ± 0·15 cal. at 25° C.

Coding of Open and Closed Carbon Chains

IN a previous communication[1], a method of coding open-ended carbon chains was suggested, which amounted, in effect, to forming the autocorrelation function of the net. This code had the advantage of being nearly unambiguous, but suffered from the drawback that, while the code of any given net could be determined straightforwardly, the net corresponding to a given code could not. A. Savitsky has suggested (private communication) that, nevertheless, this code could be useful as a check; that is, if added to the usual chemical name of a given compound, this code could serve to verify whether the topology of the compound reconstructed from the name is the correct one.

If so used as a check, complete unambiguity is of lesser importance, and a probabilistic point of view can be adopted. Thus, if a C_n net can have $N(n)$ different possible configurations, and if there are $m(n)$ ambiguities, the probability that, once having reconstructed the incorrect configuration, the code of this configuration is identical to the code of the correct configuration can be written as:

$$p = \frac{2m}{N(N-1)}$$

With this fresh point of view, the question was then examined whether, when extending the code proposed to nets containing closed chains, the appreciable number of ambiguities encountered would still leave p tolerably small, and whether p would tend to decrease for increasing n.

The postulate was made, when making this extension, that rings of 5, 6 and 7 carbon atoms only would enter into consideration. The code was formed, in line with the procedure followed for open chains, by counting the number of pairs of carbon atoms at minimum distances 3, 4, etc.

Table 1

n	N	m	p	m_1	p_1
7	15	0	0	0	0
8	34	4	0·71%	0	0
9	85	13	0·36%	4	0·14%
10	220	50	0·21%	24	0·24%

The findings are summarized in Table 1 in which the number of ambiguities were counted as 1, 3, 6, etc., for the double, triple, quadruple, etc., occurrence of the same code. The conclusion, implicit in the fourth column, is that p exhibits a satisfactory tendency to decrease with increasing n.

When extended to closed chains, the location code, formed by counting, for any one carbon atom, the number of other carbon atoms at distances 1, 2, etc., appears to be less satisfactory for increasing numbers of atoms. The probability of determining an erroneous position having the same location code as the correct one, $p_1 = \frac{2m_1}{N\,n(n-1)}$ where m_1 designates the number of location ambiguities (not counting those due to the molecule symmetry) is indicated in the last column.

I thank Prof. A. I. M. Keulemans, who directed my attention to this problem, and Prof. C. Koningsberger for a discussion of the most reasonable postulates to be made for closed chains.

Existence of Two Soil Species in Detergency Investigations

ALTHOUGH a considerable amount of research has been devoted to the examination of detergency, little work has been done on rates of soil removal. Durham[1] has commented on the need for kinetic studies in detergency research. We have examined the kinetics of detergency in a model circulation cleaning system. In this model system a detergent solution (0·03 M sodium hydroxide) is pumped from a 50-gallon tank through a short length of 1½-in. diam. pipe in a closed system. Test strips of stainless steel 3·6 cm × 32 cm are soiled on one side with a very thin layer of pure synthetic tristearin labelled with carbon-14. The test strip is placed in the pipe, the detergent solution is pumped past the strip for a fixed time under closely controlled conditions after which the pipe is drained and the strip is removed. The amount of tristearin taken off the strip is found by measuring the radioactivity before and after each treatment. By means of repeated cleaning treatments on one strip, a cleaning curve is obtained.

A typical cleaning curve is shown in Fig. 1 where log tristearin (measured as counts per 10 min) is plotted against the number of 10-sec washings. Because of the contribution of a time-independent mechanism to the total cleaning[2], the abscissa units are number of washings rather than the time of washing. Cleaning curves obtained over a wide range of experimental conditions are of the same general shape as Fig. 1.

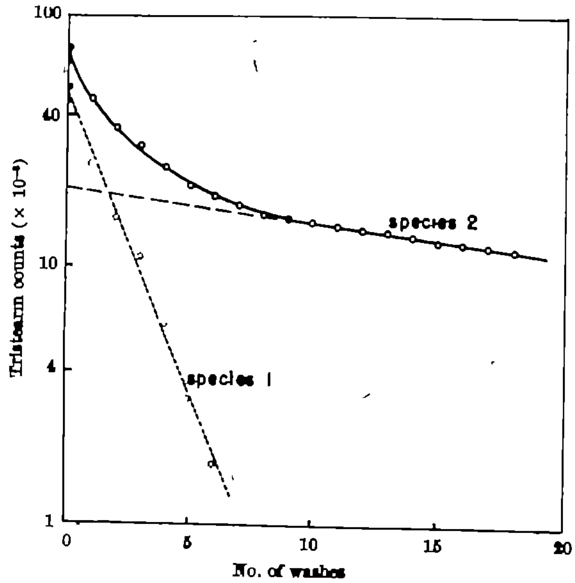

Fig. 1

The shape of the cleaning curve is similar to that obtained for the sum of two independent first-order processes occurring at different rates, for example, the over-all decay of a mixture of two radioisotopes, one with a much longer half life than the other. When the linear portion of the cleaning curve is extrapolated back to zero washes and the extrapolated line subtracted from the curve, the result is a second straight line with a much steeper slope. The line marked species 1 in Fig. 1 is obtained in this way.

This result could be explained by assuming that two species of tristearin are present, species 1 and species 2, each of which is removed from the surface independently and simultaneously by a first-order process, species 1 being removed much faster than species 2. Using kinetic theory:

$$\frac{-\mathrm{d}(A)}{\mathrm{d}t} = k_1(A), \text{ and } \frac{-\mathrm{d}(B)}{\mathrm{d}t} = k_2(B)$$

where (A) and (B) are the amounts of species 1 and 2 respectively at any given time, k_1 and k_2 are the rate constants and $k_1 > k_2$, t is the number of washes (constant time per wash).

Re-arranging and integrating gives:

$$\ln(A) = \ln(A_0) - k_1 t, \text{ and } \ln(B) = \ln(B_0) - k_2 t$$

where (A_0) and (B_0) are the amounts of species 1 and 2 at zero time. The total amount of tristearin present at a given time $= (A) + (B)$.

The experimental cleaning curve is described with a high degree of precision by the sum of the values of (A) and (B) for each value of t. From Fig. 1, for example, A_0, B_0, k_1, k_2 can be evaluated, giving the equations:

$$\ln(A) = 10{\cdot}88 - 0{\cdot}574t \text{ and, } \ln(B) = 9{\cdot}99 - 0{\cdot}0337t$$

It should be pointed out that the close agreement between the experimental cleaning curve and the sum of two independent simultaneous first-order processes is entirely empirical. There is no theory in existence at this time that would predict a relationship of this kind.

We have established that the existence of two soil species does not arise from impurity or polymorphism in the tristearin; that species 2 is not a mono-molecular layer; and that redeposition of the removed soil is highly unlikely. The proportion of species 2 is dependent on the thickness and age of the soil film, temperature of washing, and possibly other parameters that are unknown at this time, but it is not affected by the flow rate of the detergent solution. The effect of temperature, flow rate, and time of washing treatments on both rate constants k_1 and k_2 has been measured by the method described above.

Examination of the literature shows that the cleaning curves obtained by other workers using a wide variety of soils, surfaces, detergents and cleaning conditions are similar to Fig. 1 and could probably be reduced to the sum of two independent first-order reactions occurring simultaneously; a species 1 being removed at a fast rate and a species 2 being removed at a slow rate. We believe that this phenomenon is not restricted to thin films of tristearin on stainless steel but that two distinct soil species are present in most, if not all, thin soil films present on most surfaces. The nature of the forces that cause species 2 to be so resistant to removal from a surface can only be surmised at this time.

The existence of two soil species in variable proportions probably accounts for much of the variability that is encountered in detergency testing and research. Other problems of cleaning, such as the greying of textiles after repeated washings, might be explained by the gradual accumulation of the resistant species 2 soil.

This investigation was supported in part by research grant *EH* 176 of the U.S. Public Health Service.

RADIOCHEMISTRY

Viscosity of Single-stranded Deoxyribonucleic Acid after X-irradiation in the Native State

Several authors[1] have discussed the ionizing radiation which causes single-stranded as well as double-stranded breaks in DNA. The single-stranded breaks seem to occur more frequently. Butler's[2] observation that the loss in molecular weight due to radiation is more intensive after denaturation of DNA by heating confirms this idea. The work of Doty *et al.*[3] provides a method for separating the two DNA strands without further degradation of the polynucleotide chain. I used this method to study the radiosensitivity of the single strand DNA.

Calf thymus DNA was prepared according to the method of Kay *et al.*[4]. The intrinsic viscosity $[\eta]$ was determined at 21° C in 0·01 M sodium chloride using a four-bulb multigradient viscosimeter of the Ubbelohde type to allow an empirical extrapolation to zero gradient. Denaturation was completed within 10 min at 90° C followed by rapid chilling. The viscosity of native thymus DNA was 38·0 dl./g; the viscosity of the single strand DNA, 20·5. The DNA was irradiated in the native state (0·05 per cent in 0·01 M sodium chloride) and then denatured within 30 min. Fig. 1 shows the viscosity of the native DNA and that of the single strand one after irradiation as percentages of the control. The irradiation data are: 150-kV X-rays, 20 m.amp, filter : 2·0 mm aluminium, *FD*, 10 cm,

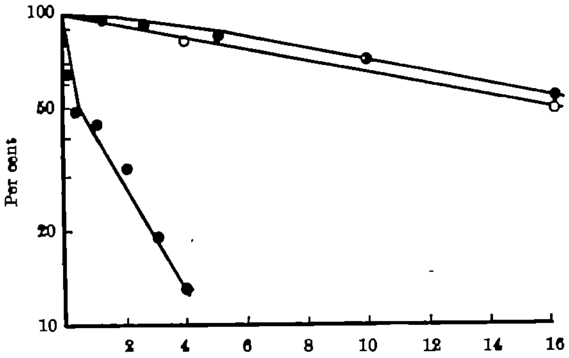

Fig. 1. Radiation effect on DNA as percentage of the control. Open circles, viscosity of native DNA; closed circles, viscosity of the single-stranded DNA; half-filled circles, breaking of the hydrogen bonds. 0·05 per cent DNA in 0·01 M sodium chloride

dose rate : 3,150 r./min). We also determined the amount of open hydrogen bonds in the native irradiated DNA according to a method described in an earlier article[5].

The viscosity of the native DNA and the hydrogen bonds between the two strands have nearly the same radiosensitivity; the D_{37} is about 30,000 r. After separation of the strands, however, the viscosity drops to 50 per cent after 500 r. The dose effect curve seems to have two components: one with D_{37} of 700 r., the other with D_{37} of 2,500 r. The two components of this curve may be discussed in a similar way as Latarjet *et al.*[6] did when considering the inactivation of the transforming factor in the DNA, where the D_{37}-values of the two components also have a ratio of 1 : 4 (1,000 and 4,000 kr.).

The breaks of the single strands are permanent in native DNA over a longer period. If the DNA is denatured only 24 h after irradiation of 500 r., the viscosity of the single strands decreases to 40 per cent of the control instead of 50 per cent. This means that there is a small 'after effect' of the irradiation.

If DNA is first denatured and then irradiated, the loss of viscosity is very small. After 1,000 r., no change of the viscosity was observed. The same effect has been described by Marmur *et al.*[7] after irradiation of DNA with ultra-violet light. The high sensitivity of the single nucleotide chain in native DNA might be explained by the fact that the target volume in the stiff double helix is larger than the target in the coiled single-stranded DNA.

RADIATION CHEMISTRY

Possible Radiation Damage Effects in Barium Chromate Crystals

BARIUM chromate obtained by the method elaborated in our laboratory[1–3] forms crystallites the shape of which depends on the kind of nucleus on which the crystallite has been formed. Under special conditions, for example, by fractional precipitation using the same method or by precipitation from dilute solutions, reagent grade potassium chromate produces sediments of prismatic-shaped barium chromate crystallites having a rhombic cross-section.

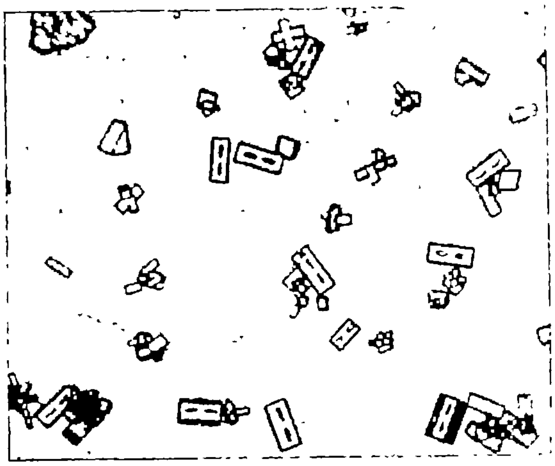

Fig. 1. × 400

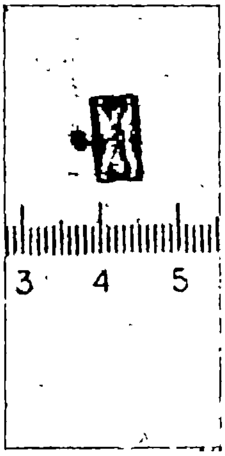

Fig. 2. × 400

Very often it has been observed that two elliptical 'gas bubbles' inside the prisms were formed. Crystallites of smaller size show two 'funnels' on the ends, instead of the 'bubbles', while others show only two or four dark points (Figs. 1 and 2). A similar feature was observed by us earlier, while precipitating barium chromate from solutions containing uranium and radium[4]. Observations described elsewhere[1,3] show that crystallites are formed on nuclei consisting of foreign substances. It is supposed that, in the case recorded here, barium chromate crystallizes on isomorphous radium chromate nuclei, traces of radium coming from uranium and thorium always present in chromite ores.

The radioactive decay of radium causes strong radiation damage effects similar to those described, for example, by Yoshida[5] and Vineyard[6]. The great energy of the decay as also the concentration of the source—that is, the crystal nucleus—produces effects sufficiently strong as to be visible by simple microscopical observation. Also it has been shown by us (by slightly levering the tube of the microscope) that the crystalline substance in the vicinity of the 'bubble' is of greater optical density and acts as a regular optical lens. These observations fit very well to the features of vacancies and interstitial formation as postulated for radioactivity effects in crystal lattices. The 'funnels' already mentioned have been observed on very small objects 5–7μ long. This fact seems to be in accordance with a similar effect described for uranium metal by Rogers and Adams[7].

In some experiments crystallites showing radiation damage effects have been obtained, where no further changes could be detected. In other cases crystallites of exactly the same shape showed no effects of this type. Differences, as such, can be ascribed to the different sizes of radium chromate nuclei, or to different radium isotopes present, that is, radium-224 ($t_{\frac{1}{2}}$ = 3·64 d.), radium-226 ($t_{\frac{1}{2}}$ = 1620 y.) and radium-228 ($t_{\frac{1}{2}}$ = 6·7 y.). The strongest damage is expected to be caused by radium-224. Many other observations made are in good accordance with the interpretation of facts presented here.

CERAMICS

A Simple Flame Fusion Apparatus

THE need for large single crystals of refractory oxides has been ever increasing in recent years. In many instances further technological advances are being hampered by the lack of materials of suitable purity and perfection. One of the major sources of contamination of materials prepared at high temperature is the container in which the material is heated. The flame fusion technique is one high-temperature crystal growth method which overcomes the container problem as the material under investigation acts as its own support. A rather complete review of the advantages, limitations, and operation of flame fusion furnaces is given by Popov[1] in a book edited by Shubnikov and Sheftal.

This communication describes a simple portable flame fusion apparatus which can be constructed in most laboratories with readily available materials.

The apparatus consists of three major components: (1) the feed hopper and burner assembly; (2) lowering mechanism; (3) the gas system. The usual feed hopper assembly consists of an outer and inner hopper. The inner hopper is fitted with a fine mesh sieve which is vibrated by a tapper mechanism for control of feed flow. A new design of a one-hopper feed assembly has been incorporated into a flame fusion apparatus. In this version continuous and uninterrupted feed rates are accomplished[2]. The feed hopper is designed such that commercially available burner assemblies can be used and interchanged with ease.

The pedestal on which the crystal is grown must be lowered at a rate equal to the growth rate of the crystal. In addition the rate of lowering must be variable to coincide with slow or rapid crystal growth. It is also very important that the lowering mechanism transmit as little vibration as possible to the growing crystal. A compact and versatile lowering mechanism was designed to eliminate the difficulties usually encountered. A variable-speed d.c. motor and a gear train system permit the growing boule to be lowered in the continuous range from zero to 4 in. per h. The lowering mechanism is equipped with an independently variable rotation mechanism which can rotate from a fraction to 100 r.p.m. by suitable choice of gears and motors. The housing for the lowering mechanism is shock mounted and can be positioned by means of a two-dimensional slide rest. A schematic diagram of the lowering and rotation mechanism is shown in Fig. 1.

VERTICAL DRIVE VARIABLE GEAR BOX

Fig. 1. Lowering mechanism

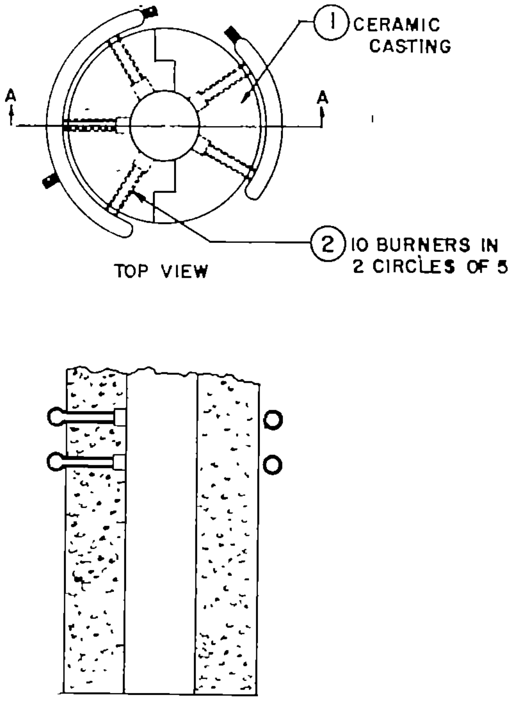

Fig. 2. Annealing furnace

A refractory furnace muffle with tongue and groove joints was cast from 33-*HD* alundum (Norton Refractories, Worcester, Mass.) to contain the heat source. An adaptation of this muffle has been designed as an annealing furnace to reduce the strains in growing boules by *in situ* annealing. This furnace consists of two rows of five burners each using oxy-hydrogen gas. The burners are positioned and the manifold cast in a refractory muffle as shown in Fig. 2.

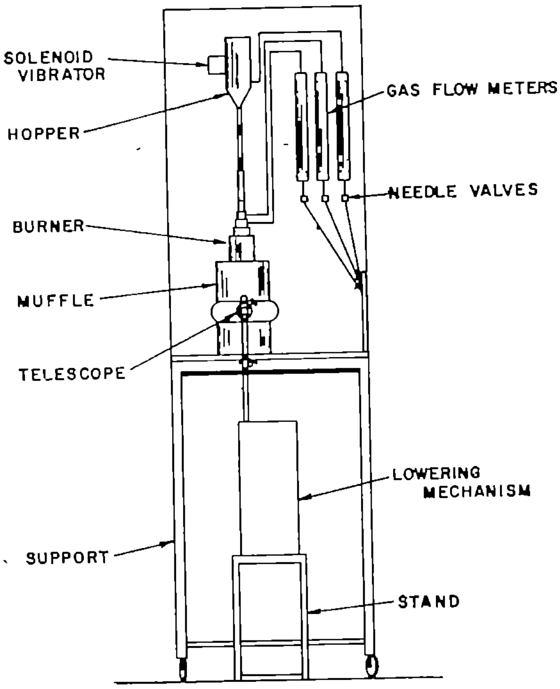

Fig. 3. Schematic drawing of apparatus

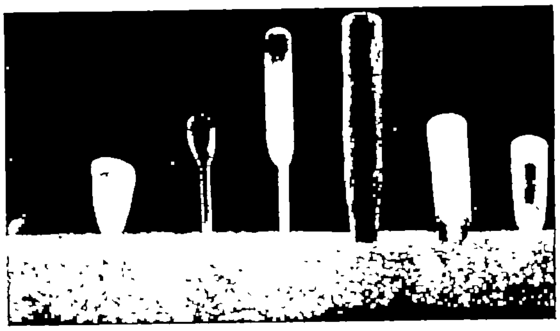

Fig 4. Photograph of typical boules

The entire apparatus is mounted on a portable frame which can be relocated with ease. The location of the flow meters, precision needle valves, feed assembly, burner, furnace muffle, telemicroscope and lowering mechanism are shown schematically in Fig. 3. The support frame is provided with casters and jack screws for purposes of relocation and levelling, respectively.

The apparatus has been used for preparing numerous crystals of refractory oxides including transition metal and rare earth oxide doped titanium dioxide, aluminium oxide and spinels.

Suitable titanium dioxide feed powder was prepared by calcination of the oxalate[3]. The transition metal impurities were added in the form of sulphates prior to calcination.

Cerium, chromium, iridium, iron, manganese, nickel, niobium, praseodymium, tantalum, vanadium, and yttrium in weight percentages of from 0·001 to 1 were successfully incorporated in titanium dioxide. Magnetic resonance investigations of some of these crystals are reported elsewhere[4].

Aluminium ammonium alum was calcined at 1,050° C to prepare a suitable aluminium oxide feed material. Reagent grade sulphate was added prior to calcination in the preparation of the spinels and doped spinels. Single crystals of $MgAl_2O_4$-Al_2O_3 : Cr^{3+} grown with this apparatus have been investigated[5].

A photograph of typical boules is shown in Fig. 4.

I thank Mr. Maxwell Hopkins for help in designing the lowering mechanism, and Messrs. E. Aleshin, R. F. Bates and R. Arlett, who assisted in the growth of some of the crystals.

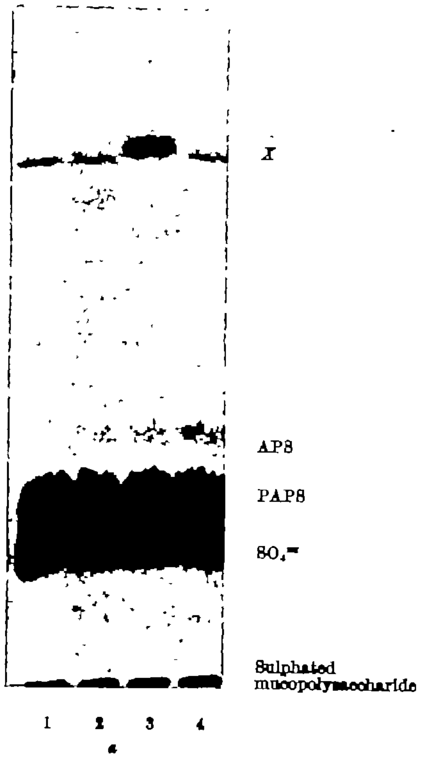
BIOCHEMISTRY

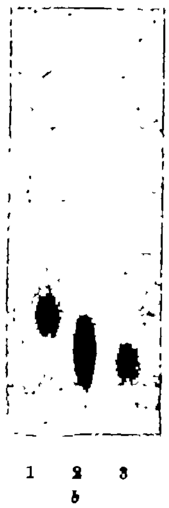
Presence of Œstrogen Sulphokinase in Chick Embryonic Cartilage

Enzymes capable of conjugating steroids to form the sulphate esters have been found only in the liver[1,2]. Although unfractionated liver preparations are able to sulphate a wide range of steroids, Nose and Lipmann[3] were able to separate an enzyme fraction which sulphated œstrone from one which sulphated dehydroisoandrosterone. A partial separation of the activities towards œstrone and *p*-nitrophenol was obtained. Results indicated that several rather specific steroid sulphokinases exist. Phenol sulphokinase, on the other hand, is relatively unspecific and has been found in such tissues as liver, kidney, intestinal mucosa and granulation tissue[4]. In the work reported here, extracts of chick embryonic cartilage were found capable of sulphating œstrogenic steroids but not a variety of other steroids tested.

During a study of the $[^{35}S]$ sulphate metabolism of cartilage derived from chick embryos, calf embryos and a human chondrosarcoma, extracts of each of these tissues activated the $[^{35}S]$ sulphate to adenosine-3′-phosphate 5′-sulphatophosphate and transferred the sulphate group to exogenous phenol or *p*-nitrophenol. This was shown by comparison with authentic material in a number of solvent systems. When incubated with steroids and chromatographed, the chick cartilage extract alone was capable of forming new $[^{35}S]$ sulphate ester zones in certain cases. Of the steroids tested, œstrone, α-œstradiol and œstriol were sulphated, but pregnan-3α,20α-diol, dehydroisoandrosterone, androsterone, testosterone and cortisone were not affected (Fig. 1). Active enzyme was found in the condyles of the tibias and femurs and also in the sternum of 15-day-old chick embryos. Extracts of condyle and costal cartilage of 12-week-old calf embryos and the cartilage matrix of a human chondrosarcoma arising in the sternum were inactive.

The zone *X*, present in the control of Fig. 1*a*, was found to be formed by a wide range of tissue extracts on incubation with $[^{35}S]$ sulphate. Its properties will be described in greater detail elsewhere[5]. An increase in the level of radioactivity was found in this zone in chromatograms of incubations containing œstrone and α-œstradiol. Œstriol gave a new zone with a lower R_F. All the other steroids gave autoradiographic patterns identical to the control. The radioactive material in the *X* zones, from chromatograms of incubations containing œstrone and α-œstradiol, were eluted and re-chromatographed in solvent 3 of Schneider and Lewbart[6]. This demonstrated that a new radioactive species had been formed in the presence of the steroids (Fig. 1*b*). Corresponding eluates of *X* zones, from incubations with mammalian cartilage extracts in the presence and absence of œstrone, are shown in Fig. 1*c* for comparison. Radioactivity in the œstrone sulphate position is absent in this case. Proof that the radioactive component, formed in the presence of œstrone, was the sulphate ester was obtained by two-dimensional co-chromatography with authentic material. The autoradiograph and the chemical stain, as revealed by spraying with Zimmerman reagent, were exactly superimposable. When incubation mixtures containing œstriol were subjected to two-dimensional chromatography in the system described by Bostrom[7] for studying $[^{35}S]$ sulphate metabolites in urine, the results shown in Fig. 2 were obtained. An additional $[^{35}S]$ zone is obtained in the presence of œstriol and is in the 'steroid sulphate' region of the chromatogram. In addition, it is in the exact position for œstriol sulphate, relative to œstrone sulphate, as depicted by Bostrom in work with $[^{35}S]$ steroid sulphates formed by rat liver[7].





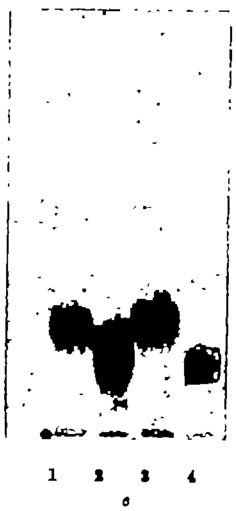


Fig. 1a. Autoradiograph of chromatogram of incubation mixture in isobutyric acid, 0·5 N ammonium hydroxide (5 : 3). The mixture contained ATP, 5 μmoles; $MgCl_2$, 6 μmoles; *tris* buffer, pH 8·2, 60 μmoles; carrier-free $[^{35}S]$ sulphate, 25 μc. and high-speed chick embryonic cartilage extract, 0·2 ml in a total volume of 0·7 ml.[11]. Steroid, 0·5 μmole was added as an alcoholic solution to the empty tube and evaporated prior to addition of the other components. 1. Control. 2. Addition of œstriol. 3. Addition of œstrone or α-œstradiol. 4. Addition of other steroids mentioned in text

Fig. 1b. Autoradiograph of eluates of *X* zones from chromatograms shown in Fig. 1a. Chromatography carried out in ethyl acetate, *n*-butanol, conc. ammonia, water (180 : 20 : 20 : 180) (ref. 6). 1. Control. 2. Incubations containing œstrone. 3. Incubations containing α-œstradiol

Fig. 1c. As for Fig. 1b. 1. *X* zone from control using chick cartilage extract. 2. *X* zone from chick cartilage and œstrone. 3. *X* zone from chondrosarcoma or calf embryonic cartilage extracts and œstrone. 4. Authentic œstrone sulphate

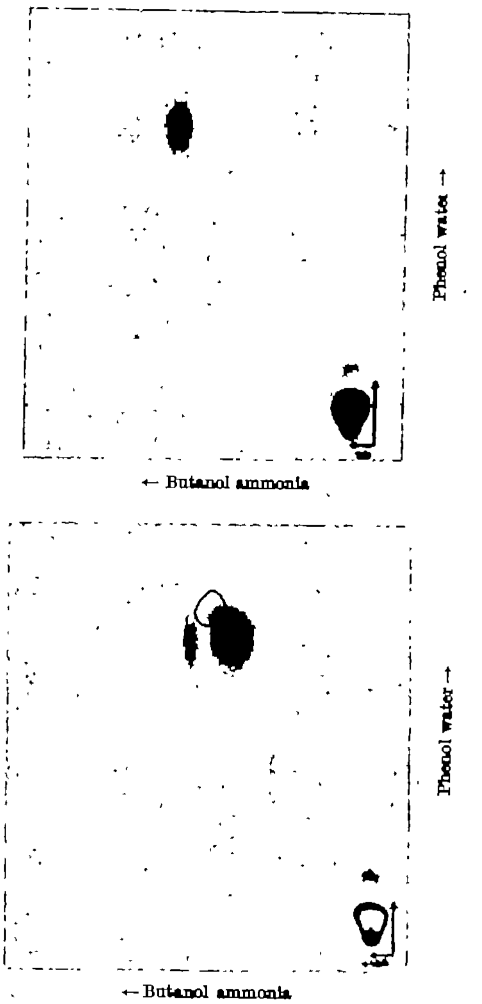

Fig. 2. Autoradiographs of two-dimensional chromatograms of incubation mixtures given in Fig. 1a. Top: control. Bottom: incubation containing œstriol. The circle outlines the position of authentic œstrone sulphate

In mammalian cartilage extracts, the ability to sulphate simple phenols and the inability to sulphate phenolic steroids very probably indicate that two separate enzymes are responsible for sulphating the phenolic group of these two classes of compounds[8]. The presence in the chick cartilage of an enzyme system capable of sulphating steroids is the first instance of such activity in a tissue other than liver. This unique behaviour of chick cartilage in its effect on the phenolic steroids could mean that the phenol sulphokinase of this species is capable of conjugating a wider spectrum of phenols than is the case with the mammalian enzyme. Alternatively, a specific phenolic steroid sulphokinase may be present. Although conjugation is generally believed to 'detoxify' or result in loss of the physiological activity of steroids, œstrone sulphate has been reported to be biologically active[9]. While this has been quoted as evidence for steroid sulphatase activity *in vivo*[10], Roy is of the opinion that this view is premature and there is nothing against the idea that such steroid sulphates might be active *per se*[4]. Some debate would then surround the proposal that œstrogen sulphokinase in chick cartilage plays the part of controlling the level of free physiologically active steroid by converting it into a water soluble form.

I thank K. N. Wynne for helpful discussion.

Separation of Polypeptides bound by Albumin in Human Plasma

THE role of plasma albumin in maintaining oncotic pressure is generally known, but its significance as a potent binder of other substances is little appreciated. In addition to binding and transporting materials such as steroids, bilirubin, fatty acids, hormones, and dyes[1], albumin may similarly distribute many biologically important polypeptides. Therefore, the hypoalbuminæmia of certain disease states, including uræmia, hepatic failure, and chronic infection, may be associated with diminished transport of polypeptides to their sites of action and detoxification.

Groups of polypeptides bound to plasma albumin have not been demonstrated previously. This communication describes the separation of such a group.

Blood from normal subjects and uræmic patients was collected, under ice, in plastic bags containing the anti-coagulant, disodium ethylenediaminetetraacetate. It was centrifuged immediately at 4° C. The plasma thus separated, in amounts of 130–200 ml, was dialysed against a volatile buffer, triethylamine/acetic acid (TEA), at starting *p*H 9·0–9·3 at 4° C for 16 h to remove all unbound dialysable substances including electrolytes. Albumin, more than 95 per cent pure and unchanged electrophoretically, was separated by continuous-flow paper electrophoresis at 580–620 V (ref. 2). Less than 5 per cent α-1 globulin was also present.

The albumin was then redialysed against the TEA buffer for 24 h and the dialysate concentrated under vacuum, lyophilized, and saved for later chromatography. This specimen served as the chromatography control for materials liberated by acidification of the albumin. The albumin was then dialysed against 1 N acetic acid for two 24-h periods and the dialysates again concentrated under vacuum, lyophilized, and saved for chromatography.

By Folin-Lowry protein test[3] and ultra-violet absorption at 280 mμ, differences were found between the acetic acid dialysates and control specimens. In successive 24-h dialyses, progressively smaller amounts of peptide material were liberated. By these tests, acetic acid dialysates contained up to 10 per cent protein material per gram of albumin whereas the control samples contained a negligible quantity.

Ascending chromatography of these samples was performed with a butanol/acetic acid/water solvent in proportions of 4 : 1 : 5; Whatman number 3 paper; a 16-h time period; and amidoschwarz, Reindel-Hoppe protein[4], and ninhydrin stains. The acetic acid dialysates differed significantly from control specimens. Better separation of the constituents was achieved using high-voltage electrophoresis for 3 h at 3,000 V, using a 3 per cent ammonium carbonate buffer (Fig. 1). Since these substances are dialysable, give a protein reaction, absorb ultra-violet light at wave-length 280 mμ, stain with amidoschwarz, and on hydrolysis show an amino-acid pattern, it is concluded that they are polypeptides.

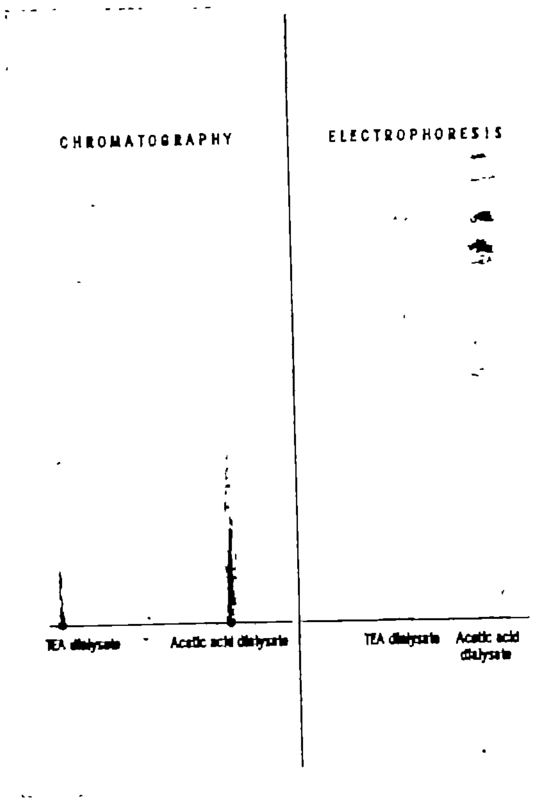

Fig. 1 Chromatographically, a significant difference is noted between substances liberated by acetic acid treatment and that obtained by dialysis against the basic TEA buffer. Better definition is achieved when the acetic acid dialysate is subjected to high-voltage electrophoresis. On this retouched figure from a normal subject, staining of the specimens is with amidoschwarz. Grossly, the patterns obtained from normals and uræmics appeared similar

Treatment with acetic acid at *p*H 2–3 converts albumin from its usual configuration to its expanded form[5], and binding sites are exposed and disrupted. The release of bound peptides by exposure to low *p*H is therefore not unexpected. It is necessary, however, to exclude the possibility that the peptides detected after acid treatment arose from proteolytic degradation of albumin itself. The amino-acid composition of the dialysable material is quite distinct from the overall amino-acid composition of albumin; but this does not disprove selective rupture of labile bonds. Analysis of the sedimentation diagrams of the albumin, however, gave no evidence of heterogeneity of the protein; that is, no dimers or fragments were detectable either before or after dialysis against acetic acid. The sedimentation coefficient of the albumin was 2 per cent lower (4·0 svedbergs) after treatment with acid, but this difference is not necessarily significant since the variation is within the range of experimental accuracy. The diffusion coefficient, derived from the sedimentation schlieren pattern[6], was not changed significantly. The molecular weight of albumin before and after acid treatment was approximately 67,000 Electrophoretic diagrams of the albumin before and after acid treatment also gave no evidence of molecular heterogeneity. There is, therefore, no reason for believing that hydrolytic or proteolytic degradation of the albumin molecules occurs. Finally, failure of serial microbiological studies to reveal bacterial growth excluded this possible cause of albumin breakdown.

The biological significance of these bound polypeptides remains undefined. Work now in progress on normal and abnormal subjects aims at comparing polypeptide patterns by 'fingerprint technique', and to determine their amino-acid composition.

This work was supported, in part, by grants from the American Heart Association, the Health Research Council of the City of New York (contract *U*-1022), and the U.S. Public Health Service (*H*-4148). Acid Phosphatase and Catheptic Activity in Rheumatoid Synovial Tissue

Acid phosphatase and cathepsin are two of the hydrolytic enzymes shown by de Duve[1] to be present in the lysosomal fraction of liver, and similar particles have been shown in many other tissues[2]. Increases in lysosomal enzymes have been shown to be present in cases of rapid tissue breakdown[3,4]. The synovial tissue in a rheumatoid arthritic patient may proliferate rapidly, forming many villi, and can extend as the so-called pannus tissue growing over the articular cartilage. When this pannus tissue forms, erosion of the cartilage takes place. An increase in enzymes of the lysosomal type might therefore be expected in rheumatoid tissue.

Rheumatoid synovia were obtained from patients undergoing synovectomy of the knee. For comparison 'normal' synovia were obtained from patients undergoing menisectomy. Each synovium was separated from the fatty underlayer of tissue and frozen over solid carbon dioxide. While frozen, the tissue was chopped finely and weighed. A representative sample was used after appropriate treatment[5] for deoxyribonucleic acid phosphorus[6] (DNAP) and ribonucleic acid phosphorus[6] (RNAP) determination and the remainder homogenized in ice-cold water. The homogenate was spun at 4° C for 15 min at 12,000 r.p.m. The nitrogen content of the residue and acid phosphatase and catheptic activities of the supernatant were determined[7-9].

The choice of a basis for comparing enzyme activities in proliferating heterogeneous tissue such as synovium is difficult. Consequently, results are expressed on a DNAP, RNAP and nitrogen basis as well as wet weight. The DNAP/g wet weight in rheumatoid synovia is 284·5 ± 14·67 g while that for normal is 65·85 ± 6·81 g; the RNAP-level is 184·7 ± 11·24 g and 79·07 ± 7·10 g respectively. Thus in the proliferating tissue the ratio of nuclear material to cytoplasm is doubled.

Table 1

Catheptic activity at *p*H 3·6 (10^{-4} m.equiv. tyrosine released in 20 min ± *S.E.*) of synovial tissue
Substrate haemoglobin

	per g wet weight	per mg N	per μg RNAP	per μg DNAP
Normal (6)	21·45 ± 6·43	1·36 ± 0·35	0·26 ± 0·070	0·34 ± 0·11
Rheumatoid (8)	84·29 ± 11·31	6·57 ± 0·93	0 47 ± 0·070	0·31 ± 0·03

Acid phosphatase activity at *p*H 5 (μg phosphorus released in 20 min ± *S.E.*) of synovial tissue
Substrate β glycerophosphate

	per g wet weight	per mg N	per μg RNAP	per μg DNAP
Normal (6)	67·73 ± 12·23	5·82 ± 2·31	0·92 ± 0·22	1·13 ± 0·28
Rheumatoid (8)	647·32 ± 57·54	50·50 ± 5·30	3·70 ± 0·54	2·34 ± 0·31

No. of tissues in brackets.

Increases in the concentration of both enzymes were found irrespective of the basis for comparison except in the case of cathepsin/μg DNAP (Table 1).

Significant increases in two hydrolytic enzymes which could cause the breakdown of tissues if released in an active form have thus been demonstrated in rheumatoid synovia. No attempt was made to differentiate between bound and free enzyme activity as synovial tissue is difficult to homogenize and the subcellular particles are damaged. If these enzymes are normally enclosed in lysosomal particles in synovial tissue a high free activity might be expected in rheumatoid tissue as the lactic acid production is high[10] and low *p*H values cause rupture of lysosomal walls[2]. An added factor may be that of increased local joint temperature during the inflammatory process[11], as both lysosomal membranes[12] and collagen[4] are known to be affected by increased temperature.

Optimal Conditions and Comparative Effectiveness of Dimethyl Sulphoxide and Polyvinylpyrrolidone in Preservation of Bone Marrow

The growing interest in dimethyl sulphoxide (DMSO) as an effective additive in low-temperature preservation of bone marrow prompted us to gather more information on the optimal conditions of its protective action. Several factors were examined: the concentration of the protective additive in the freezing medium, the length of the equilibration period of the cells with the additive at 0° C and at room temperature, and the toxicity of DMSO to bone marrow. A series of parallel experiments with polyvinylpyrrolidone (PVP) was conducted to compare its effects with those of DMSO in the preservation of bone marrow.

Bone marrow cells were obtained from the femurs of rats of an inbred Long-Evans strain 6–8 months old. The marrow was homogenized by aspiration with a syringe, strained, and the cells suspended in Hanks's tissue culture medium. After dividing the suspension into a number of equal parts, each part was centrifuged and resuspended in 1 ml. of the freezing medium consisting of various concentrations of DMSO in Hanks's solution, and of 10 per cent (w/v) PVP in Hanks's solution. The preparations were either frozen immediately or kept for various lengths of time at 0° C or at room temperature and then frozen. The freezing was done in accordance with our previous procedure[1], the cooling rate being 1° C/min and ice formation initiated at $-5°$ C by seeding. After the temperature reached $-25°$ C the preparations were transferred to an alcohol bath at $-79°$ C for 30 min. They were rapidly thawed by immersion into a water bath at 37° C. Immediately afterwards the preparations were washed by diluting with 4 ml. of Hanks's solution and centrifuging for 5 min at 900 r.p.m. The cells were resuspended in Hanks's culturing medium containing 10 per cent PVP and 33 per cent rat serum. The culturing and the assessment of cell viability by phase microscopy was carried out in accordance with our previous technique[1].

When various concentrations of DMSO were examined in the preservation of bone marrow, it was found that 10 per cent (v/v) offered the optimum protection, the cell survival being over 50 per cent. The viability declines sharply with slightly lower (7·5 per cent) or higher (12·5 per cent) concentrations (Fig. 1). Much lower viability was obtained with both 5 and 15 per cent.

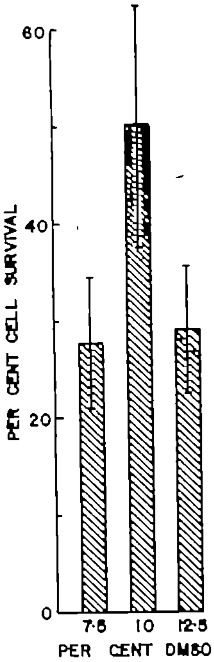

Fig 1. Effect of various concentrations of dimethyl sulphoxide on cell survival after freezing, vertical lines representing standard errors

To determine the optimal equilibration period of the cells with the additive, the cells were suspended in 10 per cent DMSO and either frozen immediately or after 10-, 30-, or 60-min exposure both at 0° C and at room temperature (Fig. 2). The exposure for 10 min at 0° C prior to freezing allows sufficient permeation of the additive into the cells to yield the optimal viability. Longer exposure lowers the cell viability; exposing the cells at room temperature decreases viability more than that at 0° C.

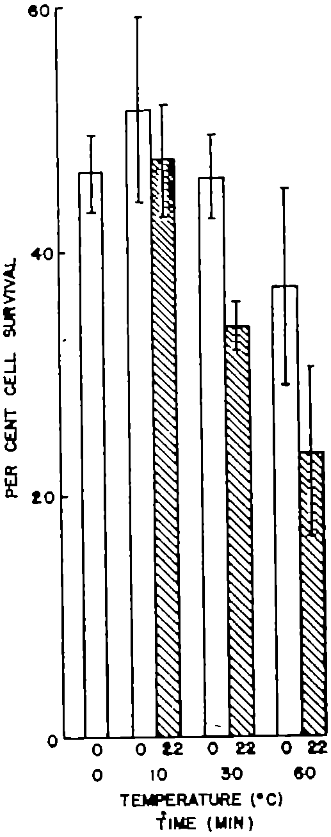

Fig. 2. Optimal exposure time of bone marrow cells to dimethyl sulphoxide (10 per cent) prior to freezing at 0° C and 22° C, vertical lines representing standard errors

The toxicity of DMSO was studied by addition of 0·1, 0·5, 1·0, 3·0, and 5·0 per cent (v/v) DMSO into the culturing medium in which the cells were then incubated for 24 h. We found a progressive decrease in the number of viable cells with increasing concentration of the compound. The bar graph in Fig. 3 shows that 3·0 per cent is much more toxic than 0·1 per cent DMSO, the viability being, respectively, 3 and 44 per cent. No cells survived a 24-h period of incubation with a 5 per cent concentration of this compound. When cells were subjected to a short period (10 min) of exposure to 10 per cent DMSO at 0° C and

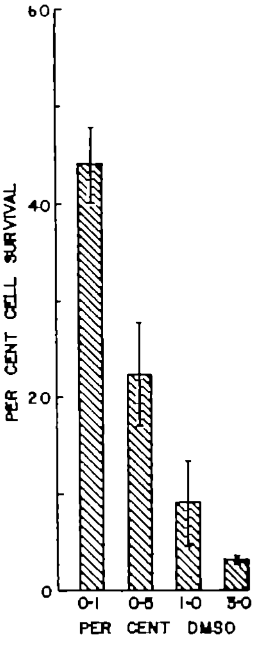

Fig. 3. Toxic effect of various concentrations of dimethyl sulphoxide in bone marrow culture after 24 h of incubation, vertical lines representing standard errors

then washed and cultured, only 70 per cent of the cells remained viable.

In discussing the results of this work, the average cell recovery value of 50 per cent obtained here with DMSO under optimal conditions and based on our method of assaying by tissue culturing and phase microscopy[1] is in close agreement with the results reported by Ashwood-Smith[2], according to which, bone marrow retained 50 per cent ability to synthesize proteins and lipids after being preserved with DMSO.

Our study indicates the considerable toxicity of DMSO to bone marrow cells. When the optimum equilibration time of 10 min (Fig. 2) was studied for its toxic effect, this short period of contact with DMSO reduced the viability of unfrozen cells by 30 per cent when compared with untreated cells. The decline of viability after freezing from the optimal value of 50 per cent when equilibration periods longer than 10 min are used is apparently due to the toxic effect of DMSO. The toxicity of this compound must be responsible for the sharp decrease of cell viability after preservation with DMSO in concentrations higher than 10 per cent (Fig. 1). This toxicity necessitates either the prompt removal of DMSO from the preparation after thawing, or dilution, or immediate administration to the recipient, which results in a rapid dilution of DMSO to a non-toxic concentration.

In comparing DMSO to PVP as a preservative, we found no sharp decrease in viability with an increase of PVP concentration from 10 to 20 per cent (w/v). The broader optimal range is perhaps indicative of the non-toxicity of PVP; the optimum concentration of PVP, however, is 10 per cent. An equilibration period with PVP is unnecessary since it is an extracellular preservative, as was shown in our previous communication[3]. This is substantiated in this investigation by the fact that there is no difference in viability whether the preparations treated with PVP were frozen immediately or after several hours of exposure. The prolonged exposure to PVP has no toxic effects such as those found with DMSO. When 10 per cent PVP is present in the tissue culturing medium there is no detectable decrease in cell viability after 24 h. Since PVP is non-toxic, there is no need to remove it from the preparation after thawing.

In conclusion, regarding the optimum recovery of cells after freezing with both preservatives, although DMSO offers, on the average, 50 per cent survival as compared with 30 per cent attained with PVP, there is a much larger variability range in the protective action of DMSO than that of PVP. We feel that, because of the many precautions which must be exercised with DMSO that are not necessary with PVP, the latter additive is simpler to handle and the results with it are more predictable.

Immunoelectrophoretic Characterization of Proteolytic Enzymes

THE detection of proteolytic activity after electrophoresis in agar gel has been described previously[1,2]. It has been shown with a number of hydrolytic enzymes[3] that the precipitation lines formed by the antigen–antibody reaction after immunoelectrophoresis in agar gel exhibit enzymatic activity. This enzymatic activity can be demonstrated qualitatively after washing and drying the slides in the usual way by utilizing conventional histochemical techniques.

The analysis of proteolytic activity by the usual staining procedures frequently reveals the substrate as well as the enzyme since both are usually proteins or protein-like substances.

The method reported here is based on the principle that the proteolytic enzyme located in a specific antigen–antibody arc will degrade an appropriate substrate on a second slide when the latter is superimposed so that the two agar surfaces are contiguous. After incubation the indicator slide is removed and stained in the usual way. The area of enzymatic activity is revealed as a clear zone against a dark background. Thus, precise correlation of a specific antigen–antibody arc with its enzymatic activity is achieved.

Using a crude mixture of human urinary macromolecular components and serum antibodies produced by rabbits against these components, a wide variety of precipitation lines was demonstrable when the modified microscopic slide method of Scheidegger[4] was used (Fig. 1, slide *A*). After 3 days of washing in 0·9 per cent sodium chloride to remove excess proteins, the slide was immersed in glycine–hydrochloric acid buffer *p*H 2·0 for 15 min. At the same time, a saline agar slide was kept for 30 min in a solution containing 1 per cent hæmoglobin in 0·1 M glycine–hydrochloric acid buffer *p*H 2·0 (Fig. 1, slide *B*).

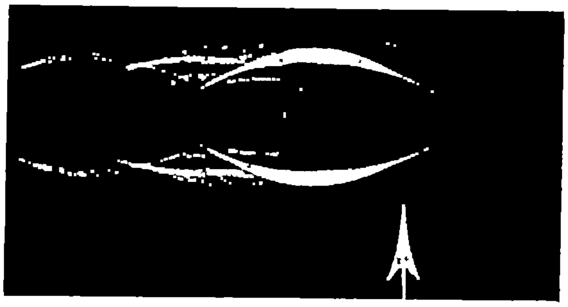

Fig. 1. Slide *A*—Agar immunoelectrophoresis after two days development. Veronal buffer $\mu = 0{\cdot}05$, *p*H 8·2, 7 V/cm, 1 h. Origin: Crude mixture of human urinary macromolecules. Trench: Rabbit serum antibodies against these macromolecules. Arc with arrow corresponds to arc of slide *B* exhibiting proteolytic activity

Slide *B* (Fig. 1) was then placed carefully on to slide *A*, agar-to-agar, so that a uniform and tight contact between the surfaces of the agar layers was obtained. The slide 'sandwich' was incubated in a moist chamber for 1 h. The slides were then separated and fixed for 2 h in 50 per cent ethanol containing 5 per cent acetic acid. Finally the plates were stained with amido black.

The result is shown in Fig. 2, slide *B*. The transparent arc indicating digestion of the hæmoglobin corresponds, when matched with slide *A*, to the location and shape of the arc marked with an arrow in Fig. 1.

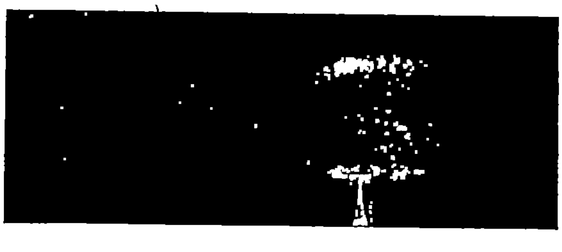

Fig. 2. Mirror image of slide *B* stained with amido black as explained in text after incubation. Demonstration of proteolytic activity by transparent area against evenly dark background

The same slide *A* can be re-used by repeating this 'sandwich' technique. Work is in progress to apply this method to the demonstration of other enzymes.

PHYSIOLOGY

Activity of Fusimotor Fibres Innervating Muscle Spindles in the Intercostal Muscles of the Cat

IT has been shown that thoracic motoneurones are monosynaptically excited by the lowest threshold afferents in the intercostal nerves[1]. These afferents are assumed to arise from primary endings of the muscle spindles present in cat intercostal[2] muscles. The intercostal muscle spindles are shown here to be regulated through their fusimotor fibres by a central control closely resembling that which governs the activity of alpha respiratory motoneurones.

The sensory and motor innervation of the external (inspiratory) and internal (expiratory) intercostal muscles is through separate nerves which provide fine filaments (0·1–0·2 mm diam.) to their respective muscles[1]. These filaments contain large and small-diameter myelinated fibres (Fig. 1*A*). The filament in Fig. 1*B* is from an intercostal nerve de-afferented by dorsal root section distal to the dorsal root ganglion; both large and small diameter motor fibres are present. In the main intercostal nerve from which the filament in *B* arises, there were two groups of fibres ranging from 2–7μ and 10–18μ in diameter, with peaks at 5μ and 13μ respectively. As for limb muscle nerves[3], this bi-modal distribution is related to the presence of muscle spindles.

Cats were lightly anæsthetized with sodium pentobarbital or urethane and chloralose and recording was made of the efferent discharges present in more than 60 isolated filaments that innervated either the external ('inspiratory nerve filament') or internal ('expiratory nerve filament') intercostal muscles (*Th* 4–*Th* 11). Recordings from expiratory nerve filaments are shown in Fig. 2*A*, *B*, and *C*, and from an inspiratory filament in *D*. Spikes of two distinct sizes are present, and the frequency and pattern of these two types of discharge showed characteristic differences. In the expiratory filaments, the small spikes fired either periodically during the expiratory pause (*A*) or continuously throughout the entire respiratory cycle (*B* and *C*). In this latter case the frequency immediately increased at the onset of the expiratory pause as seen in *B*, where a single small spike fired at approximately 6 imp./sec in mid-inspiration and accelerated to 25–30 imp./sec towards the end of expiration, and in *D* where the frequency of the small spike approximately doubled from 50–100 imp./sec; progressive recruitment of small spikes throughout the expiratory pause is also common. Almost invariably, the onset of large spike activity occurred much later in the expiratory pause, and the maximum discharge frequency ranging from 8–12 imp./sec, as in *A*, *B* and *C*, was usually much lower than that of the small spikes. Small and large spikes are also present in inspiratory nerve filaments, but in contrast their periodic activation or their periodic acceleration in frequency, as seen in Fig. 2*D*, always occurred in inspiration, the onset of small spike activity usually preceding that of the large spikes. Although other patterns of activity were seen in quiet respiration, due principally to different levels of anæsthesia, the expiratory and inspiratory phasing of the activity in filaments innervating the internal and external intercostal muscles respectively was an invariable finding.

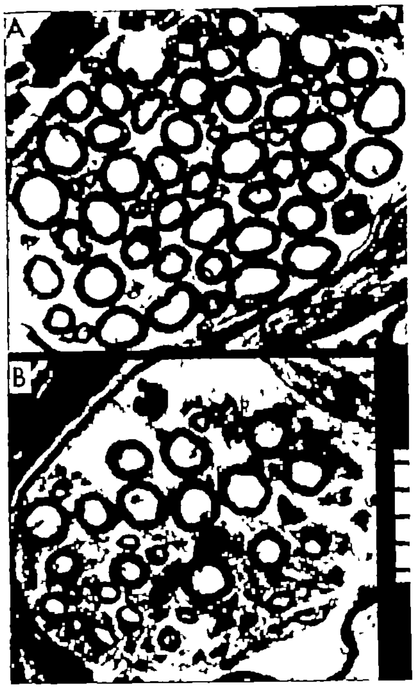

Fig. 1. *A*, Transverse section of normal 'expiratory nerve filament' (*Th*. 8) stained by the Flemming–Wolter method, as described by Williams and Wendell-Smith (ref. 7); *B*, 'expiratory nerve filament' (*Th*. 8) de-afferented by section of the dorsal roots distal to the ganglion 34 days previously, same animal as in *A*, contralateral nerve (scale 10μ)

As the recordings were made from whole, naturally occurring nerve filaments, it is assumed, following Hunt[4], that the direct relation between spike height and fibre diameter[5] is preserved and that the small and large spikes arise in fibres belonging to the groups of small and large

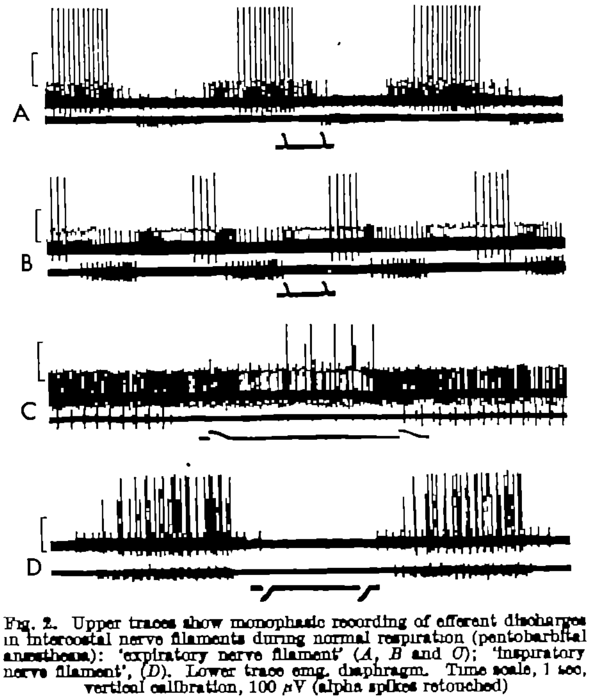

Fig. 2. Upper traces show monophasic recording of efferent discharges in intercostal nerve filaments during normal respiration (pentobarbital anæsthesia): 'expiratory nerve filament' (*A*, *B* and *C*); 'inspiratory nerve filament', (*D*). Lower trace emg. diaphragm. Time scale, 1 sec, vertical calibration, 100 μV (alpha spikes retouched)

diameter fibres demonstrated histologically. In other experiments it was shown electromyographically that the activity of motor units correlated only with the activity of the large spikes in the nerve recordings, hence it is concluded that the small spikes must arise in fusimotor fibres. Other significant findings were: (1) Inhalation of carbon dioxide enhances and hyperventilation abolishes the periodic discharge of alpha and fusimotor fibres, although during artificial respiration the large spikes of the expiratory filaments may be activated with each inflation of the lungs due presumably to a proprioceptive reflex activated by stretch. (2) The activity of both alpha and fusimotor fibres in inspiratory and expiratory nerve filaments respectively is augmented during the 'inspiratory' and 'expiratory' activating reflexes of Hering and Breuer. (3) The periodic activity of fusimotor fibres is not dependent on thoracic movements since it persists in the 'Flaxedil'-paralysed preparation not being respired artificially, and also after dorsal root section. Dorsal root section does, however, abolish the activity of some large spikes, even in quiet respiration.

Recently, Critchlow and Euler[6] obtained indirect evidence of a tonic and periodic modulation of intercostal fusimotor fibre activity which they attributed to a spinal reflex initiated by movements of the thoracic wall. This is not the conclusion reached here, where direct recording of inspiratory and expiratory intercostal fusimotor fibre activity has shown it to be controlled by a central mechanism closely resembling that regulating alpha respiratory motoneurones.

The significance of this central control is seen as follows. Failure of the extrafusal muscle fibres to shorten at the same rate as the intrafusal fibres, due to resistance to air flow to and from the lungs, would lead to an increased discharge from the muscle spindles with the consequence that the monosynaptic pathway previously described[1] would exercise an increased excitatory drive on the intercostal motoneurones. There would be summation with the 'central respiratory drive potential'[1] and so an increase in the discharge frequency of active motoneurones and a recruitment of others into activity. Thus, these results throw great emphasis on the importance of fusimotor fibre activity in the regulation of normal and forced respiratory movements.

Reduction by Chlorpromazine of Ulcers due to Acute Starvation in Mice

EVIDENCE has accumulated indicating that starvation induces acute ulceration in the gastric glandular mucosa of mice[1] but not in rats[2,3], and that chlorpromazine inhibits ulceration in the Shay rat[4]. Also, recent evidence indicates that chlorpromazine reduces gastric acid and/or pepsin secretion in a number of circumstances in man and in dogs[5-8]. The investigation recorded here was undertaken to establish whether the tranquillizer, chlorpromazine, could prevent or decrease the incidence of acute gastric ulceration in mice as caused by starvation. In addition, a survey of the incidence of gastric glandular ulcers in normal, well-fed mice of both sexes was undertaken to establish this parameter, and to serve as a basis for comparison of the starvation procedures.

A total of 400 adult Swiss mice were utilized in the experiments. In the initial experiment 50 male and 50 female, well-fed, normal mice were killed by chloroform, and the gastric glandular mucosa of each mouse was immediately examined grossly for the presence of hæmorrhagic ulcers of any severity. In every subsequent starvation experiment approximately 50 mice of the same sex were put together in a large cage (24 in. × 14 in. × 14 in.) or were housed in groups of 10 mice per small cage (10 in. × 7·5 in. × 6 in.). The fasted mice were not fed during the three-day duration of each experiment, but water was available *ad libitum*. During this period the experimental mice were injected subcutaneously in the inguinal region twice a day (12-h intervals) with chlorpromazine ('Thorazine'), and control mice were injected similarly with water. All mice were individually weighed prior to each injection, and experimental mice received 10 mg chlorpromazine per kilogram body-weight (approximately 0·1 c.c.) for the initial injection, and 5 mg/kg for each of the remaining five injections. At the end of the third day the mice were killed with chloroform and autopsied immediately. Because of the minute size of the mouse stomach attempts were not made to quantitate grossly the severity of ulceration; stomachs were simply categorized as ulcerated or normal. It was found during an experiment with grouped male mice that the pugnacity and cannibalism characteristic of this sex during fasting resulted in very high mortality rate (65 per cent). Thus, data on fasting male mice were assumed invalid and incomplete, and are not included here.

Table 1. CHLORPROMAZINE REDUCTION OF ACUTE STARVATION ULCERS IN MICE

Treatment	No. of animals	Mean weight at autopsy (g)	No. of animals with ulcers	Percentage of animals with ulcers
Normal males	50	29·4	2	4*
Normal females	50	29·4	0	0
Starved females water-control (subcutaneous—twice daily)	92	19·4	27	29·4
Starved females, chlorpromazine (10 mg/kg, initial subcutaneous injection, 5 mg/kg, subsequent subcutaneous twice-daily injections)	87	20·0	15	17·2†

* Denotes a value significantly higher than female value ($P < 0.05$).

† Denotes a value significantly lower than control value ($P < 0.01$)

The results of the experiments are illustrated in Table 1. It was observed that two male mice in the presumably normal population of 50 male and 50 female mice possessed gastric glandular ulcers. Statistical evaluation (χ^2 method) indicates a significant difference ($P < 0.05$) between sexes in this regard, but the overall rare occurrence (2 per cent) of ulcers in normal laboratory mice concurs with reports of other normal laboratory species[9]. It was most notable that a very significant ($P < 0.01$) reduction of gastric glandular ulcers occurred in mice treated with chlorpromazine.

Each dose-level (10 mg/kg and 5 mg/kg) induced lethargy, decreased motor activity, and a pronounced decrease in postural muscle tone in all treated animals within 30 min after administration. Although the mechanism by which starvation induces ulcerogenesis in mice is not known, it has been reported that the blood level of glucose in dogs decreases during fasting[10]. If this phenomenon is consistent in mice, it may be speculated that gastric secretion is stimulated by the stress effect of hypoglycæmia as it is in man[8]. Unfortunately, the validity of recent reports in regard to alterations in intra-gastric *p*H in fasted mice is abated by complications of intragastric hæmorrhage, which would tend to elevate the *p*H of gastric contents[1]. In the present investigation, it is plausible that chlorpromazine reduced the incidence of ulceration by means of its well-established inhibition of gastric acid secretion. Indeed, other investigators have demonstrated that chlorpromazine inhibits the late phase of gastric secretion stimulated by the stress effect of insulin hypoglycaemia[6]. Furthermore, if starvation ulcers in mice are induced by a hypoglycaemia-hypersecretion effect, chlorpromazine would perhaps additionally negate the cause (hypoglycaemia) of hypersecretion, since it has been demonstrated that chlorpromazine induces hyperglycaemia in mice[11].

Stimulation of Bone Resorption by Parathyroid Hormone in Tissue Culture

GAILLARD[1] has demonstrated resorption in cultures of embryonic bone when parathyroid hormone is added to the medium. We have used this response to assay parathyroid activity by measuring the release of calcium from bone during cultivation.

Albino rats 15–16 days pregnant (dated from time of sperm-positive vaginal smears) were injected with 200–400 μc. of calcium-45 as calcium chloride. Three days later the 18–19-day-old embryos were removed, the radius and ulna were dissected out, their cartilaginous ends cut off, and the shaft washed in Eagle's medium in Hanks base[2] at pH 7. These bones were then cultivated in small embryological watch-glasses containing 0·5 ml. of medium. They were placed on pieces of 'Millipore' filter supported at the surface of the medium by a metal screen. The medium was a mixture of 50 per cent human or rat serum and 50 per cent Eagle's maintenance medium in a modified salt solution. The initial calcium concentration was 1·8–2·2 m.moles/l., inorganic phosphorus concentration 1·3–2·5 m.moles/l., and sodium bicarbonate 25 m.moles/l. The cultures were incubated for 72 h at 37° C under an atmosphere of 5 per cent carbon dioxide, 20 per cent oxygen, and 75 per cent nitrogen. To measure the response to parathyroid hormone, 0·005 ml. of varying dilutions of a single lot of commercial parathyroid extract containing 0·2 per cent phenol ('PTE', Eli Lilly and Co.) was added to 0·5 ml. of medium bathing 1 bone rudiment. The opposite untreated limb served as a control for each treated limb; the medium contained 0·005 ml. of the 'PTE' diluent (0·2 per cent phenol in 0·9 per cent sodium chloride solution). In separate control assays the bones were treated with diluent or with inactive parathyroid extracts and compared with untreated bones. To assess the role of physicochemical exchange of calcium between bone and medium 'PTE'-treated and untreated bones were cultivated after the cells had been killed by heating to 47°–48° C for 1 h.

At the end of incubation the amount of calcium-45 released from the bone to the medium was measured in a liquid scintillation counter[3] and the stable calcium concentration in the medium determined by micro-titration[4]. The ratio of calcium in media from the treated bone to that in the untreated paired bone culture was used to permit comparison of experiments in which different amounts of calcium-45 were initially present in embryonic bone and in which there were small differences in the initial calcium concentrations in the medium. In each assay experiment the response of 3 or 4 pairs of bones of similar size were tested for a given treatment.

Pairs of control bones, one of which was treated with an inactive parathyroid extract or with phenol diluent, showed similar concentrations of stable calcium in the medium and released the same amount of calcium-45 during cultivation. The final calcium concentration was close to the initial value of 1·8–2·2 m.moles/l. (Table 1).

Table 1. EFFECT OF 'PTE' ON MEDIUM CALCIUM CONCENTRATION AND CALCIUM-45 RELEASE FROM EMBRYONIC BONE

Figures are mean and standard error of the ratio of treated versus untreated paired cultures

Treatment	No. of pairs	Treated/untreated Calcium concentration	Calcium-45 release
Control	30	1·0 ± 0·01	1·00 ± 0·01
'PTE' 0·01 unit/ml.	25	1·02 ± 0·02	1·12 ± 0·02*
'PTE' 0·1 unit/ml.	28	1·04 ± 0·02	1·66 ± 0·12*
'PTE' 1 unit/ml.	24	1·14 ± 0·02*	2·36 ± 0·16*

* Significantly different from control and from other doses of 'PTE', $P < 0·01$.

Twelve pairs of killed bones were compared with surviving control bones from the same litter. The dead bone usually took up some calcium from the medium so that the final calcium concentration in the medium was 11 per cent lower than for controls. Calcium-45 release was only 39 ± 4 per cent of that for living control bones. This finding suggests that considerable resorption and remodelling occurred in the control cultures and is consistent with the histological appearance of abundant osteoblasts plus a few osteoclasts in these bones. Adding 'PTE' to the medium had no effect on calcium-45 release or stable calcium equilibrium in cultures of killed bone. When 'PTE' was added to living bone cultures, release of calcium-

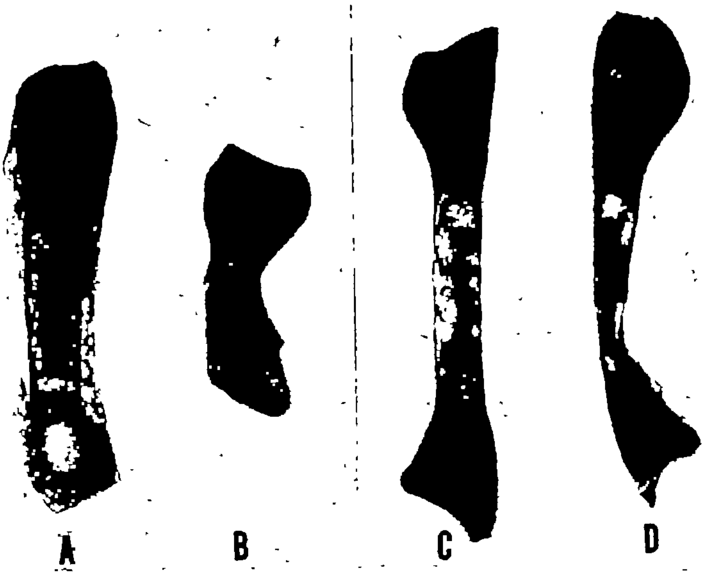

Fig. 1. Paired radii from two 18-day rat embryos after 3 days cultivation. *A* and *C*, untreated controls; *B*, effect of 1·0 unit 'PTE'/ml.; *D*, effect of 0·1 unit 'PTE'/ml. Cartilage has not been cut off prior to culture to show its relative preservation. (Azan stain, × *c*. 33)

45 to the medium was increased roughly in proportion to the dose administered. A dose of 1·0 unit/ml. caused almost complete resorption of bone matrix (Fig. 1) and increased calcium-45 release 2–3-fold while 0·1 unit/ml. usually caused less resorption. The histological changes resembled those described by Gaillard[1]. There was a marked increase in osteoclasts, some fibroblastic proliferation, and a disappearance of osteoblasts. The increase in calcium-45 release with 0·01 unit/ml. of 'PTE' was significant but small, and in 2 of 7 assays the value was within the control range. Histologically, cultures treated with 0·01 unit/ml. of 'PTE' resembled controls. Although the rise in stable calcium concentration in the medium paralleled calcium-45 release, the change was smaller and not significant except with 1·0 unit/ml. of 'PTE', presumably because of the relatively small amount of stable calcium available for release from bone compared with the amount present in the medium. Since calcium-45 was initially present only in the bones its release provided a more direct and sensitive measure of resorption.

A number of factors which affect the response to 'PTE' have been identified. A low initial concentration of calcium in the medium itself caused disappearance of matrix and proliferation of osteoclasts but addition of 'PTE' caused further resorption. If medium phosphate was increased above 3 m.moles/l., or if *p*H was raised above 7·5 by adding sodium bicarbonate, the 'PTE' effect on resorption was inhibited. Ordinarily, medium *p*H was between 6·8 and 7·4 at the end of cultivation. At the lowest *p*H values higher stable calcium concentrations were found in the control medium, but a further increase in calcium concentration was found in 'PTE'-treated cultures. This 'PTE' effect was not due to a greater acidification of the medium since there was no *p*H difference between medium from paired treated and untreated bones. The size and calcification of the explants were critical. Some 18-day embryo bones were too small and had not incorporated sufficient calcium-45 for assay. The bones of large 19-day embryos were less sensitive to 'PTE', perhaps because the bones did not survive well in culture.

These experiments confirm Gaillard's observation that parathyroid hormone stimulates bone resorption *in vitro* and show that this resorption can be measured as the release of labelled calcium from embryonic bone rudiments into the medium. The results are consistent with there being a direct effect of 'PTE' on calcium transport. The response is related to the dose of parathyroid extract.

This work was begun while I was a Special Research Fellow of the U.S. Public Health Service at the Strangeways Research Laboratory, Cambridge, England. I thank Dr. Honor B. Fell, director of the Laboratory, for her encouragement and advice.

PHARMACOLOGY

Nature of Acetylcholine-like Activity released from Brain *in vivo*

ACETYLCHOLINE-LIKE activity appears in saline solution applied to the surface of the brain by means of a cup, when cholinesterase is inhibited locally[1]. When the cup is placed on the somatosensory cortex, the activity in the solution increases if the contralateral paw is electrically stimulated at a low frequency[2]. Similar acetylcholine-like activity can be recovered from the cortex and the caudate nucleus using Gaddum's push-pull cannula[3]. Recently evidence was brought forward by Hosein *et al.*[4] that the acetylcholine-like activity of brain homogenates treated with trichloroacetic acid was largely due to coenzyme-*A* esters of γ-butyrobetaine, crotonbetaine and carnitine and to propionyl and butyryl choline. In view of this, it was of interest to see whether evidence could be found for the release of these esters from brain *in vivo*.

The area of maximum evoked potentials in the somatosensory cortex following the stimulation of the contralateral fore-limb of a cat anaesthetized with 0·6 ml/kg 'Dial' and injected with 2 mg/kg atropine sulphate was localized by means of a wick electrode. Gaddum's push-pull cannula[3] was introduced at this location approximately 2 mm deep and Locke's solution was perfused through it at a rate of 0·25 ml./10 min. After perfusing the cortex for 20 min with Locke's solution containing 5 × 10^{-4} (v/v) diisopropylphosphofluoridate, perfusate was collected for 2 h during which the contralateral fore-limb was stimulated continuously with pulses of 1 msec duration at a rate of 1/sec. With the 3·0 ml. perfusate collected, 2 + 2 point assays were performed on a longitudinal strip of leech muscle suspended in a microbath[6,7] and on the blood-pressure of the eviscerated cat sensitized by 0·1 mg/kg eserine[8]. Similar assays were performed with a sample of γ-butyrobetaine ethyl ester, kindly supplied by Dr. Hosein.

Table 1. ACTIVITY OF BRAIN PERFUSATE AND OF γ-BUTYROBETAINE ETHYL ESTER IN TERMS OF NANOGRAM OF ACETYLCHOLINE CHLORIDE. 5 PER CENT FIDUCIAL LIMITS IN PARENTHESES

	Cat's blood pressure	Leech muscle	Ratio: Cat's blood pressure/Leech muscle
1 ml. perfusate	23·0 (19·3–29·8)	18·0 (15·0–22·5)	1·26
1 μg γ-butyrobetaine ethyl ester	14·0 (11·5–17·1)	0·48 (0·38–0·61)	29·2

As shown in Table 1, the activity of the perfusate in terms of acetylcholine was quite similar on the two preparations, while γ-butyrobetaine ethyl ester was about 30 times weaker on the leech muscle than on the blood-pressure.

Secondly, 0·15 ml. of a perfusate obtained from the somatosensory cortex as described here and estimated to contain 50 ng/ml. acetylcholine equivalent was applied to a 15-cm wide Whatman No. 1 filter paper and developed in water-saturated *n*-butanol for 15 h by descending chromatography. Similarly, 0·15 ml. of acetylcholine (50 ng/ml.) and γ-butyrobetaine ethyl ester (0·1 mg/ml.), both in Locke's solution, were applied and developed. After drying, strips were eluted with 20 ml. methanol, the methanol evaporated under nitrogen and the residue dissolved in 0·25 ml. of diluted Locke's solution and assayed on the leech muscle.

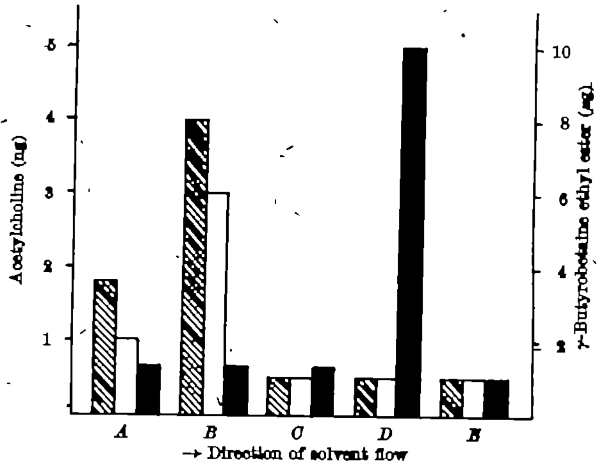

Fig. 1. Hatched, acetylcholine; white, brain perfusate; black, γ-butyrobetaine ethyl ester. *A*, R_F −0·05 – +0·05; *B*, R_F 0·05–0·15; *C*, R_F 0·15–0·30; *D*, R_F 0·30–0·50; *E*, R_F 0·50–0·70. Acetylcholine and brain perfusate assayed against acetylcholine chloride as shown on the left, γ-butyrobetaine ethyl ester assayed against itself as shown on the right

Results in Fig. 1 show that most of the activity of the perfusate could be recovered at R_F 0·05–0·15, where also acetylcholine was found, while γ-butyrobetaine migrated to R_F 0·30–0·50. These findings do not provide any evidence for the release of betaine esters from the brain *in vivo* but rather show that acetylcholine or a very similar ester is the transmitter at the cholinergic synapses in the cortex of the brain.

Dose-response Relations of Amphetamine–Barbiturate Mixtures

MIXTURES of amphetamine and barbiturates are fairly widely used in psychiatry for treating some kinds of neurotic patients. Relatively little seems to be known about the effects of such mixtures from laboratory experiments on animals or man. On most kinds of response the two types of drug separately have opposite effects, since barbiturates are general depressants of the central nervous system and the amphetamines are general stimulants. In small doses, however, barbiturates can produce stimulant effects on animal activity[1–4], as measured, for example, by 'activity cages'.

In previous experiments[5] it was found that very small doses of amphetamine sulphate (0·75 mg/kg) and amylobarbitone sodium (15 mg/kg) which individually had little effect could, when given in combination with each other, markedly increase the spontaneous activity of rats in an unfamiliar environment, even though most of the animals were ataxic and moved clumsily. The dose ratio (1 : 20) was different from those used therapeutically since it involved much more barbiturate. For example, 'Drinamyl' (Smith, Kline and French) contains dexamphetamine sulphate and amylobarbitone sodium in a ratio of 1 : 6·5; on the assumption that dexamphetamine sulphate may be about 1½ times as potent as amphetamine sulphate[6], the ratio in these experiments was therefore of the order of 1 : 30.

In the first series of the experiments recorded here, amphetamine sulphate and amylobarbitone sodium in this same ratio were studied separately and in combination over a range of doses in order to determine whether, at its peak dose, a mixture of them did in fact produce greater stimulant effects on the spontaneous activity of rats than could be obtained with either drug on its own. In order to study the relation between spontaneous activity and ataxia, records of the rats' footprints were obtained[7,8] during a standard run and their spacing was analysed. A second set of experiments was then carried out which was similar in all respects except that dexamphetamine sulphate and amylobarbitone sodium were used in the 'Drinamyl' ratio of 1 : 6·5.

The apparatus used to study spontaneous activity was a symmetrical Y-shaped runway similar to that previously described[8]. A trial consisted of placing a rat in the centre of the Y and leaving it in the apparatus for 5 min; the number of times it entered the arms with all four feet was the measure of activity. The rats were 329 Lister hooded females aged 115–140 days which had been reared under standard conditions. In the first series, 10 rats, randomly selected, were used at each dose and 16 rats were saline controls; in the second series the numbers were 8 and 15 respectively. The drugs were dissolved in saline so that the volume injected, subcutaneously, was 2 c.c./kg; 35 min after the injection each rat was given a single trial in the runway, and immediately afterwards the record of footprints was made.

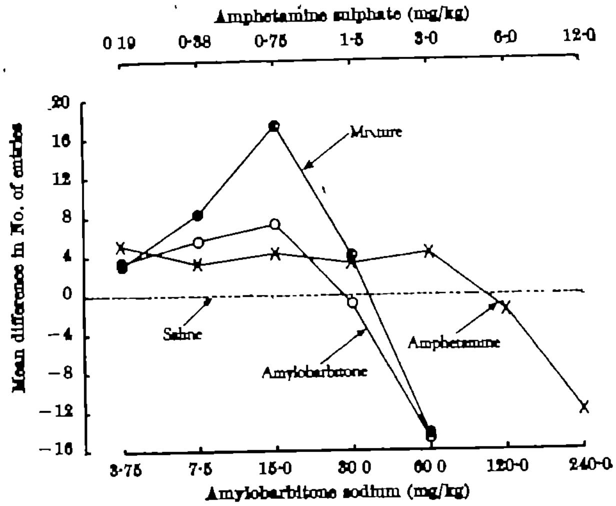

Fig. 1. Results of first series of experiments: activity of rats influenced by amphetamine sulphate and amylobarbitone sodium, given separately and in combination, over a range of doses. The figure shows the number of entries into the arms of a Y-shaped runway during 5 min, expressed as mean differences from the activity of the saline control group the mean number of entries of which was 14·7, *S.D.* 5·8. Each point represents the mean results for a different group of ten rats. The ratio between the two drugs was kept constant at 1 : 20

Fig. 1 shows the results of the first series of experiments. At its peak the activity with the drug mixture was indeed found to be greater than activity with any of the doses of the separate drugs, and it was more than twice that which was found with saline ($t = 5·6$, df 51, $P < 0·001$). Amylobarbitone alone produced a curve which was similar to but much flatter than the mixture curve, with a peak which was observed to be directly below that of the mixture curve. Amphetamine by itself produced in the first five doses used slightly more activity than saline, and the overall mean difference (4·0 entries) is statistically significant at the 5 per cent level. In the highest doses all three substances, including amphetamine, inhibited activity almost completely.

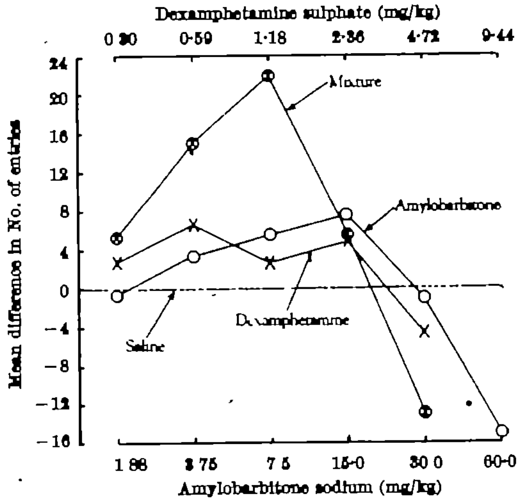

Fig. 2. Results of second series of experiments. Conditions were similar to the first series, except that dexamphetamine sulphate and amylobarbitone sodium were used, in the ratio of 1 : 6·5 ('Drinamyl' ratio). There were eight rats per group

Fig. 2 shows the results of the second series of experiments where proportionately about 6 times more amphetamine was used. It can be seen that the shape of the mixture curve was similar to that in the first series; but the peak of activity occurred at half the previous dose of amylobarbitone, that is, at 7·5 mg/kg, combined with 1·18 mg/kg dexamphetamine, which corresponds to more than twice the dose of amphetamine sulphate at the peak dose in the first series of experiments. The difference between the peak mixture activity and activity with saline was again significant at the 0·1 per cent level. As before, the largest doses of all three substances inhibited activity almost completely.

Various aspects of the footprint records were examined, and it was found that the regularity of the spacing of the prints was a useful measure of ataxia[8]: the spacing was regular in animals given saline and became irregular in animals given amphetamine–barbiturate mixtures, and the irregularity became greater the larger the dose. In the first series of experiments the smallest dose at which significant ataxia was detected was the peak activity dose ($P < 0{\cdot}001$), but in the second series ataxia was only detected at double the peak dose ($P < 0{\cdot}001$). Hence, in the first series, where proportionately much more barbiturate was used, the peak mixture dose markedly increased the rats' spontaneous activity even though it also made them ataxic, while in the second series, where the 'Drinamyl' ratio was used, the peak mixture dose produced a similar increase in activity but no ataxia.

We are grateful to Profs. H. O. Schild and A. Summerfield and to Dr. J. H. Gaddum for discussing this work with us, and to Mr. J. K. Hall for statistical help. The work was supported by research grant MY–3313 from the National Institute of Mental Health, U.S. Public Health Service

HÆMATOLOGY

Hæmoglobins of *Galago crassicaudatus*

Galago crassicaudatus is a nocturnal, arboreal prosimian Primate of relatively wide distribution in Africa. Recently we have examined hæmoglobin from 19 individuals of this species. All the animals came from the Sokoke forest, two to three miles west of the town of Gedi in south-eastern Kenya. The pelage colours of the 19 animals, all from the same population, spanned the characteristic shades and markings of the subspecies *G. c. agisymbanus*, *G. c. lasiotis*, *G. c. panganiensis*, *G. c. kikuyuensis*, *G. c. crassicaudatus* and *G. c. argentatus*[1]. The last-named variety, however, has characters other than the superficial ones of pelage markings and colour which make a distinction between it and the other five useful for the present. Our long-standing suspicion that the sub-species, other than the *argentatus*, are merely normal colour variations within *G. crassicaudatus* seems to be confirmed.

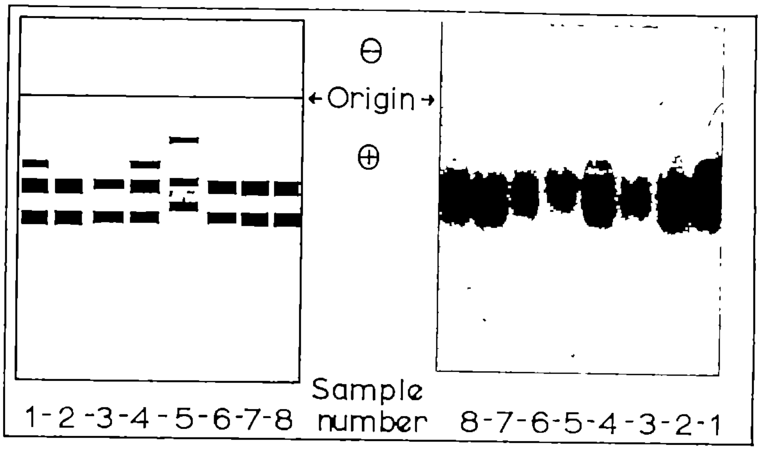

Fig. 1. A typical starch gel of galago hæmoglobins. The right-hand part is a photograph of the half of the gel stained with benzidine. The left-hand part is a diagram of the other half of the same gel after it was stained with amido-black. All samples except sample No. 5 are from galagos. Sample No. 5 shows hæmoglobins A_2, S and A, in order of increasing anodic mobility, from a human AS heterozygote; the dotted area in the diagram indicates the position of human hæmoglobin F in this system

Blood was drawn from the femoral veins of the tranquillized galagos into 7 ml. sterile vacuum tubes containing 0·7 ml. anticoagulant (citric acid, sodium citrate, and dextrose). Cells and plasma were separated by centrifugation and hæmolysates prepared in the usual manner[2].

Electrophoresis of hæmoglobin was in vertical starch gels made with *tris* borate buffer, pH 8·6 (0·027 M *tris*-(hydroxymethyl)aminomethane plus 0·020 M boric acid). Buffer in the electrode vessels was 0·27 M *tris* and 0·20 M boric acid. Electrophoresis was carried out for 7 h at approximately 10 V/cm at room temperature. At the end of a run, gels were chilled for 0·5 h at 10° C and then sliced. One half was stained with amido black and the other with a benzidine reagent.

Hæmolysates were tested for alkali-resistant hæmoglobin by the denaturation technique of Singer *et al.*[3].

Fig. 1 shows a typical gel. The half of the gel which was stained with benzidine was photographed. The other half was diagrammed after being stained with amido black. There are two hæmoglobin patterns to be seen in the galago samples on this gel. One has three distinct bands, the other has two. Ten samples had two bands and nine had three. The smeared band which has moved farthest anodally is, we believe, analogous to human A_2 or 'senescent' hæmoglobin. The slowest, or most cathodal, band moves farther, or faster, than the A_2 human band. As can be seen in Fig. 1, the fastest galago hæmoglobin has moved farther than human A, and the band with intermediate mobility has moved slightly farther than human S, but not as far as human F. The presence of minor hæmoglobin components in these galago samples, analogous to those in human hæmolysates, is not clearly demonstrated on these gels. This point awaits analysis of the hæmolysates by ion-exchange chromatography[4].

The results of alkali denaturation tests show an average value, for 19 samples, of 27·7 per cent alkali-resistant hæmoglobin. The individual values ranged from 19·2 to 36·3 per cent. In a previous communication[5] we reported slightly higher average values (36 per cent) in a group of 23 *G. crassicaudatus*.

There is no obvious association, in the present group of 19 samples, between higher or lower percentages of alkali-resistant pigments and the number of bands found on the starch gels. Nor is there any relationship between pelage colour of the animal and number of bands found after electrophoresis. We have not yet identified the alkali-resistant pigment with any of the components discovered on electrophoresis of the samples. There may be striking structural similarities between human alkali-resistant fœtal hæmoglobin and galago hæmoglobin.

This work was supported by grant *RG* 6053 of the U.S. Public Health Service and was carried out during the tenure of a National Science Foundation senior postdoctoral fellowship held by one of us (J. B.-J.). The facilities of the Wellcome Trust Laboratory at the Medical Research Laboratory, Nairobi, Kenya, were generously made available by Dr. H. Foy and Dr. A. Linsell. Effect on Antibody Production of Injection of an α_2-Protein Fraction

While investigating the effect of large doses of fractions of blood on the survival of rat skin homografts, it was found that intraperitoneal injections of an α_2-protein fraction from human, rat, rabbit, or bovine sera could prolong the survival of homografts in outbred albino rats. At the time of writing, 4 of 20 of these grafts have survived for eight and 4 of a further 20 for six months and are still apparently healthy. This fraction was prepared from whole serum by a modification of the chromatographic method of Steinbuch and Quentin[1] on DEAE cellulose. Of Steinbuch and Quentin's three fractions only that eluted with 0·5 molar *p*H 5 acetate buffer was effective. Kamrin[2] had previously produced a marked prolongation of survival of rat skin homografts by injecting a series of plasma fractions, of which the most potent contained the highest concentration of α_2-protein. It seems, therefore, that the fractions used by Kamrin and the fraction I have used probably contain a common active principle.

The work with the 0·5 molar eluate has also shown that this fraction inhibits the production of antibodies to other antigens.

The immune elimination technique of Talmage *et al.*[3] was used as an index of antibody production. 10 mg of human albumen labelled with iodine-131 was injected into six rabbits each of which had received 100 mg of the eluate intraperitoneally 30 min after being given the antigen and again three days later. There was no evidence of immune elimination in five of the six rabbits, but in the remaining rabbit immune elimination was observed on the eighth day. Nine rabbits injected only with the labelled human albumen all showed immune elimination between the eighth and eleventh days ($0{\cdot}01 > P > 0{\cdot}001$).

In rabbits injected intravenously with 1·0 ml. of packed, washed human red cells hæmagglutinating antibody developed in each of nine control animals, but it could be detected in only two of ten animals treated by intraperitoneal injection of 100 mg of the eluate given 2 h before injection of the red cells.

The timing of the injection of the protein fraction was found to be important. Suppression of immune elimination of iodine-131-labelled human albumen was observed in all animals receiving the fraction 1 or 2 h before administration of the antigen. Normal immune elimination was observed in all animals receiving the fraction 4 h after the antigen. The production of hæmagglutinating antibody was unaffected if the fraction was injected later than 15 min before the antigen, and was most effective if given 2 h before.

It therefore seems likely that the protein fraction affects the early stages of the immune response.

PATHOLOGY

Platelet Clumping *in vivo*

Wharton-Jones[1] and Bizzozero[2] showed that, when an artery was injured, white masses would build up at the site of injury and embolize. Honour and Ross-Russell[3] examined this response to injury in considerable detail in arteries on the surface of the rabbit brain. They showed that the white bodies were composed of closely packed but morphologically discrete platelets, and they were unable to influence the rate of formation of the white bodies or their size by heparin, anti-histamines, or 5-hydroxytryptamine (5-HT) antagonists. The demonstration by Gaarder *et al.*[4] that adenosine diphosphate (ADP) was capable of producing clumping of human platelets *in vitro*, led Mitchell and Sharp[5] to investigate related substances, together with other substances normally carried by the platelet. They confirmed that ADP clumped citrated human platelets at a concentration of 0·04 μg/ml. and that adenosine triphosphate (ATP) was much less active, a concentration of 1·5 μg/ml. being required. They also found that human platelets were clumped by 5-HT, and by noradrenaline at a concentration of 0·06 μg/ml. Rabbit platelets were clumped by ADP at a concentration of 0·05 μg/ml., were much more sensitive to ATP than human platelets, 0·22 μg/ml. sufficing to produce clumping, were insensitive to noradrenaline, and showed a variable response to 5-HT.

These observations led us to examine the effect of ADP, ATP and 5-HT on injured brain vessels in the rabbit.

(1) *The major injury.* The cerebral cortical arteries of anæsthetized rabbits were exposed and observed microscopically using the techniques described by Honour and Ross-Russell[3]. An artery 100–200μ in diameter was then pinched firmly with needle-pointed ophthalmic forceps, producing slight external bleeding, and transient vaso-constriction. When this subsided a steady succession of white bodies would form at the site of injury and embolize. The application of ADP, ATP and 5-HT solutions to the external surface of such a site did not modify the size or rate of production of the white bodies which were forming spontaneously.

(2) *The minor injury.* If, however, a cortical artery was gripped gently with the forceps, no external bleeding occurred and apart from transient vaso-constriction the site looked normal. No white bodies formed spontaneously, but the application to such a site of ADP, ATP or 5-HT dissolved in 0·9 per cent saline produced white bodies, which continued to build up and embolize so long as the active agent was applied, production stopping as soon as the application was discontinued. The lowest concentration of these agents which would produce white bodies when applied to the outside of a minimally injured rabbit brain artery was determined, each substance being tested on 8 rabbits. The results were:

Substance	Range of lowest effective conc. (μg/ml.)	Mean (μg/ml.)
ADP	0·25–16·0	3·0
ATP	0·25–16·0	5·3
5-HT	0·125–32·0	4·8

Application of the test solutions to uninjured cortical arteries did not produce white bodies.

(3) *Effect of 5-HT antagonists.* Minor injuries were inflicted on cortical arteries in two rabbits and their

responsiveness to externally applied ADP, ATP and 5-HT was tested. The rabbits were then given 15 mg and 60 mg respectively of the 5-HT antagonist *Ro*-3-0837 intravenously (4·4 and 19·5 mg/kg; the material was supplied by Roche Products). After the administration of the 5-HT antagonist, externally applied 5-HT in any concentration was not capable of producing white bodies, whereas ADP and ATP applied to the same site produced white bodies at concentrations identical to those found before the 5-HT antagonist was given.

Application of the antagonist locally in low concentrations also abolished the 5-HT response; dripping *Ro*-3-0837, 25 µg/ml., on to a minor injury site rendered it unresponsive to 5-HT, but did not modify the response to ADP and ATP. Parenteral and local application of 5-HT antagonists to animals with major injuries, where a steady stream of white bodies was forming spontaneously, did not modify the rate of production or size of the white bodies, suggesting that the site of major injury is producing its white bodies by a mechanism which does not involve 5-HT induced clumping.

(4) *Effect of enzyme inhibitors*. The substances tested were dissolved in 0·9 per cent saline, and applied for 10 min to the external surface of an artery with a major injury which was producing white bodies spontaneously. The substance was then washed off with saline and the effect on white-body production was observed.

(*a*) *Sodium fluoro-acetate*, 1 mg/ml. For the first 15 min after the beginning of the application the white bodies continued to appear, but they then diminished in size, fragmented during formation, and production stopped altogether at 20 min. No further white bodies were produced during a 2-h observation period.

(*b*) *Sodium mono-iodoacetate*, 750 µg/ml. 20 min after beginning the application the white bodies became smaller, small masses of platelets could be seen streaming off their surface as they were building up, and at 30 min, no further white bodies developed. The site remained quiescent for some 30 min, when tiny white bodies began to form and embolize, gradually getting bigger, until at about 90 min the injury site was behaving in the same way as in the control observation period.

(*c*) *Sodium azide*, 10 mg/ml. White body production stopped at 5 min and did not begin again in a 2-h observation period.

(*d*) *Potassium cyanide*, 25–1,000 µg/ml., and

(*e*) *2:4 dinitrophenol*, 12·5–125 µg./ml., showed no effect on white-body formation.

The external application of ADP, ATP and 5-HT to a major injury site the spontaneous white-body production of which had been stopped with fluoroacetate, or iodoacetate, produced white bodies as long as their application was continued; an application rate of 0·1 to 0·2 µg/min of ADP produced a succession of white bodies similar in size and timing to those occurring before the enzyme poison had been applied.

These observations show that agents which will produce clumping of citrated rabbit platelets *in vitro*, such as ADP, ATP and 5-HT, can also produce platelet masses in injured brain arteries. Our investigations of the effect of the various enzyme poisons suggest that the phenomenon first observed by Wharton-Jones[1] of white-body production in injured arteries may be related to the release from the damaged tissues in the artery wall of substances similar in properties to ADP, which instruct the passing platelets to clump together.

Auto-Immune Selection of Carcinoma Cells in Man

IN 1954 it was suggested by Green[1] that normal cell contain an antigen which is absent from tumour cells and that, in the presence of an 'auto-immune' reactio in which carcinogenic substances behave as haptenes the tumour cells have a selective survival advantage Loss of tissue-specific antigen has been demonstrated i the cells of experimental tumours of hamster kidney[2, and rat liver[2,3], and spontaneous tumours of human skin and gastro-intestinal tract[4] by the use of heterologou antibodies. Recently it has been shown that some cell of most tumours of the human thyroid appear to be defi cient in a thyroid-specific auto-antigen[5] which is presen in the epithelial cells of normal and hyperplastic thyroids primary explants of thyroid cells in tissue culture wer used and the antigenicity of the cells was demonstrate by their susceptibility to the cytotoxic effects of a natur ally occurring thyroid-specific auto-antibody[6] frequentl found in the serum of patients with chronic thyroiditis.

If the kind of antigenic modification of tumour cell described here selectively favours the growth or sprea of tumours and is not merely a reflexion of the reduce specialized function common in neoplastic cells[7], ther should be an increased tendency to formation of tumours i diseases associated with auto-immunization. This is th case in two (and possibly all) of the three common disease in man in which auto-antibodies are known to be forme specifically against epithelial cells. Auto-antibodies agains cytoplasmic particles of thyroid epithelial cells are com mon in the serum of patients with chronic thyroiditis[8,9 a condition in which the incidence of thyroid carcinom is significantly increased[10–12]. Due to the clinical latenc of chronic thyroiditis it is unknown if this conditio precedes the development of carcinoma. Auto-antibodie against colonic epithelial cells[13] have been demonstrate in ulcerative colitis, and this disease definitely precede and markedly predisposes to carcinoma of colon[14].

It has recently been shown that patients with Addi sonian pernicious anæmia have auto-antibodies whic react with the parietal cells of the body and fundus of th stomach[15,16]: it is probable[17,18] but not certain[19] tha gastric carcinoma develops more frequently than would b expected in patients suffering from this disease. (There i no evidence that the carcinoma of the stomach in pernici ous anæmia arises from the cells against which the anti bodies apparently develop.)

These findings suggest that auto-antigen loss an immunological selection occur in certain tumours of th thyroid, the colon and possibly the stomach in man.

IMMUNOLOGY

Non-immune Gel Precipitin Tests with an Enzyme Antigen

The appearance of non-immune precipitin bands in gel diffusion tests may result from manipulation of the physical environment while the immuno-diffusion test is in progress[1]. Interactions of serum with granulocytes[2] and tissue extracts[3], or reaction of albumin with hæmoglobin[4] though not antigen–antibody reactions also produce precipitates in agar. When one of the reactants can express a second biological function other than its antigenicity under the conditions of the gel test, then such non-specific precipitin lines are likely to occur. Our experience with bovine carboxypeptidase *A* and its rabbit antiserum ultimately revealed two independent artefacts of a type we had not seen referred to elsewhere.

Recrystallized carboxypeptidase *A* of commercial origin known to behave as a single molecular species though displaying limited tryptic and chymotryptic activities was the immunizing antigen. Rabbits were immunized with a Freund's adjuvant-antigen emulsion[5]. The antigen used in the gel tests had both tryptic and chymotryptic activities removed by diisopropylfluorophosphate (DFP) treatment. The gel tests were performed in a 0·5 per cent sodium chloride, 0·5 per cent phenolized agar (1 per cent) dispensed in 5-ml. volumes on to 49 mm² cover-glass plates and incubated at 37° C for 24 h. These slides were very convenient since on completion of the tests the agar films could be dried, stained and mounted between two additional cover glasses in an aluminium frame for viewing. The wells for antigen and antiserum were cut with a cork borer of 6 mm inside diameter attached to a vacuum line and placed 6 mm apart. All were charged with approximately 0·2 ml. of reactant with the antigens at a concentration of 1 mg/ml.

When the rabbit antiserum was tested against the carboxypeptidase antigen two bands appeared (Fig. 1). The heavier band was nearer the well containing antiserum and a lighter, less discernible band was nearer the well of antigen. Neither of these appeared with normal sera. It was suspected one of these might be due to the trypsin or chymotrypsin contaminants, which though enzymatically inactive because of the treatment with DFP were still functional antigenically. Accordingly, both were analysed in the gel test, but only chymotrypsin produced a precipitate with the immune serum. This band was quite diffuse, physically unlike either of the carboxypeptidase bands and did not merge with either of them (Fig. 1). It stained readily with sudan black B but not bromphenol blue, suggesting a lipid origin. It was also formed with normal rabbit, human, horse and guinea pig sera. The antiserum would not provoke positive passive cutaneous anaphylactic reactions[6] in guinea pigs with chymotrypsin as the antigen nor agglutinate chymotrypsin coated latex particles although both these tests were positive with carboxypeptidase *A*. Therefore, we believe the chymotrypsin band is spurious and arises from enzymatic liberation of lipids from lipoproteins.

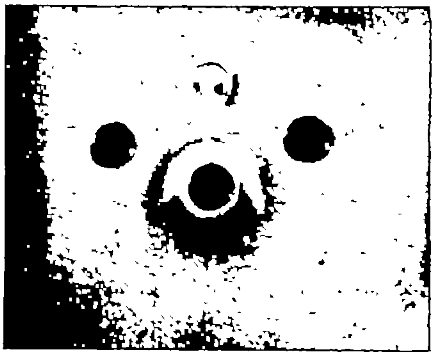

Fig. 1. Reactions of anticarboxypeptidase (lower well) with heated carboxypeptidase, carboxypeptidase and chymotrypsin (left, upper and right wells respectively)

However, the nature of the extra carboxypeptidase band remained unidentified. Believing it might arise from the natural heat instability of the enzyme, an enzyme solution was held at 37° C and aliquots removed periodically over a 5-h period. Each sample was assayed in the gel test and for enzyme content by hydrolysis of carbobenzoxyglycyl-L-phenylalanine[7]. After 5 h, only 10 per cent of the original enzyme activity remained and the previously heavier band in the gel test became even more intense. We consider this band to represent a degradation product of the enzyme which remained antigenic and stimulated formation of a second antibody.

Spurious precipitin bands may thus arise from the enzymatic activity of an antigen functioning only as an enzyme or, conversely, the antigenic activity of an enzyme functioning only as an antigen. Consequently, immunodiffusion investigations of cell extracts, culture filtrates or other enzyme-containing solutions may be anticipated to produce precipitates due to their enzyme content alone and these precipitates must be distinguished from true antigen–antibody reactions. Instability of labile antigens such as enzymes may require enzyme assays simultaneously with serological procedures to ensure that the serological test is dependent on the enzyme's antigenic function and not to some degraded form of the enzyme.

Cheek Pouch of the Syrian Hamster and Immunity to Heterotransplantation of a Murine Leukæmia

The consistent failure of *AK*–4 leukæmia of the *AKR* mouse to grow in the cheek pouches of normal or cortisone-treated hamsters is in contrast to the routine heterotransplantability of certain other murine leukæmias[1,2]. Other investigations in these laboratories have demonstrated the accelerated rejection of second-set *AK*-4 heterografts in the cheek pouch, suggesting that the primary inability of the neoplasm to grow in hamster pouches is attributable to an immune response on the part of the host[3]. Since a method for successfully transplanting *AK*–4 in lethally irradiated hamsters has been devised[4], in which cell suspensions of the leukæmia are introduced intravenously by orbital puncture, the hamster's acquisition of immunity to the neoplasm may be examined not only with the leukæmia undergoing rejection[3], but also with the leukæmia actively growing.

Unpublished studies subsequent to the original report[4] revealed that a predictable transplantability of *AK*–4 may be achieved by a total-body dose of 1,500 r. and an intravenous inoculum of 5·0 × 10⁷ leukæmic cells within 6 h after irradiation: 100 per cent of recipients evidenced transplantability of the tumour as indicated by unusually uniform implantation of the inoculum in the regional draining (cervical) lymph nodes, sternal bone marrow, and

* Experimentals and controls challenged with $5\cdot0 \times 10^7$ *AK*–4 cells i.v. at 1,500 r.
† Two inoculations, 2–3 weeks apart.
‡ Six-day blood count. Numbers in parentheses are number of animals on which average total white count is based.

spleen, with dissemination of leukæmic cells into the liver, kidney, and blood of the recipient prior to death at 5–7 days. The total white count at 5–6 days was of the order of magnitude of 10^4–10^5 nucleated cells per mm^3 venous blood, as opposed to about 10^3 cells per mm^3 in uninoculated, irradiated controls.

Transplantability of the neoplasm having been achieved under these special conditions, the specific objects of the present experiments were to determine: (*a*) whether prior exposure of the host to the prospective challenging cells would prevent implantation and dissemination of a challenging dose of intravenously administered *AK*–4 cells following irradiation; (*b*) what effect the route of administration (including the cheek pouch) of the sensitizing inoculum would have; (*c*) whether prior exposure of hamsters to leukæmic cells of other mouse strains would produce immunity to *AK*–4 challenge.

Within 6 h prior to challenge with $5\cdot0 \times 10^7$ *AK*–4 cells, previously sensitized experimentals and normal controls, anæsthetized by intraperitoneal 'Nembutal', were irradiated together by Siemens technique *A*: a clinical X-ray unit with the factors 250 kVp, 15 m.amp, additional filtration 0·5 mm. copper, 1·0 mm. aluminium, half value layer copper 1·75, dose rate in air 95 r./min, target distance 15 cm, 340° arc.

As in previous experiments[4], *AK*–4 cells for the challenging inocula were obtained from the spleens and lymph nodes of carrier lines of *AKR*/*Jax* mice: the leukæmic tissues, forced through a stainless steel screen (1/32 in. opening), were suspended in physiological saline or Eagle's basal medium, either alone or supplemented with calf serum[5]. Cell concentrations of the resultant suspensions were determined by the usual hæmocytometric methods for white cells, and final concentrations were adjusted to $1\cdot0 \times 10^8$ cells per ml. A dose of 0·5 ml., containing $5\cdot0 \times 10^7$ cells, was injected into each of the irradiated hamsters by orbital puncture, using 1 ml. tuberculin syringes equipped with 24 or 27 gauge needles.

The sensitizing inocula were similarly prepared from the spleens and lymph nodes of *AKR* mice bearing *AK*–4, or from solid subcutaneous growths of *P*–1534, *L*–1210, and *E*9514*A*, maintained by serial transfer in *DBA*/2 and *C3H* mice respectively. Suspensions of $1\cdot0 \times 10^8$ cells were further diluted to obtain sensitizing inocula of the desired concentration (Table 1). Intravenous sensitization was accomplished by orbital puncture, cheek pouch sensitization by methods previously reported for the implantation of cell culture suspensions into the cheek pouch[6]. Two sensitizing inocula were administered 2–3 weeks apart, and the animals were given one to two month's rest before irradiation and challenge.

The total white count of the blood of 5–6 day survivors of irradiation and challenge was determined by the usual methods; occasional transplants of leukotic whole blood of controls to mice resulted in leukæmia, confirming the morphological diagnosis. At death, subjects were autopsied, and representative tissues were fixed in 10 per cent formalin, and stained with hæmatoxylin and eosin for microscope evaluation. An attempt was made to examine the sternal bone marrow, liver, kidney, and spleen of every animal, but each group was finally evaluated on the basis of the proportion of recovered organs definitely judged to be infiltrated with leukæmic cells.

The results, summarized in Table 1, show that hamsters exposed to two inocula of any of the leukæmias so examined, administered by any of the routes used herein, failed to present evidence of leukæmic repopulation of the bone marrow, or leukæmic infiltration of the viscera. Control hamsters exhibited uniform infiltration of the bone marrow, liver, kidney, and spleen, with total white counts of $1\cdot1 \times 10^4$ to $1\cdot5 \times 10^5$ nucleated cells per mm^3 blood at 5–6 days, as compared to counts of $3\cdot9$–$5\cdot9 \times 10^3$ in sensitized hamsters.

The failure of the sensitizing inocula of *P*–1534, *L*–1210, and *E*9514*A* (neoplasms transplantable in the cheek pouch) to implant and disseminate when introduced centrally is corroborative evidence of special transplantation properties of the cheek pouch—what Billingham *et al.*[7] have termed the 'immunological privilege' of the cheek pouch. The characteristic failure of *AK*–4 cheek pouch transplants to grow, however, and the occasional failure of, for example, *L*–1210 (two instances of which are incorporated in the present experimental series) indicate that cheek pouch privilege is not universal. Further, since the failure of these neoplasms to grow as cheek pouch transplants resulted in immunization of the hosts against intravenous transplants of *AK*–4, it may be inferred that graft antigen was capable of leaving the cheek pouch, in contrast to the reported inability of skin isoantigens to do so[7]. Thus, at least some instances of cheek pouch transplantation failure may have an immunological basis, despite the pouch's immunological privilege.

The strong immunity to *AK*–4 challenge resulting from the rejection of murine leukæmic cells which characteristically do not grow in the cheek pouch (*AK*–4) or from the rejection of murine leukæmic cells transplantable in the pouch but which fail to grow when inoculated into non-privileged sites (*P*–1534, *L*–1210, *E*9514*A*) is revealed by these experiments to be species-specific rather than individual-specific, and is not abrogated by a total-body dose of 1,500 r., although, as the controls clearly show, that dose of irradiation is sufficient to permit first-set grafts of the neoplasm to implant, grow, and disseminate. The transplantation immunity induced under the stated conditions was of at least 1–2 months duration, but present experiments indicate that the regression of one cheek pouch implant of a murine leukæmia may result in immunity, detectable by these methods, as early as 17 days, or as late as 10 months, following sensitization.

A curious and unforeseen result of the present experiments was the slight but definite radiation-protective effect specific to the prior exposure of *AK*–4 challenged hamsters to *AK*–4 cells. Seven of 38 hamsters pre-treated with and challenged with *AK*–4 cells survived the lethal effects of exposure to 1,500 r., as opposed to none of 14 hamsters pre-treated with other strains of leukæmic cells, and none of 24 unsensitized, irradiated control hamsters. This association between radiation protection and heterotransplantation immunity is being further examined.

We thank Dr. G. J. D'Angio, of the Department of Radiology of the Children's Hospital Medical Center, Boston, for irradiating the hamsters used in this work.

Repression of Delayed Hypersensitivity to Conjugated Serum Albumin during Immune Paralysis induced in Guinea Pig by Heterologous Proteins

IT has been recently reported from this laboratory[1,2] that administration of large doses of bovine serum albumin (B.S.A.) to guinea pigs suppresses the antibody response to an immunizing dose of unrelated heterologous proteins. This effect can only be demonstrated when the immunization is performed several days after the commencement of the paralysing treatment. Moreover, in a previous investigation[3], it has been shown that similar treatment with other serum proteins is also capable of producing an inhibition of the delayed form of hypersensitivity.

In this communication, additional results dealing with the patterns of inhibition of delayed type of hypersensitivity in animals receiving large amounts of heterologous proteins are presented.

In all experiments, adult guinea pigs (350–450 g) of the *K* strain were used. Immune paralysis was induced by administering different doses of purified heterologous proteins: bovine serum albumin (B.S.A.); human serum albumin (H.S.A.); bovine γ-globulins (B.G.G.) and human γ-globulins (H.G.G.). The proteins were injected either intravenously or/and locally in the foot pads.

The delayed type of hypersensitivity was induced by injection of picrylated guinea pig serum albumin prepared according to the technique described by Benacerraf and Gell[4]: 0·1 ml. of mixture of equal parts of a saline solution containing 250 μg/ml. of picrylated guinea pig serum albumin and complete Freund's adjuvant was injected in each foot pad. The induction of the immune paralysis preceded by several days the sensitization with picrylated guinea pig serum albumin and was then continued for 4–7 days (Tables 1 and 2).

The degree of sensitization is determined by the size of the skin reactions elicited by intradermal injections of increasing concentrations of picrylated guinea pig serum in 0·1 ml saline, and was evaluated by the mean diameter of the skin reactions measured 24 h after challenge.

From the figures given in Table 1, it is evident that, by using the aforementioned method of sensitization, a strong degree of hypersensitivity could be regularly obtained in the control groups of animals, and that the size of the skin reactions is, to a certain extent, a function of the antigen concentration.

The cutaneous reactions, determined at the different time intervals after sensitization, were of the delayed type: they began to appear 6–8 h following the injection of antigen and reached their maximal intensity about 24 h later. In any event, no initial œdema or hæmorrhagic spots, characteristic of the Arthus type of hypersensitivity, were observed.

Intravenous injections of B.S.A. do not seem to affect the intensity of the reactivity to the picrylated guinea pig serum albumin (Exp. 1); although this treatment was previously found to be effective in suppressing the humoral antibody production and the anaphylactic type of hypersensitivity to ovalbumin and rabbit γ-globulins[3]. Treatment with H.S.A. by both intravenous and local routes exerts a definite inhibition of the delayed hypersensitivity provided that it has been started 10 days prior to sensitization (Exp. 2). When the paralysing pretreatment time is reduced to 3 days, the inhibitory effect disappears.

γ-Globulins, whether of bovine or human origin, were, on the whole, much more efficient than albumins in their inhibitory effect. This is evidenced by the fact that γ-globulins, injected in smaller amounts and for shorter periods before sensitization, produced regularly the same effect as H.S.A.: a more or less complete repression of the cutaneous reactions (Exps. 3 and 4). Human γ-globulins are also effective when injected separately by either the intravenous or local route (Exps. 5 and 6).

The results shown in Table 1 emphasize two important conditions for obtaining the inhibition of the delayed hypersensitivity: (1) induction of immune paralysis should in general precede sensitization by several days; (2) the injection of the paralysing antigen by the local route appears to be of a decisive importance.

Table 1. EFFECT OF PARALYSING TREATMENT WITH DIFFERENT SERUM PROTEINS ON DELAYED TYPE HYPERSENSITIVITY TO PICRYLATED GUINEA PIG SERUM ALBUMIN (PIC.GP.S.A.)

	8 Treated	6	6·6	16·3

* 300 mg/24 h intravenously and 40 mg/24 h locally.

The results shown in Table 2 provide information concerning the duration of the inhibition of the delayed hypersensitivity produced by immune paralysis. In these series of experiments, the treatment with H.G.G. was initiated 7 days before sensitization and continued for an additional 7 days with daily injections. Both paralysing and sensitizing injections were given only in the two hind foot pads. Under these conditions a complete suppression of the delayed hypersensitivity was observed in all the treated animals when tested with picrylated guinea pig serum albumin on the seventh day following sensitization. However, 14 days after sensitization, the recurrence of a certain degree of hypersensitivity, as evidenced by cutaneous reactions, to the highest doses of antigen was already noticed and this phenomenon became more pronounced 21 days later. After two months, the reactions in the γ-globulin-treated animals were of the same intensity as in the controls. From the results reported here it can be inferred that the inhibition of the delayed hypersensitivity, induced by immune paralysis, is a transient phenomenon. It persists as long as the paralysing treatment is continued and then gradually subsides with the discontinuance of treatment.

Our results indicate that repeated injections of high doses of heterologous proteins, a condition which is known to induce immune paralysis, can also abolish the delayed type of hypersensitivity to haptene-conjugated proteins in guinea pigs.

In this respect γ-globulins were more efficient than serum albumins. Complete suppression of the delayed hypersensitivity was only obtained when the paralysing treatment was initiated several days previous to the sensitization and when both systemic and local routes of administration were used. These observations suggest that the immunologically competent cells which are mainly located in the regional lymph nodes have to be reached previous to sensitization by adequate concentrations of the paralysing antigens. The fact that the inhibition of the delayed hypersensitivity subsides rapidly after cessation of the paralysing treatment (whereas the immune tolerance to paralysing agent will persist for several months) may be related to the local persistence of the sensitizing antigen incorporated in Freund's adjuvant. On the other hand, the concentration of the paralysing antigen in the lymph node cells decreases rapidly after the end of the treatment. These findings suggest the possibility of a quantitative relationship between the concentration of the paralysing antigen in the lymph node cells and the degree of their unresponsiveness to a sensitizing agent.

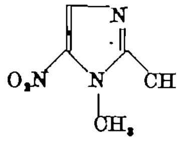
Dimetridazole: Absorption, Excretion and Metabolism in Turkeys

HISTOMONIASIS in turkeys (turkey blackhead) is caused by the protozoan flagellate *Histomonas meleagridis* and it can be controlled effectively with dimetridazole (1,2-dimethyl-5-nitroimidazole) given orally[1,2].



Since dimetridazole is given in the food continuously to prevent histomoniasis and at higher levels for shorter periods in the food or in drinking water to treat outbreaks of the disease, it is important to ascertain the metabolic fate of dimetridazole in the turkey and also to ensure that no significant amounts of the drug or its metabolites accumulate in the tissues to become constituents of a potential human food-stuff.

Absorption and excretion of dimetridazole. Single doses of dimetridazole (100 to 300 mg/kg as an aqueous solution of the dihydrogen phosphate) were administered orally to turkeys which had been deprived of food for the previous 24 h. Faeces and urine were thereafter collected for 3 successive days and the samples were examined by polarography and colorimetry. Results obtained by the two techniques were in excellent agreement and showed that 64 per cent of the dose was excreted within three days. These findings were supported by the use of radioactive dimetridazole which was labelled with carbon-14 in the 2–C and 2–CH_3 positions. (We thank Monsieur Roy and Monsieur Colson of the Département Nucléaire of the Société Rhône-Poulenc for supplying us with the labelled dimetridazole used in these experiments.) Turkeys which had received a single oral dose of dimetridazole (32 mg/kg) containing 60–100 µc. of radioactivity excreted 90 per cent of the dose in urine, faeces and expired air within three days, and 80 per cent was recovered within two days.

Polarography measured all 5-nitroimidazoles present, that is, dimetridazole and any metabolites which retained the nitro group, and it was sensitive to 0·05 to 0·1 µg/g depending on the sample size[3]. The colorimetric method, which was based on the reduction of the 5-nitro group to an amino compound which could be diazotized and then coupled with *N*(1-naphthyl)-ethylenediamine[4], detected dimetridazole, metabolites containing the nitroimidazole moiety and any 5-amino derivatives. Its sensitivity was 0·5 µg/g. The radiochemical method in which urine, faeces and expired air ($^{14}CO_2$ trapped as $Ba^{14}CO_3$) were counted with a thin end-window Geiger–Müller tube measured not only dimetridazole but also all possible metabolites in which either or both the carbon-14 atoms were retained, including carbon dioxide. This method was sensitive to about 0·03 µg/g.

Tissue residues of dimetridazole. Tissue residues of dimetridazole and its metabolites were studied polarographically and radiochemically. Initially, turkeys were given free access for six days to drinking water which contained dimetridazole (0·05 per cent) and they each ingested about 200 mg of the drug per day. The birds were killed 0, 1 or 2 days after the medicated water had been withdrawn, and samples of serum, liver, kidney, heart, muscle and skin were removed immediately for polarographic assay. No detectable residues (less than 0·1 µg/g) of dimetridazole or its metabolites were found in the serum or tissues of birds killed two days after medication had been stopped. These results were later confirmed by administering a single oral dose (32 mg/kg) of dimetridazole labelled with carbon-14 to turkeys which were killed three days later when samples were removed as before for polarographic and radiochemical examination. The concentration of dimetridazole and its metabolites found in these tissues by both methods was < 0.05 μg/g and < 0.03 μg/g respectively.

Metabolism of dimetridazole. Dimetridazole and its metabolites present in urine were separated by paper chromatography with several solvent systems. Six metabolites (I, II, IV, V, VI, and VII) were observed when the developed chromatograms were examined in ultra-violet light or were sprayed with appropriate reagents. In addition, a seventh metabolite (III) was detected by chromatography and autoradiography of urine from a bird dosed with ^{14}C-labelled dimetridazole. Metabolites IV, V, VI, and VII have been positively identified by comparing their R_F values in several solvent systems and their colour reactions with those of synthetic reference compounds. The major metabolite, metabolite V (44·4 per cent of total excreted drug), was 1-methyl-5-nitroimidazol-2-ylmethyl hydrogen sulphate. Metabolite IV (25·8 per cent of total excreted drug) proved to be 1-methyl-5-nitroimidazole-2-carboxylic acid and metabolite VI (9·4 per cent of total excreted drug) was 2-hydroxymethyl-1-methyl-5-nitroimidazole. Unchanged dimetridazole (metabolite VII) accounted for only 3·2 per cent of the excreted material. Metabolite I was shown to be a conjugated glucuronide of a nitroimidazole, probably the 2-hydroxymethyl derivative (metabolite VI).

When dimetridazole is administered orally to turkeys nearly all the excreted drug is in a metabolized form and the basic metabolic pathway apparently involves oxidation of the 2-methyl group to 2-hydroxymethyl. This hydroxymethyl derivative then undergoes either conjugation or further oxidation. The nitro group appears to resist reduction in the body and about 90 per cent of the excreted drug consists of various nitroimidazoles.

Dimetridazole has been used: (1) at 0·0125 per cent in food continuously to prevent histomoniasis; (2) at 0·05 per cent in food for 10–14 days or in drinking water for 6 days to treat the disease. Condren *et al.*[5] administered dimetridazole in food at 0·025 and 0·05 per cent to turkeys for 24 weeks and showed polarographically that two days after withdrawal of the medicated food the tissues contain no significant residues. In the work recorded here, where turkeys had received dimetridazole (0·05 per cent) in drinking water for six days, no compounds containing a nitro group were detected polarographically in the tissues two days after medication had ceased. The absence of tissue residues, indicated by the polarographic technique, is confirmed by the radiochemical measurements with birds that had received a single oral dose of dimetridazole labelled with carbon-14. This observation is of importance because the radiochemical method will reveal all metabolites which contain carbon-14, including those not detected polarographically. The evidence obtained by Condren and ourselves indicates, therefore, that no detectable residues (< 0.02 p.p.m.) of dimetridazole or its metabolites are present in the tissues of turkeys three days after administration of the drug has ceased at prophylactic (0·0125 per cent) and therapeutic (0·05 per cent) levels.

Experimental Induction of Ciguatera Toxicity in Fish through Diet

CIGUATERA fish poisoning is widespread in the tropical Pacific and the Caribbean, causing recurrent outbreaks of illness in persons consuming snappers, groupers, jacks, barracudas, and other species that may contain ciguatera toxin[1-3]. The existence of ciguatera toxin in a fish appears to be controlled by some factors in its environment; many suggestions have been made as to the environmental factors concerned, ranging from dumped war material[3] to "flowering of coral"[4]. The most coherent hypothesis is that of Randall[5], who compiled circumstantial evidence and suggested that the origin of the toxin is in a benthic organism, perhaps an alga, and that it is passed through the food chain in the process of normal feeding.

The following observations made during field studies and during investigations at the Hawaii Marine Laboratory in the past two years favour this hypothesis: (1) a number of obligate herbivorous fishes such as *Acanthurus triostegus* (Linnaeus) and *Ctenochaetus striatus* (Quoy and Gaimard) from toxic areas in the Line Islands are toxic; (2) these herbivorous fishes are found in the stomach contents of the large carnivores such as the snappers and groupers which are also toxic; (3) only the larger carnivores appear to be toxic in affected areas. Randall[5] suggests the last may be because most of the herbivorous fishes are high-bodied, so that only the larger carnivores are capable of readily ingesting them.

However, the crux of the food chain hypothesis rests on three presumptions: (1) that the fish can acquire the toxin in their diet; (2) that the toxin can be eaten by the fish without detrimental effects; (3) that the toxin so ingested can be stored within the body of the fish in a pharmacologically unchanged condition. If these conditions cannot be obtained, the hypothesis would have to be discarded. Until now there has been no evidence that such food transmission was indeed possible.

In the course of work on the origin of ciguatera toxin, a simple feeding experiment was carried out using non-toxic *Acanthurus xanthopterus* Cuvier and Valenciennes from Hawaii. These surgeon fish are common market fish in Hawaii and have never been known to cause ciguatera in this archipelago[6]; they have also been fed to mongooses, the test animal for ciguatera toxin[7], as part of their non-toxic maintenance diet, for more than seven years without causing any reactions.

Starting in 1958, four of these fish were maintained in two running sea-water aquaria of about 120-gallon capacity; the two fish in each tank were separated by a screen allowing the passage of water but not food. One of each pair was fed on alternate days 10 grams of the flesh of *Lutjanus bohar* (Forskål) from the Line Islands which had been proved to be moderately to highly toxic (+3 to +5 reaction—see footnote to Table 1) when fed to a mongoose at a dose equivalent to 10 per cent of the body-weight of the mongoose. The other fish in the tank was fed comparable amounts of the non-toxic tuna, *Katsuwonus pelamis* (Linnaeus).

On several occasions the circulating sea-water failed and the fish died. These specimens were frozen soon after death and were kept in a frozen state. As the Hawaii Marine Laboratory burned to the ground in December 1961, destroying the experimental facilities and preventing continuing studies, it was decided to determine the toxicity of these fish at this time.

Unfortunately in the fire were lost all records of the experiment, including the length of time each fish was kept and the amount of toxic food fed. We recall that the longest period a test specimen was fed was about 18 months; the shortest, about 6 months. However, it can be easily recalled that this feeding of toxic fish flesh did no apparent harm to the specimens of *A. xanthopterus*, which grew as well as did their tank-mates fed on a non-toxic diet.

Table 1. TOXICITY OF FOUR SPECIMENS OF *Acanthurus xanthopterus* MAINTAINED ON A DIET OF TOXIC *Lutjanus bohar* (FORSKAL) AS DETERMINED BY THE MONGOOSE FEEDING BIOASSAY

	Weight of *A. xanthopterus* (g)	Tissue fed to mongoose	Dosage in % body-weight of mongoose (approx.)	Maximal reaction* in mongoose in 48 h
(1)	256	Flesh	30	5
		Flesh	8	5
		Flesh	10	4
		Viscera	2	3
(2)	217	Flesh	23	1
		Viscera	2	2
(3)	119	Flesh	10	1

(4)	94·5	Flesh	5	5
		Flesh	5	2
		Flesh	2	5
		Viscera	2	5

* Mongoose reactions (see Banner *et al.*, ref. 1): 0, no reaction; 1, slight weakness and flexion of the forelimbs; 2, slight motor ataxia, more pronounced flexion of the forelimbs and weakness of the hind limbs; 3, moderate ataxia with weakness and partial paralysis of limbs and body musculature; 4, acute motor ataxia and extreme weakness, capable of only limited movement, or coma; 5, death.

As we now lack laboratory facilities, the more sensitive mouse tests[8] cannot be used in the assay of the toxicity of the test fish; the results of the mongoose feeding test are given in Table 1.

The results show conclusively that the fish did acquire toxicity. It was unfortunate that control fish were not saved, as were the test fish; however, there is no reason to suspect that the controls have developed toxicity.

The tests, then, show that the toxin causing ciguatera may be passed through the food chain, without apparent change in the toxin and without apparent harm to the carrier.

New long-term experiments are now in progress utilizing live *Lutjanus bohar* to confirm this experiment.

Furunculosis in Salmon Kelts

DURING the spawning season of 1960–61 investigations were initiated in Ireland into the occurrence of furunculosis among spawning and spawned salmon. In that season 159 kelts were examined from four rivers; only one fish gave a positive reaction[1]. These investigations were continued during the spawning season of 1961–62 when 49 kelts were examined. All fish were dead when taken from the water. The distribution and results are given in Table 1.

Table 1

River	No. of kelts examined		Hatchery or naturally spawned	Result of test	Period
	Male	Female			
River Owenea (Co. Donegal)	25	11	All hatchery stripped	All negative	January 9—February 7, 1962
River Erne (Co. Donegal)	4	2	All naturally spawned	All negative	March 15—May 29, 1962
River Blackwater (Co. Waterford)	—	1	Hatchery stripped	Positive	December 6, 1961
River Boyne (Co. Meath)	1	—	Naturally spawned	Positive	December 3, 1961
River Lee (Co. Cork)	2	—	Hatchery stripped	Negative	January 23, 1962
River Moy (Co. Mayo)	3	—	Naturally spawned	1 positive	March 1–3, 1962
Total	35	14		46 negative 3 positive	

As can be seen, three fish (6·1 per cent) gave a positive reaction.

I thank Mr. E. Murphy, of the Veterinary College of Ireland, Ballsbridge, Dublin, who undertook bacteriological examination of these fish.

Primary Productivity of Periphyton

THE difficult problem of assaying biomass and rates of colonization by periphyton in fresh and saline waters has been recognized for many years. The most common method used in these investigations has involved the measurement of rates of colonization by periphyton on artificial substrata. The literature on this subject has recently been reviewed by Cooke[1], Sládečková[2], and myself[3]. Very few of these investigations are concerned with measurements of photosynthetic rates of algal periphyton under natural conditions. A method for measuring productivity of periphyton *in situ* in lakes and ponds would be useful for comparative studies of the relative importance of each of the photosynthetic producer components, that is, phytoplankton, periphyton, and macrophytes.

A technique utilizing carbon-14 as a tracer was developed for assaying the *in situ* productivity of periphyton. The methods were similar to those that I developed[4] for submerged macrophytes. Transparent and opaque 'Plexiglas' chambers[4], cylindrical, open at one end, and containing an injection port, were inserted into the substratum along littoral transects perpendicular to the shoreline enclosing the algal-encrusted rocks and sediment. Each chamber was inoculated with 1 ml. of carbon-14 as sodium carbonate of known assay determined by gas-phase analysis and comparison to National Bureau of Standards samples. After incubation for a 4–6-h period the surface cm of sediment was removed and stored frozen over a strong desiccant under vacuum. Immediately prior to analysis the samples were exposed to fumes of hydrochloric acid for a 10–15-min period to remove any radiocarbon precipitated as monocarbonates. The algal periphyton, primarily epipelic and epilithic, was combusted from the sediments using a Van Slyke wet carbon combustion. The $^{14}CO_2$ was evolved at atmospheric pressure, treated[4], and flushed with pure carbon dioxide into an evacuated ionization chamber. Radioassay was accomplished directly using a Dynacon electrometer[5]. Total inorganic carbon available for photosynthesis was determined titrimetrically. In addition, a carbon-14 isotope effect of 6 per cent was used in the computations.

Estimates of littoral periphyton standing crop using pigment analyses are seriously impaired by the interference of the absorption spectra of chlorophyll degradation products. To circumvent partially this problem a modified technique of chlorophyll extraction was utilized. Replicate cores of the surface substrata were collected at intervals along the transects mentioned above. The pigments of the upper cm of the sediments were extracted in 90 per cent alkaline aqueous acetone in the

Table 1

	Annual mean productivity* (mg C/m²/day)	Total annual mean productivity† (kg C/lake/day)
Phytoplankton	249·3	101·0
Periphyton	781·5	75·5
Macrophytes	76·5 (372·3)‡	1·4 (6·6)‡
	1,057·3	177·9

* Annual mean of water column for the phytoplankton, mean of littoral one for periphyton and macrophytes.

† Total annual mean for the lake compensating for changes in the volume for phytoplankton and areal fluctuations of the littoral zone (periphyton and macrophytes).

‡ Data in parentheses are mean values for the growing season (75 days) of the macrophytes.

dark at 4° C to remove the chlorophylls and naturally occurring pigment degradation products. Similarly, replicated samples were extracted in acidic 90 per cent acetone to convert the chlorophylls to pheophytins. Extracts were analysed at 665, 645, 630, 510, and 480 mμ (Beckman *DU* spectrophotometer). Background absorption not a result of the chlorophylls between 600 and 700 mμ was usually negligible; where significant it was subtracted from the specific density readings. Chlorophyll *a* ('functional chlorophyll') of the periphyton was determined by difference using the density values for chlorophyll *a* and pheophyton *a*, accounting for shifts in the spectra from extinction coefficients for the pigments in acetone at this wave-length. The extinction coefficient of pheophyton *a* in 90 per cent acetone was estimated from known values in other solvent concentrations and therefore the values must be viewed as approximate. Corrected values were then used in the formulæ of Richards[6] with necessary volume modifications.

The primary productivity of the littoral periphyton was determined in a large, saline lake, Borax Lake, of northern California in 1961–62 (Fig. 1). Shallow closed lakes of this type are subject to considerable fluctuation in volume and the amount of littoral area available for periphytic colonization varies accordingly. Changes in volume of the lake and area of the littoral zone at each sampling interval were calculated by planimetry from morphometric measurements of the basin made at the time the lake was surveyed in December. This method provided a means of estimating the total primary productivity of the lake on a more realistic basis (Table 1). The littoral zone of Borax Lake is remarkably uniform, consisting largely of small angular pebbles heavily encrusted with periphyton in spring and summer months, and leads from a gentle slope to the ooze of the flat, deeper areas. The uniform littoral region is small compared with the total area of the basin, but it constitutes a major region of primary productivity.

Correlations were generally poor between the productivity (Fig. 1) and estimates of the mean biomass of the littoral periphyton from pigment analyses (Fig. 2). Only during periods of high productivity did similar trends appear. The lack of correlation was probably the result of numerous variables, for example, light, nutrition, etc., that affect the momentary concentrations of the pigments. Evidence is rapidly accumulating[7] that pigment estimates of producer biomass must be interpreted with considerable caution.

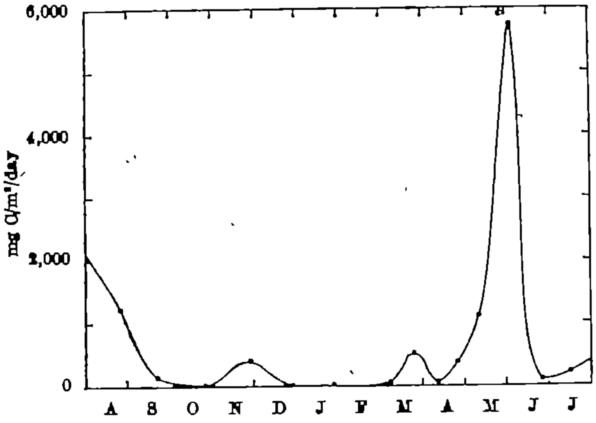

Fig. 1

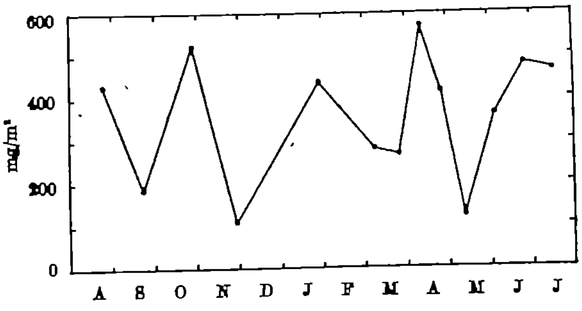

Fig. 2

Hitherto the contribution of the littoral producers to the total photosynthetic carbon fixation has generally been regarded as insignificant as compared with that of the phytoplankton. Neglect of the sessile producers is perhaps warranted in certain large, deep lakes. However, the periphyton and macrophytes constitute a major or, perhaps, the predominant source of photosynthetic energy fixation in many shallow lakes, ponds, marshes, and rivers.

Effect of Kinetin on Powdery Mildew

IN work on wheat stem rust, Person *et al.*[1] observed that detached leaves from resistant plants which become susceptible and chlorotic when floated on water maintain their green colour and rust resistance when floated on a kinetin solution. A review of the effects of kinetin (6-furfurylaminopurine) on various plant tissues has been made by Parthier[2].

This communication deals with activity of kinetin against fungi causing powdery mildew in plants.

To screen chemicals for chemotherapeutic effect on powdery mildew, cucumber leaf disks 12 mm in diameter were floated on an aqueous solution of the compound to be tested, and inoculated by dusting conidia of *Erysiphe cichoracearum* on the upper surface. The evaluation was made after 8 days of incubation in the greenhouse at 17°–21° C. Under the conditions of the test, 10–20 p.p.m. of kinetin checked completely development of the powdery mildew, while abundant growth of the fungus was present on check disks (Fig. 1). A possibility that inhibition of this obligate parasite could be due to damage or death of the host tissues was ruled out by the fact that inoculation was again successful if it was performed two days after replacement of the kinetin solution by water. Other powdery mildews, such as *Erysiphe polygoni* on lupins, beets and peas, *E. graminis* on wheat, rye and barley, *Podosphaera leucotricha* on apple, *Sphaerotheca pannosa* on roses, and *Sphaerotheca humuli* on strawberries, were also inhibited on leaf disks by the kinetin.

For anatomical investigations of the effect of kinetin on development of powdery mildew, the cucumber leaf disks

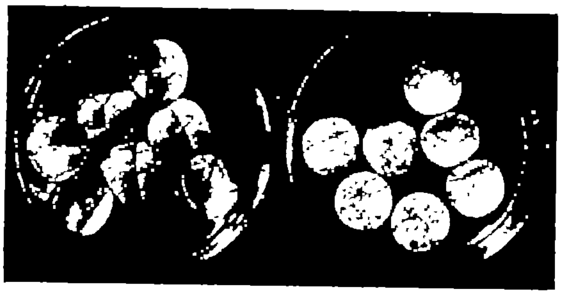

Fig. 1. Activity of kinetin on cucumber powdery mildew. Leaf disks floating on 20 p.p.m. kinetin (left, no development of powdery mildew) and water (right, covered with powdery mildew)

were floated on an aqueous solution made up to 20 p.p.m. kinetin, and inoculated by dusting with conidia of *Erysiphe cichoracearum*. After three days the inoculated epidermis was stripped, stained with cotton blue in lactophenol and subjected to microscopic examination. It appeared that neither the germination of the conidia nor the penetration of the fungus into the epidermis of the host tissue was in any way different from that in the control disks floated on water. However, on formation of the first haustorium, the development of the fungus had stopped on treated disks while the control showed an average of 7–8 haustoria per conidium during the same interval of time. These observations lead to the assumption that the action of kinetin on powdery mildew occurs inside the host epidermis. However, it is not yet clear whether kinetin acts directly on the haustorium of the fungus or via the metabolism of the host plant.

Reversal of the effect of kinetin (20 p.p.m.) on powdery mildew was in evidence when folic acid (50 p.p.m.) was added to the solution, indicating a possible relation of kinetin to the metabolism of folic acid in host or parasite. Parabenzoic acid utilized in the same manner failed to circumvent the action of kinetin on the fungus.

The attempts to control powdery mildew of cucumber systematically by application of a 300 p.p.m. kinetin solution to bare roots of cucumber plants failed. Also foliar application of kinetin by spraying a 1,000 p.p.m. solution on the leaves one and two days following the inoculation was not successful. Insufficient transport of the chemical in plant tissue may be a factor in this mode of application[2].

Kinetin appeared inactive against the other fungi which were tested. In analogous experiments with leaf disks, a solution containing 100 p.p.m. kinetin failed to reduce development of chocolate spot (*Botrytis fabae*) of dwarf French beans and 20 p.p.m. was ineffective against bean rust (*Uromyces appendiculatus*). *In vitro* the spore germination of *Ascochyta pisi*, *Botrytis fabae* and *Aspergillus niger* was not affected in a solution containing 1,000 p.p.m. kinetin, and mycelial growth of these fungi, placed on potato dextrose agar plus 100 p.p.m. kinetin, was not reduced.

The two components of kinetin, namely, adenine and furfuryl alcohol, showed no activity against powdery mildew, singly or in combination, as a 100 p.p.m. solution in the leaf disk test. However, on further testing of about 80 purines and pyrimidines, 6-azauracil appeared highly active against cucumber powdery mildew[3].

MICROBIOLOGY

Polyimines Mutagenic for Bacteriophage *T4B*

Certain highly reactive polyimines have been suggested for use as sterilizing agents in the control of insect populations[1]. These compounds are radiomimetic, and the possibility arises that they are mutagenic. The mutagenic activities of four such compounds have been examined by testing for the induction of *r* mutants in bacteriophage *T4B*: 2,2,4,4,6,6-hexa(1-aziridinyl)-2,4,6-triphospha-1,3,5-triazine ('Apholate')[2], *tris*(1-aziridinyl) phosphine oxide (APO)[3], *tris*(1-(2-methyl) aziridinyl) phosphine oxide (MAPO)[2], and ethylene glycol bis-((1,2) propylene)-carboxamide (EGPC)[3].

The compounds were dissolved in M/15 phosphate buffer at *p*H 7 and were brought immediately to 37°. A pre-warmed aliquot of *T4B* in buffer was added, and samples were taken at intervals to be assayed for the surviving fraction of bacteriophage and the proportion of *r* mutants. Stocks of *T4B* containing a low background of *r* mutants were used, and *r* mutants were counted by visually screening plates containing about 1,000 plaques growing on *E. coli B*. Conventional bacteriophage methods were used[4].

T4B was inactivated exponentially by all four compounds. The rates of inactivation were greater at *p*H 6 than at *p*H 7, and some of the compounds themselves may be unstable in aqueous solution below *p*H 7.

Table 1

Compound	Conc. (wt/wt)	Rate k (min^{-1}) of inactivation	Mutations per lethal hit
'Apholate'	0·005	50–100	$< 0{\cdot}3 \times 10^{-4}$
MAPO	0·005	4·12	$4{\cdot}3 \times 10^{-4}$
APO	0·005	21·0	$2{\cdot}9 \times 10^{-4}$
EGPC	0·0005	154	$3{\cdot}2 \times 10^{-4}$

The results are given in Table 1. MAPO, APO and EGPC were highly mutagenic, while 'Apholate' was not detectably mutagenic in these tests. Inactivation rates obtained with 'Apholate' varied about two-fold in different experiments. Although the rates of inactivation of *T4B* by the compounds varied considerably, mutations per lethal hit were approximately constant for APO, MAPO and EGPC, suggesting that these three compounds may have similar chemical mechanisms of mutagenesis.

The high mutagenicity of APO, MAPO and EGPC indicate that their use as insect sterilizing agents should be confined to systems avoiding their free distribution in Nature, especially where transmission to human beings could occur. Although 'Apholate' was not demonstrably mutagenic in these tests, its close chemical relationship to the other compounds indicates that it might well be mutagenic under other conditions.

This work was supported by U.S. Public Health Service grant *E*3203.

Increased Survival of Ultra-violet-irradiated *Shigella sonnei* by decreasing the Surface Tension

The role of the surface tension of the suspending medium in the susceptibility of bacteria to ultra-violet irradiation, to our knowledge, has not been examined. During a course of investigations on the effect of ultra-violet light on *Shigella sonnei* we observed a very interesting relationship between the surface tension (air to liquid) of the fluid in which the organisms were irradiated and the ability to recover from the damaging effects of the irradiation. We have found that, within certain limits, a reduc-

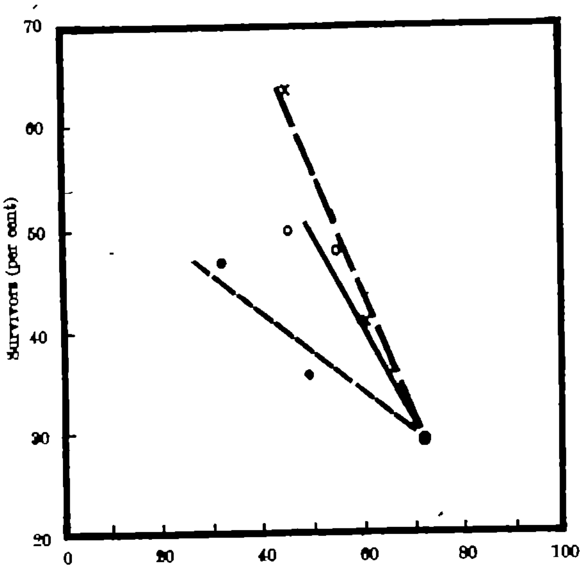

Fig. 1. Survival of ultra-violet-irradiated *S. sonnei* irradiated in buffers of different surface tension values. ×, Sodium taurocholate; O, 'Tween 20'; ●, sodium sulphosuccinate

tion of the surface tension resulted in increased survival of the irradiated cells.

S. sonnei, strain 5044–59, was obtained from Dr. W. H. Ewing, Communicable Disease Center, Atlanta, Georgia. The organisms were irradiated in buffer solutions adjusted to different surface tension values. 'Tween 20', sodium taurocholate, and sodium sulphosuccinate were the surface-tension depressants used. The agents were added to the buffer solutions and the surface tension of the solutions was measured with the Du Nuoy (Cenco) tensiometer. Readings were made at room temperature (approximately 23°–25° C); the average of three readings was recorded. The apparent surface tension which was read directly from the scale of the tensiometer in dynes/cm was corrected by dividing the values by the density of the solution being assayed and then multiplying the value by a correction factor which was dependent on the apparent surface tension reading and a ratio R/r (the radius of the platinum ring, R/the radius of the wire, r). The value of R/r was supplied by the manufacturer of the tensiometer. 24-h cells of *S. sonnei* were washed and resuspended in buffer to yield an optical density of 0·15. 5-ml. aliquots of the cell suspensions were irradiated at various surface tension values. Controls consisted of aliquots of unirradiated cells held in the buffers at the same surface tension values. A General Electric 15-W 'germicidal lamp' (*G15T8*), which emitted waves of approximately 2537 Å, was used. Under the conditions of these experiments the radiation intensity was 17·2 ergs/sec/mm². The total ultra-violet dose to which the cells were exposed was 258 ergs/mm² (15 sec); preliminary experiments have revealed that this dose resulted in a surviving fraction of approximately 30 per cent.

Fig. 1 summarizes the results. It can be seen that, in general, all three surface-tension-lowering agents increased the recovery of irradiated cells. However, sodium taurocholate was considerably more protective than sodium sulphosuccinate even though the surface tension values were similar. One possible explanation for this may be that sodium sulphosuccinate exhibited some chemical toxicity in addition to its surface tension-lowering properties. Since these experiments did not rule out the possibility that the agents examined had protective activity against ultra-violet light we increased the concentration of the agents studied to determine their protective role. Increasing the concentration of the surface-active agents did not further depress the surface tension since the maximum level of depression had already been obtained. Increased amounts of the surfactants did not increase the protection against ultra-violet light. Possibly maximal chemo-protection, if involved, had been reached.

We have demonstrated that cells irradiated in buffer with lowered surface tension survived ultra-violet irradiation better than cells irradiated at 70 dynes/cm the surface tension of the medium ordinarily used. We do not know at this stage whether the lowered surface tension reduced the absorption of ultra-violet light by the cells or if toxic substances produced by irradiation were inactivated or less stable at the lower surface tension values. Our investigations have shown that various factors affect the ultra-violet susceptibility of *S. sonnei* such as age of the organism[1] and exposure to starvation[2].

PSYCHOLOGY

Acoustic Confusions and Memory Span for Words

PREDICTION of the short-term memory span for sequences of items has been a crucial problem in testing the value of information theory as a model for remembering. A number of authors[1–3] have presented data which show that observed spans fall between predicted values and values which would obtain if span were independent of information per item. In all these cases the underlying assumption made was that if an item was forgotten the alternative items in the vocabulary were available as responses with equal probability.

I have, however, shown[4] that for the case of visually presented letter sequences this assumption is false. If an item is forgotten: (1) the alternative items are not equiprobable responses, and (2) the probability of their occurrence can be predicted by reference to a confusion matrix of listening errors when the same items are heard through white noise in a conventional intelligibility study. This result suggests, at least for verbal material, a model for predicting memory span in terms of the probability of acoustic confusion within the test vocabulary, which may be quite independent of the information per item. These contentions are supported by two experiments.

In both experiments the test material consisted of 5-word sequences which, using a memory drum, were visually presented word by word at a rate of 1 word/sec. No word was repeated in one sequence. At the end of each sequence subjects wrote down what they could recall in the correct order.

Experiment 1. Twelve naval ratings each did two conditions, half in the order (*a*), (*b*), half (*b*), (*a*). Each condition used 20 sequences. Condition (*a*): ten-word vocabulary composed of five pairs of visually different homophones, namely: *sum, some, ruff, rough, rays, raise, court, caught, past, passed*. Condition (*b*): ten-word vocabulary composed of common acoustically dissimilar words, namely: *beat, deep, fall, glue, mine, nose, play, rich, soil, town*.

Performance was scored in terms of percentage of sequences correctly reproduced. For conditions (*a*) and (*b*) the means were respectively 10·0 per cent and 58·3 per cent. No subject performed better on (*a*) than on (*b*).

Experiment 2. Eighteen different naval ratings each did two conditions, half in the order (*b*), (*c*), half (*c*), (*b*).

Each condition used 40 sequences. Condition (*b*) used the same vocabulary as in (*b*) of the first experiment. In condition (*c*) every word in the entire test (200 words) was different, and all were common four-letter nouns or verbs drawn from the *AA* and *A* lists of Thorndike and Lorge[5].

The respective mean percentage correct sequences for the (*b*) and (*c*) conditions were 68·7 per cent and 43·4 per cent. These means are significantly different ($t = 4{\cdot}26$; $P < 0{\cdot}001$).

The result of Experiment 2 is compatible with an informational model of short-term memory. But the (*b*) conditions in the two experiments are identical (apart from the number of sequences presented), and the subjects are comparable. Furthermore, the difference between the (*b*) condition scores for the two experiments is not significant (Mann–Whitney test, $P > 0{\cdot}1$). One might therefore be justified in regarding condition (*b*) as a subject matching test, and so compare the mean scores of (*a*) and (*c*). In this case a Mann–Whitney test shows the difference to be highly significant ($P < 0{\cdot}001$). This result is not compatible with an informational model.

Taken together these results provide far more support for a memory span model based on probability of acoustic confusion than for one based on information theory. I have shown that, if vocabulary size is constant, memory span is a function of probability of acoustic confusion. I have further shown that varying the vocabulary size may lead to either greater or smaller memory span. It seems *a priori* that the 200-word vocabulary of condition (*c*) has a smaller probability of acoustic confusion than the (*a*) vocabulary, and a greater one than the (*b*) vocabulary, and that these are the relationships on which the results depend.

Relationship between Degree of Learning and Retention

Underwood[1] has argued that the major factor determining retention is the previous learning experience of subjects. On the basis of data from a series of earlier experiments by many different workers he suggests that recall of verbal material is a function of the number of previous lists learned. The more lists previously learned, the lower is the recall score after 24 h. Underwood claims that this is due to an increase in proactive inhibition from each list learned. In this way proactive inhibition is considered to be the main causal factor affecting recall performance.

The following two experiments have attempted to assess the importance of proactive inhibition in the learning situation Underwood discusses. The first experiment used the same design as in the work cited by Underwood. Six lists of paired associate items were learned by the anticipation method. One list was learned to the criterion of a single correct trial on each of six successive days, and each list was recalled on the following day before learning of the next list commenced.

The percentage recall for each list is shown in Fig. 1 (Exp. 1). Although percentage recall declined over successive lists, this decline was not so great as Underwood's composite curve from previous experiments would suggest. It is felt that this is because Underwood's curve combines data from paired associate and serial learning tasks; recall of serial lists is expected to be worse than recall of paired associate lists.

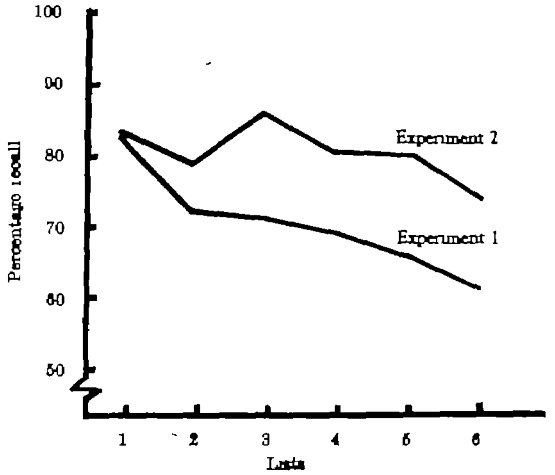

Fig. 1. Percentage recall after 24 h for six successive lists under two experimental conditions of learning

On the other hand, it was found that mean number of trials to reach the learning criterion declined steadily from 11·40 to 6·85 over the six lists. The average degree of learning of items declined in a similar fashion. Degree of learning is here operationally defined as the number of times an item is correctly anticipated during learning. The mean number of correct anticipations per item for list 1 was 5·90, and for list 6 this figure was 3·86.

The relationship between degree of learning of individual items and the probability of recall of those items was investigated for each of the six lists. It was found that probability of recall of items was directly dependent on degree of learning. It has been already reported that mean degree of learning of items in each list declined with each additional list learned. Since probability of recall is found to be dependent on degree of learning, it is felt that the observed decline in mean degree of learning provides a more economical explanation of the decline in recall scores than does an explanation invoking an additional concept, proactive inhibition.

A second experiment investigated the relationship between degree of learning and retention of items over the same six lists when trials to criterion were held constant for each list. Mean degree of learning of items was found to increase over the six lists. The recall performance is again shown in Fig. 1 (Exp. 2). It can be seen that no consistent decline in recall scores occurred in these conditions. As in the previous experiment, it was found that probability of recall was directly dependent on number of correct anticipations (that is, on degree of learning).

While the variations in degree of learning over the six lists are again taken to be the major determinant of recall score, it is however likely that an additional factor is affecting the results of the second experiment. There was a significant tendency for a given degree of learning to be associated with a lower probability of recall with each additional list learned. It is possible that this represents proactive inhibition, although other possibilities cannot be ruled out (for example, a decline in the amount of extra-experimental rehearsal of items). A similar tendency was observed in the results of the first experiment, but this was not statistically significant. If this second factor in the results of these two experiments is in fact proactive inhibition it clearly is not the main causal factor determining recall of items.

This work was supported by a grant from the Department of Scientific and Industrial Research to the Department of Psychology, University of Sheffield.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, March 11

Institution of Mechanical Engineers, Industrial Administration and Engineering Production Group (at 1 Birdcage Walk, Westminster, London, S.W.1).—All-day Discussion on "Metallurgical and Engineering Problems in the Machining of Materials".

Institution of Mechanical Engineers, Manipulative and Mechanical Handling Machinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 4 p.m.—Symposium on "Noise in Weaving Machinery".

University of London (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Dr. B. Ackner: "Emotional Reactions to Physical Illness".*

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. D. W. Sciama: "The Unity of the Universe".

Institution of Electrical Engineers, Electronics Division P.G.E8 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. L. Lewin: "Microwave Theory or Microwave Green Fingers ?"

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1 (at 5.30 p.m.—Prof. Reinhold Baer (Frankfurt am Main): "The Reduced Rank of a Group".*

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"Lords of the Forest" (Colour film).

Women's Engineering Society (at "Hope House", 46 Great Peter Street, London, S.W.1), at 7.30 p.m.—Dr. A. R. Flint: "The Channel Bridge Project".

Monday, March 11—Tuesday, March 12

Society of Chemical Industry, Chemical Engineering Group, the **Institution of Chemical Engineers, South-Eastern Branch;** and the **Institute of Petroleum** (at the Royal Commonwealth Society's Assembly Hall, Craven Street, London, W.C.2)—Symposium on "Fluidisation".

Monday, March 11—Thursday, March 14

Oil and Colour Chemists' Association (at the Royal Horticultural Society's Old and New Halls, London, S.W.1)—Fifteenth Technical Exhibition.*

Tuesday, March 12

British Computer Society (at the Northampton College of Advanced Technology, St. John Street, London, E.C.1), at 9.30 a.m.—All-day meeting on "Data Transmission".

University of London (at Wye College, Wye, near Ashford, Kent, at 5 p.m.—Prof Asger Klougart (Copenhagen): "Recent Advances in Danish Horticulture".*

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers, Power Division (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. Davis. "Lightning Flashovers on the British Grid".

Institution of Electrical Engineers, Science and General Division P.G.S8 (at Savoy Place, London, W.C.2.) at 5.30 p.m.—Discussion on "The Financial Background to Engineering Decisions" opened by Mr. R. E. Burnett.

University of London (at Imperial College of Science and Technology, Prince Consort Road, London, S.W.7), at 5.30 p.m.—Prof. R. W. H. Sargent: "Chemical Engineering and Engineering Science" (Inaugural Lecture).

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. A Scheinin (Turku, Finland): "Vital Microscopy of the Dental Pulp".*

Institution of Mechanical Engineers, Automobile Division (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. J. F. Alcock and Mr. W. M. Scott: "Some More Light on Diesel Combustion".

Institut Français du Royaume-Uni (at Queensberry Place, London, S.W.7), at 6.30 p.m.—Prof. Etienne Wolff "Les Agents Provocateurs des Malformations" (La Production Expérimentale de Monstruosités).

Wednesday, March 13

Society for Analytical Chemistry, Biological Methods Group (at the Friends Meeting House, Euston Road, London, N.W.1), at 10 a.m.—*Symposium* on "The Pharmacological Screening of New Drugs".

University of London (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 2 p.m.—Prof. G. Causey: "The Principles of Electron Microscopy for Histologists".*

Colour Group (Great Britain) (in the new Physics Department, Imperial College of Science and Technology, London, S.W.7), at 3 p.m.—Annual General Meeting. 3.35 p.m.—Dr. R. W. G. Hunt: "Printing Colour Negatives".

Geological Society of London (at Burlington House, Piccadilly, *London*, W.1), at 5 p.m.—Mr. R. G. Park: "The Structural History of the Lewisian Rocks of Gairloch, Wester Ross"; Dr. D. R. Bowes, Dr. A. E. Wright and Mr. R. G. Park: "Layered Intrusive Rocks in the Lewisian of the North-West Highlands of Scotland".

Institution of Electrical Engineers, Electronics Division (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. O. Carter: "Pulse Techniques in Line Communications".

University of London (at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 5.30 p.m.—Dr. F. R. Johnson: "The Reactions of Epithelium to Injury"* (Last of three lectures on "The Scientific Basis of Dentistry" organized by the British Postgraduate Medical Federation.)

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Prof. A. Rodger: "The Selection of Managers".

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Prof. S. S. Kutateladze: "Heat Transfer in Boiling".

Institute of Information Scientists (at the Swedenborg Society Hall, 20 Bloomsbury Way, London, W.C.1), at 6.15 p.m.—Mr. P. J. Geary. "Compilation of State-of-the-Art Surveys".

Institute of Metal Finishing, Organic Finishing Group (at the British Institute of Management, 80 Fetter Lane, London, E.C.4), at 6.30 p.m.—Mr. L. A. Bashford: "Chemistry of Synthetic Resins: The Whys and Wherefores".

Society of Instrument Technology, Control Technology Section (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. J. Stafford. "The Application of Computers as a Control Aid in the Development of Hovercraft".

Institute of Biology (at the Royal Entomological Society, 41 Queen's Gate, London, S.W.7), at 7.15 p.m.—Dr. J. M. Hirst: "Fungus Spore Dispersal in Plant Diseases".

Thursday, March 14

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. D. F. Lee, Mr. J. Scanlan and Mr. W. F. Watson: "The Cyclization of Natural Rubber".

University of London (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. H. Quastler (Brookhaven): "Chemical Communication Systems in Cells".*

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. U. Grenander (Stockholm): "Probability Distributions on Algebraic Structures"* (Further lecture on March 18).

Chemical Society (at Burlington House, Piccadilly, London, W.1), at 6 p.m.—Scientific Papers.

Institution of Mechanical Engineers, Lubrication and Wear Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Elasto-Hydrodynamics".

Plastics Institute, Engineering Sub-Group (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. J. R. Martland: "Mould Design"; Mr. P. Spiro: "Electroformed Moulds"; Mr. A. S. Matthews "Special Problems Relating to Close Tolerance Injection Moulding".

Radar and Electronics Association (at the Royal Society of Arts, John Adam Street, London, W.C.2), at 7 p.m.—Mr. D. Hunter: "The Role of the Computer in Radar Systems".

Royal Institute of Chemistry, London Section (joint meeting with the **Polytechnic Chemical Society**, at the Polytechnic, Regent Street, London, W.1), at 7 p.m.—Dr. R. A. Jeffreys: "The Chemistry of Colour Photography".

Friday, March 15

Society for Water Treatment and Examination (at the Royal Society of Health, 90 Buckingham Palace Road, London, S.W.1), at 9.30 a.m.—Eleventh Annual General Meeting.

Association of Applied Biologists (in the Lecture Hall of the British Museum (Natural History), Cromwell Road, London, S.W.7), at 10.40 a.m.—Symposium on "The Effect of Environment on Crop Production".

Institute of Navigation (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 2.30 p.m.—Meeting on "The Application of Inertia Navigation Systems to Air Transport".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. R. L. F. Boyd: "Astronomy of the Sun".

Saturday, March 16

Nutrition Society (at the Hospital for Sick Children, Great Ormond Street, *London*, W.C.1), at 10.30 a.m.—All-day Meeting on "Nutritional Problems in Infancy and Childhood".

Monday, March 18

Medical Research Council (at the National Institute for Medical Research, Mill Hill, London, N.W.7), at 4.30 p.m.—Prof. S. Spiegelman (University of Illinois). "The Use of DNA-RNA Hybridization as an Analytical Tool for the Solution of Biological Problems".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Prof. Gilbert White (Chicago University): "The Contribution of Geographical Analysis to the Planning of River Development".

Society of Chemical Industry (joint meeting of the **Pesticides, Fine Chemicals** and **Microbiology Groups**, at 14 Belgrave Square, London, S.W.1), at 5 p.m.—Prof. B. Lythgoe and Dr. A. Rhodes: "The Chemical and Biological Properties of *Venturicidin*".

Institution of Electrical Engineers, Science and General Division P.G.S3 and **Power Division P.G. P7** (at Savoy Place, London, W.C.2), at 5.30 p.m.—*Dr. M. P. Reece*: "Circuit Interruption in Vacuum".

Institute of Metal Finishing, London Branch (at the Borough Polytechnic, Borough High Street, London, S.E.1), at 6.15 p.m.—Mr. R. J. Brown: "Electroplating and the Use of Plastics and Corrosion Resistant Materials".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer or Assistant Professor in Philosophy at the Memorial *University of Newfoundland*—Dean of the Faculty of Arts and Science, Memorial University of Newfoundland, St. John's, Newfoundland, Canada, and The Secretary, Association of Universities of the British *Commonwealth* (Branch Office), Marlborough House, Pall Mall, London S.W.1 (March 15).

HEAD OF THE DEPARTMENT OF ELECTRICAL ENGINEERING, Enfield College of Technology, Enfield—Chief Education Officer (F. 3), Middlesex County Council, 10 Great George Street, London, S.W.1 (March 16).

SENIOR LECTURER/LECTURER (preferably with special interests in physiology or ecology or anatomy) IN THE DEPARTMENT OF BOTANY, University of Ghana—The Registrar, University of Ghana, P.O. Box 25, Legon, Accra; or the Assistant Registrar (Overseas), University of Ghana, 15 Gordon Square, London, W.C.1 (March 18).

SECOND CHAIR IN THE DEPARTMENT OF MATHEMATICS (applicants should have special interests in the field of applied mathematics)—The Registrar, The University, Leicester (March 20).

SENIOR LECTURER or LECTURER (preferably with an interest in political philosophy) IN THE DEPARTMENT OF PHILOSOPHY—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (March 22).

LECTURER IN PHYSICAL CHEMISTRY—The Registrar, Manchester College of Science and Technology, Manchester 1 (March 23).

LECTURER or ASSISTANT LECTURER (with special interests either (a) in experimental approaches to algology, or (b) in some aspect of the fine structure of plant cells) IN THE DEPARTMENT OF BOTANY—The Registrar, University College of Wales, Aberystwyth (March 23).

CHAIR OF PHYSICAL OCEANOGRAPHY—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (March 25).

MANAGER OF THE RESEARCH REACTOR "CONSORT" now under construction at Silwood Park, the Imperial College Field Station near Ascot—Dr. P. J. Grant, Mechanical Engineering Department, Imperial College of Science and Technology, London, S.W.7 (March 25).

BIOCHEMIST (Scientific Officer grade) to work on plant enzyme reactions—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (March 30).

LECTURER IN PHYSICAL or INORGANIC CHEMISTRY; and a LECTURER IN THEORETICAL CHEMISTRY—The Secretary, The University, Edinburgh (April 1).

TURNER AND NEWALL RESEARCH FELLOW IN ENGINEERING, INORGANIC CHEMISTRY or PHYSICS—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 1).

TEACHING FELLOW (with an honours degree in science or equivalent qualifications) IN THE SCHOOL OF CHEMISTRY, University of New South Wales—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2; and the Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (April 5).

LECTURER (with postgraduate experience in research, coupled with a keen interest in teaching) IN PHYSICS at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, April 6).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOW IN CHEMISTRY, PHYSICS, ENGINEERING (including Chemical Engineering), METALLURGY, PHARMACOLOGY or related subjects—The Registrar, The University, Sheffield (April 8).

PROFESSOR IN PHILOSOPHY; and a SENIOR LECTURER/LECTURER IN PHILOSOPHY in the Faculty of Arts at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 15).

READER IN THEORETICAL PHYSICS—The Secretary of Faculties, University Registry, Oxford (April 15).

SENIOR LECTURER or LECTURER IN ENGINEERING MATHEMATICS in the Faculty of Engineering and Architecture at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (April 15).

RESEARCH ASSISTANT (organic chemist or biochemist), to undertake work on polysaccharides of intervertebral discs and connective tissues—The Secretary, Royal Infirmary, Bradford, 9, and the Registrar, Dept. (E/20), Bradford Institute of Technology, Bradford, 7.

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER, for research on marine plankton, hydrography and fisheries—The Officer-in-Charge, Oceanographic Laboratory, Scottish Marine Biological Association, Craighall Road, Edinburgh, 6.

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (with an honours degree in mathematics and preferably an interest in biology) IN THE STATISTICS SECTION, for duties which include consultation and research on design and analysis of experiments, and co-operation with the research staff of the Institute in the statistical aspects of the work—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 63/6.

SCIENCE AND WORLD PEACE

THE International Conferences on science and world affairs, now known as the "Pugwash Conferences", of which ten have now been held, have, as Prof. J. Rotblat justly claims in his brief history of the Conferences[*], become established as an important and effective channel of communication between scientists for the study and discussion of the most complex problems facing mankind at the present time. This standing results from the resolute efforts of a group of scientists determined to retain an independent and unbiased outlook, though Prof. Rotblat admits that gradual development, seeking, learning and blundering have also contributed. Lord Hailsham's opening address to the tenth Conference in London last September, and also the messages received from Mr. Harold Macmillan, President Kennedy, Mr. Krushchev and the Acting Secretary-General of the United Nations, Mr. U. Thant, testify to the respect which the movement already commands. Moreover, even more tangible fruit may perhaps be seen in the proposal for sealed seismic stations as a means of detecting nuclear explosions made during the final steps of the Conference itself.

The proposal, which was endorsed in Moscow a week later at the seventh General Assembly of the World Federation of Scientific Workers, and has now been adopted as part of the official Soviet proposals for controlling the cessation of nuclear tests, involves instruments for detecting seismic disturbances sealed in containers which are placed in specified positions by nationals of the country whose territory is being inspected. If inspection stations elsewhere indicate a suspicious 'event', the sealed containers from a given area around the origin of the 'event' are required to be handed over to an international authority. The problem remains of ensuring that the containers have not been tampered with and that they have actually been placed in the specified positions, but it is believed that this could be established by a skilled seismologist from an examination of the recording of background tremors.

Lord Hailsham's opening address took a much wider view, however. Challenging the validity of the assumption that existing political institutions must necessarily continue and some sort of *modus vivendi* established between existing political systems, he urged that complete disarmament required co-operation in positive measures to promote human welfare and also an examination of the need for a central political authority. This, he felt, was particularly emphasized by the nature of the nuclear weapon and by the needs of under-developed countries for aid. There was an established opportunity for international co-operation in the purely scientific field; but, as regards international aid, what was required above all was the application of known technology for the development of human happiness and culture—means which by themselves offer no political advantage to any Power Bloc over another.

What is interesting about Lord Hailsham's address is the extent to which his ideas are reflected in the statement issued after the Conference. The statement affirmed that the scientists from thirty-five countries assembled at the Conference were united by an awareness that the scientific revolution had created a radically new situation for humanity, endowing man with an unprecedented capacity for creation and destruction. Their chief concern was to prevent war and to relieve humanity of the fearful anxieties and the grave economic burdens caused by the arms race. A general war with nuclear weapons would be a disaster of unimaginable magnitude. Against global rockets with thermonuclear war-heads there is no effective defence, and in this situation the traditional view of war, or the threat of war, as an instrument of policy is obsolete. War must be eliminated from the life of mankind. Disarmament and a stable peace are essential conditions for making a new society in which poverty can be abolished and the prospect of such a world is no longer Utopian.

In the Pugwash Conferences, therefore, attention has been concentrated on the complex problems of disarmament, and discussion has led to the belief that solutions can be found for the economic problems which might be encountered while disarming, and the measures needed to ensure the confidence and security of States during the process and to keep the peace in a disarmed world. Those present reached the conclusion that in the process of general and complete disarmament the early elimination with adequate and effective verification measures, and within a short period of time, of the means of delivery of the weapons of mass destruction would constitute a satisfactory beginning when linked with substantial reductions of conventional military forces and armaments and with the solution of the problems arising from the presence of troops and bases on foreign soil.

The experience of the Conferences led them to believe that scientists have a special contribution to make to the solution of those problems. Informal discussions between scientists contribute to the understanding of different points of view; but we are in a period of very rapid change in which new problems are constantly emerging. Scientists should therefore increase their efforts to bring about disarmament and conditions of lasting peace and should invite Governments, learned societies and other institutions to support them in this task. Because increasing confidence between nations is an essential element in such progress, the Conference also considered constructive proposals for many kinds of international collaboration in science; but, the statement concluded, we are now at a stage when general statements of principles are not enough—action is needed. Some proposals to promote disarmament and human welfare need detailed study to assess their implications; others can be implemented immediately. The statement reaffirms the conviction that the goal of full disarmament and permanent peace is realistic and urgent, and part of a long struggle for the progress of mankind in which scientists have a responsible part to play; it calls on scientists everywhere in the world to join in this task.

Here the Conference is giving expression to the belief in the moral responsibility of scientists generally which the Bishop of Exeter considered more particularly in respect of nuclear scientists in a paper presented to the Conference on "Radiation and Social Ethics" at the University of Chicago on January 16. Recognition is required of the ethical dilemma which the Bishop discussed, namely, that in spite of the unpredictable results of research, the scientist must consider the probable or certain uses to which results of his successful research could be put. There is thus a certain limit of moral freedom in experiment which is probably one of the driving forces in the Pugwash movement. The Bishop pointed out, moreover, that the ethical dilemma was one which the scientist shared with the whole community of which he is a member, but he suggested that the nuclear scientist had a moral responsibility to conduct his experiments and operations so as not to endanger either the whole human race or the community adjacent to his place of work.

---

[*] *Science and World Affairs*. History of the Pugwash Conferences. By Prof. J. Rotblat. Pp. 92+4 plates. (London: Dawsons of Pall Mall, 1962.) 8s. 6d. paper bound, 14s. cloth bound. (See also *Nature*, 196, 934; 1962.)

Here the argument runs close to the subject of the second part of Dupré and Lakoff's book, *Science and the Nation: Policy and Politics* (see *Nature*, 197, 629; 1962), and to the main theme of Mr. R. Gilpin's *American Scientists and Nuclear Weapons Policy* (see p. 1035 of this issue of *Nature*). This last Pugwash Conference, in fact, raises afresh fundamental issues over the participation of scientists in politics and the way in which scientists as such can contribute to or assist in the task of Government. To some extent this was obscured by the number of the practical proposals arising out of the Conference but which only makes it the more essential for a clear understanding of the nature of politics and of the contribution of science itself.

The Conference affirmed that all its activities should be directly related to the goal of full disarmament and permanent peace even when agreeing that subjects less directly relevant might appear on the Conference agenda. The work should in itself be scientific or technical or represent a problem which could be tackled by the scientific method. It should be noted, too, that the present policy is that the Conferences should be small and non-governmental and that they should not duplicate the work of other agencies. Nevertheless, the Conferences are evidently already taken seriously in Government circles, and apart from throwing up practical suggestions which Governments could adopt they undoubtedly have an educational function among scientists themselves in respect of what is involved in negotiation if not in politics and diplomacy also. Further, they encourage and bring into prominence the special claims of scientists to debate and make recommendations on world affairs—such as their technical knowledge and habits of fruitful and objective thinking, or the professional friendship and respect between scientists of the East and of the West, which facilitate frank and cool discussion of controversial matters.

Whether more effective means can be found of mobilizing scientific talent and enabling it to act to some purpose, both at the national and at the international level, in the task of Government, is the subject of urgent inquiry in Great Britain and in the United States at least. Here the Pugwash Conferences may well help. The last Conference recommended acceptance of India's invitation for a Conference on international collaboration in the developing nations and its significance for permanent peace, for which the United Nations Conference on the application of science and technology for the benefit of the less-developed areas in February at Geneva provided some pointers.

Two other proposals were made to extend the Pugwash method. Sir Julian Huxley advocated the sponsoring of a conference on education on the grounds that advances in science are changing the requirements of education, and suggested a series of East–West meetings to discuss the aims of education in a developing world. The other proposal was for a conference on the behavioural sciences with the view of considering how science could help to remove psychological barriers to disarmament and the peaceful resolution of conflict.

Although Mr. Gilpin only makes passing reference to the Pugwash movement, his book makes a most important contribution to a discussion as to the future of the Conferences and the direction which any expansion should take. The title of the book, in fact, belittles its scope, for although the main concern is with the part American scientists have played in the development of the United States policy on nuclear weapons, that is used to illustrate the much larger theme of the relations between scientists and Government. The book is really about the nature and limits of scientific and technical advice, the implications of the relations which have already been established, and, if it does not specifically discuss the nature of politics, it is just as realistic as Prof. Miller's book, *The Nature of Politics* (*Nature*, 196, 301; 1962), and is addressed more particularly to the scientist himself.

So far as the Pugwash Conferences are concerned, Mr. Gilpin notes that its significance lies in its attempt to utilize the international character of science as a force for peace and that it is the first such movement in which social scientists have actively participated. But while he notes also, and welcomes, its more modest ambitions, and the extent to which it has succeeded in avoiding exploitation by Communist propaganda, he notes also that leadership of the movement represents only one of the schools of thought among scientists on nuclear weapons. Nor does he provide much evidence to justify the belief that the international community of science as such is a force for peace and that through appeals to Russian scientists the Soviet Union can be guided towards a more rational pattern of behaviour.

Prof. Rotblat's book is too exclusively a record of the development and the official statements of the Pugwash Conferences to discuss these vital issues, nor does it enter on the issues raised by efforts of scientists to influence Governments and to educate the public on the implications of science. It is all the more valuable that at this juncture there should appear such a careful examination of the issues as Mr. Gilpin provides, for example, in his concluding chapter on the task of political leadership and in his analysis of the reasons which led to such strongly conflicting schools of opinion among scientists themselves. Both the dominant schools of opinion in the United States are fairly treated, and the analysis indicates how much more difficult it is to reach agreed opinion on the international plane and to tender technical advice which is not the opinion of only a section of the scientific community. However, a clear understanding of what is involved in the tendering of advice, and of the impracticability of a sharp separation between scientific or technical factors and political factors, is the first step towards the more effective utilization of the scientist and technologist which world order and world peace requires.

To such an understanding Mr. Gilpin's book makes an invaluable contribution. Moreover, it is not merely the negative one of pointing to past errors and the reasons for them. It shows also how the scientist, operating at the frontiers of knowledge, provides just that note of anticipation in political and social matters that is essential ■

if a wise national policy is to be formed. Likewise, it illustrates the scientist's contribution to the analysis of its problems arising out of scientific advice which any Government ought to apply to-day. While fundamentally there is little in the book on the relations between scientist and Government that Barker and Tizard and others in Great Britain have not previously underlined, there are some particular expedients adopted in the United States which might well be considered in other settings.

Fundamentally, however, in the international context such as the Pugwash Conferences, the book is a corrective to careless thinking about the relations of expert to expert and expert to Government, to the uncritical acceptance of expert advice, or to excessive optimism as to the possibilities in a scientific approach to policy-making. It drives us back once more to the fundamental importance of education at all levels and of public understanding. If it suggests that the pace of advance is likely to be slow, and to call for hard constructive thought, for sound judgment and human insight at all times, it nevertheless firmly upholds the place of the scientist as an adviser even on non-technical matters. Supporters of the Pugwash Conferences will find much in its pages for thought and caution: they will find no reason for pessimism.

THE SCIENTIST AS POLITICIAN

American Scientists and Nuclear Weapons Policy

By Robert Gilpin. Pp. vii+352. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1962.) 56*s*. net.

THIS study of the effect of scientific opinion on the function of nuclear weapons policy of the United States has a much wider interest than its title suggests. The study of the part of the scientists in the development of nuclear weapons is a major contribution to the larger theme of the place of the expert in the formation of policy generally, the mechanism of advice and the relation between science and technology and the task of Government. The particular subject of nuclear weapons is used to illustrate this general theme, and the implications of the participation of the scientist in the task of Government, the limitations, as well as the conditions, for effective contribution are clearly indicated. The essential issues are laid bare and, with its refreshing freedom from jargon, and the curse of uninterpreted abbreviations, this well-written book is a contribution to the study of the relations between science and Government that should be as welcome and acceptable in Great Britain as in the United States. Moreover, its documentation is comprehensive and balanced, dominantly, but not exclusively, American, and while some major British sources are not mentioned, the omissions are neither such as to mar the book nor to suggest more than pardonable oversight.

Mr. Gilpin begins with a glance at the questions raised by the participation of the scientist in politics in general, and especially those arising out of the formulation and tendering of scientific advice on the solution of the vast range of problems created by the advance of science. He is concerned to discern the conditions under which such advice contributes to the taking of effective decisions, and while he is particularly impressed by the uniformity and consistency of what he terms "scientific political opinion", Mr. Gilpin is particularly helpful when he analyses the political nature of the advice tendered by scientists and notes how that advice on technical matters is influenced by the scientist's non-technical assumptions about the problems at hand. Thus, it is that agreement on the scientific facts in a situation may lead different groups of scientists to tender differing and even opposed recommendations for dealing with the situation.

From the start, Mr. Gilpin emphasizes that the very nature of the scientific and technical adviser's responsibility to combine his technical expertise with his overall understanding and good sense takes him out of the realm where the scientific method and the scientist's canons of criticism are the most relevant guides for judgment into one where wisdom is the prime desideratum. In his next eight chapters he reviews the controversies that arose between scientists themselves and between scientists and Government over the development of nuclear weapons and their use, including the effect on the structure of the American administration before returning in his final chapter to discuss, in the light of all that experience, the task of political leadership and what that involves in this rapidly changing technological age. That study, in his view, demonstrates conclusively that scientists in the United States, in one particular field at least, have become full partners with politicians, administrators and officers of the Services in the formulation of policy; accordingly it is the task of political leadership to utilize more effectively and more generally the legitimate desire of scientists to contribute to the formulation of national policy.

The value of Mr. Gilpin's contribution does not lie so much in new and constructive suggestions as in pointing to weaknesses and mistakes in the past which have made the contribution of scientist and technologist relatively ineffective—weaknesses and mistakes that are to be remedied sometimes by the administrator or statesman, sometimes by the scientist himself. There are naturally suggestions that will be noted by the alert mind for examination in settings other than the American context in which they were first tried. In this concluding chapter Mr. Gilpin is strongly reminiscent of Sir Henry Tizard's Haldane Memorial Lecture in his emphasis on the importance of education—of having administrators who understand the nature and limits of science and of scientists who understand the nature of politics and the task of administration. To the view that the scientist as such should be 'on tap' and never 'on top' he returns a firm negative, with a clear warning against exaggerating the importance of ideas in the political process gives the unequivocable affirmation that scientists have a right to advise even on non-technical matters. It does not necessarily follow that because scientists are primarily technical experts they are incompetent to advise on political or strategic matters.

Where the book is specially valuable is in stimulating thought as to the nature and limitations of scientific advice, the implications for the adviser himself, as well as for the authority responsible for deciding on any particular administrative structure for advice, and the taking of decisions. This is particularly relevant at a moment when the whole structure of Britain's Government organization for civil research and development is under review and when Government departments are already considering the recommendations of the Gibb–Zuckerman report. Mr. Gilpin demonstrates the impracticability of any sharp separation of the technical and political realms in the advice tendered by scientists. It is in this context especially that the implications of his observations on asking the right questions, on the limits within which true objectivity is possible, on the interpretation of advice, on the importance of scientific controversy and an atmosphere of intellectual give-and-take deserve to be noted and pondered critically.

Mr. Gilpin's staunch advocacy of the place of the scientist and technologist in the task of Government is not over-stated. He fully recognizes the weaknesses of the scientist himself as well as of the policy-maker. The need still exists of developing means for countering the natural inclination of the scientist to advocate technical solutions to political problems and the tendency of the administrator to accept uncritically such solutions. This is in part a task of education, but it is also a task of organization—flexible and appropriate to this purpose, including the necessary professional institutions as well as Government structure. This book is admirably suited to stimulate the thought and study which must go to the discovery of ways of integrating the technical and political knowledge in policy-making which are effective in the conditions prevalent to-day. R. BRIGHTMAN

VETERINARY SCIENCE

Advances in Veterinary Science

Vol. 7. Edited by C. A. Brandly and E. L. Jungherr. Pp. xi + 403. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.) 100s.

As in the case of previous volumes, Volume 7 of this book embraces in eight chapters a number of subjects of particular interest to veterinary scientists at this present time.

The first chapter deals with cardiac dynamics and its clinical significance. At a time when cardiac abnormalities, especially in horses and in dogs, are receiving the attention of research workers in many countries, this chapter is of particular interest and value.

The second chapter, which deals with experimental and spontaneous tumorigenesis, is of particular significance at a time when the origin of cancer is being sought and the roles of the endocrines system, viruses, parasites, food and radiation in this field are being examined. A consideration of all these factors is discussed in this important chapter.

In the realms of parasitology, current thought is largely centred on helminth immunity, a subject which is very fully dealt with in the third chapter. The widespread use of irradiated larval vaccines calls for a thorough understanding of the antibody reactions involved, and this chapter, which discusses each animal parasite in turn, covers very fully the story as it is now understood.

Of particular interest to workers in South Africa, the short but informative fourth chapter deals with enterotoxæmia-like conditions among sheep in that country.

The fifth chapter, dealing with non-specific or cross-sensitivity reactions to tuberculin in cattle, is of particular interest to scientists in all parts of the world, but more especially to those in countries where the tuberculin test is being applied as a means of eliminating or controlling bovine tuberculosis. The interpretation of the tuberculin test in cattle may be rendered complicated by the presence of the human or avian types of tubercle bacilli as well as by the presence of Johne's disease, nocardiosis, the so-called skin tuberculosis and the presence of other micro-bacteria. All the implications arising from these intercurrent infections are here discussed.

Skin diseases are dealt with in the following chapter. Of all the problems which concern the practising veterinarian, skin diseases, especially among small animals, are frequently the most baffling. The reader will find much in this chapter to enable him to crystallize his ideas on this subject and to appreciate the correlation between skin diseases in domesticated animals and those in man.

The seventh chapter is devoted to the subject of shipping fever in cattle, a condition which has been known in many parts of the world for a very long time, but about which there have been many conflicting ideas. The evidence put forward in support of a viral origin of this condition and the suggestion made that it is essentially a disease-complex rather than one of simple ætiology will attract the attention both of research workers and clinicians interested in or confronted by this problem.

The last chapter embraces the subject of mycotoxicoses. Quite recently, owners of poultry in particular have received sharp warning of the toxicity of certain mouldy feeding stuffs and it is very opportune that this subject should be so ably dealt with in this volume of *Advances in Veterinary Science*.

As in previous volumes, the author-index and subject-index leave nothing to be desired and the bibliography set out at the end of each chapter is admirably comprehensive. Chapters I, VI, and VIII, which readily lend themselves to illustration or diagram, are well supplied in that respect and their value is thereby enhanced. The authors of the several chapters are to be congratulated both collectively and individually on this production, which will be of the utmost value to its readers and which fully maintains the high standard of previous volumes.

H. BURROW

PHYSICAL CHEMISTRY IN METALLURGY

Physical Chemistry of Process Metallurgy

An International Symposium, Pittsburgh, Pennsylvania, April 27–May 1, 1959. Edited by George R. St. Pierre. Part 1: Pp. xiv + 644. 22.50 dollars. Part 2: Pp. xiv + 645–1374. 25 dollars. (Metallurgical Society Conferences, Volumes 7 and 8.) (New York and London: Interscience Publishers, 1961.)

In 1920 and again in 1949 the Faraday Society arranged symposia on the application of physical chemistry to process metallurgy. Since the latter date, there has been a considerable broadening of the field in many parts of the world, and in 1959 the American Institute of Mining, Metallurgical and Petroleum Engineers organized the conference the papers and lectures of which are contained in these volumes. How wide the interest was is shown by the fact that papers were received not only from the United States and Canada but also from Great Britain, Japan, Australia, Belgium, France and Switzerland. In any such symposium there is an inevitable variation in the quality of the contributions, but the standard here is almost invariably high, and the editors have done an excellent bit of work in their presentation. In addition to the papers themselves, the discussions add appreciably to the value of the information provided. This information is not only in the collection and re-presentation in condensed form of the authors' own work but also in not a few instances there is quite new information or new interpretations of earlier work.

Although the major emphasis is, somewhat naturally, on ferrous problems, the scope of the contributions also ranges over non-ferrous subjects varying from the vapour pressures of liquid metals and the velocity of sound in liquid lead–tin alloys to the oxygen content of copper mattes and the kinetics of the reduction of nickel sulphate in aqueous solutions. One of the outstanding features of the work discussed is the importance of the molten state, especially of slags, and the significance of the advances made to our knowledge of this field is most striking.

In spite of this, however, very much more needs to be done. As Prof. F. D. Richardson remarks in his introductory lecture to the conference, it is improbable "that in the foreseeable future we shall be able either to extrapolate our data or to calculate thermodynamic properties from first principles with the kind of accuracy that the operator of processes would like. The properties we need to know with great precision will still have to be measured. On the other hand, by means of our imperfect models and intelligent correlations, we should be able to predict accurately enough to avoid futile experiments in both works and laboratory".

The value of the symposium can scarcely be overestimated. F. C. THOMPSON

INVESTIGATION OF THE RADIO SOURCE 3C 273 BY THE METHOD OF LUNAR OCCULTATIONS

By C. HAZARD, M. B. MACKEY and A. J. SHIMMINS
C.S.I.R.O. Division of Radiophysics, University Grounds, Sydney

THE observation of lunar occultations provides the most accurate method of determining the positions of the localized radio sources, being capable of yielding a positional accuracy of the order of 1 sec of arc. It has been shown by Hazard[1] that the observations also provide diameter information down to a limit of the same order. For the sources of small angular size the diameter information is obtained from the observed diffraction effects at the Moon's limb which may be considered to act as a straight diffracting edge.

The method has so far been applied only to a study of the radio source *3C* 212 the position of which was determined to an accuracy of about 3 sec of arc[1,2]. However, *3C* 212 is a source of comparatively small flux density and although the diffraction effects at the Moon's limb were clearly visible the signal-to-noise ratio was inadequate to study the pattern in detail and hence to realize the full potentialities of the method. Here we describe the observation of a series of occultations of the intense radio source *3C* 273 in which detailed diffraction effects have been recorded for the first time permitting the position to be determined to an accuracy of better than 1″ and enabling a detailed examination to be made of the brightness distribution across the source.

The observations were carried out using the 210-ft. steerable telescope at Parkes, the method of observation being to direct the telescope to the position of the source and then to record the received power with the telescope in automatic motion following the source. Three occultations of the source have been observed, on April 15, at 410 Mc/s, on August 5 at 136 Mc/s and 410 Mc/s, and on October 26 at 410 Mc/s and 1,420 Mc/s, although in October and April only the immersion and emersion respectively were visible using the Parkes instrument. The 410 Mc/s receiver was a double-sided band receiver, the two channels, each of width 10 Mc/s, being centred on 400 Mc/s and 420 Mc/s, while the 136 Mc/s and 1,420 Mc/s receivers each had a single pass band 1·5 Mc/s and 10 Mc/s wide respectively.

The record of April 15, although of interest as it represents the first observation of detailed diffraction fringes during a lunar occultation, is disturbed by a gradient in the received power and is not suitable for accurate position and diameter measurements. Therefore, attention will be confined to the occultation curves recorded in August and October and which are reproduced in Fig. 1. It is immediately obvious from these records that *3C* 273 is a double source orientated in such a way that whereas the two components passed successively behind the Moon at both immersions, they reappeared almost simultaneously. The prominent diffraction fringes show that the angular sizes of these components must be considerably smaller than 10″, which is the order of size of a Fresnel zone at the Moon's limb.

The most interesting feature of Figs. 1(*e*) and 1(*f*) is the change in the ratio of the flux densities of the two components with frequency. The ratio of the flux density of the south preceding source (component *A*) to that of the north following source (component *B*) is 1 : 0·45 at 410 Mc/s and 1 : 1·4 at 1,420 Mc/s, indicating a striking difference in the spectra of the two components. If it be assumed that the flux densities[3] of *3C* 273 at 410 Mc/s and 1,420 Mc/s are 60 and 35 Wm^{-2} $(c/s)^{-1}$ and that over this frequency-range the spectrum of each component may be represented by $S \propto f^{n}$, then the above ratios correspond to spectral indices for components *A* and *B* of − 0·9 and 0·0 respectively. The spectral index of *A* is a representative value for a Class II radio source; but the flat spectrum of *B* is most unusual, no measurements of a comparable spectrum having yet been published. If the spectral indices were assumed constant down to 136 Mc/s then at this frequency component *A* must contribute almost 90 per cent of the total emission, a conclusion which is confirmed by a comparison of the times of immersion at 136 Mc/s and 410 Mc/s on August 5.

It has been shown by Scheuer[4] that it is possible to recover the true brightness distribution across the source from the observed diffraction pattern, the resolution being subject only to limitations imposed by the receiver bandwidth and the finite signal to noise ratio and being independent of the angular scale of the diffraction pattern. However, in this preliminary investigation we have not attempted such a detailed investigation but based the analysis on the calculated curves for uniform strip sources of different widths as published by Hazard[1]. As a first step in the investigation approximate diameters were estimated from the intensity of the first diffraction lobe and the results corresponding to the three position angles defined by the occultations and indicated in Fig. 2 are given in Table 1.

As already indicated here, the 136-Mc/s measurements refer only to component *A* and hence no diameter measurements are available for *B* at this frequency. The 410-Mc/s observations of the August occultation are the most difficult to interpret owing to the components having both comparable flux density and small separation relative to the angular size of the first Fresnel zone. At immersion the widths were estimated by using a process of curve fitting to reproduce Fig. 1(*d*); at emersion (position angle 313°) the diameter of component *B* was assumed to be 3″ as indicated by the estimates at position angles 105° and 83°. The individual measurements at each frequency are reasonably consistent but there is a striking variation of the angular size of component *A* with frequency and evidence of a similar variation for component *B*. As at the time of the August occultation the angular separation of the Sun and the source was about 50° and hence coronal scattering of the type observed by Slee[5] at 85 Mc/s is not likely to be significant, this variation in size suggests that the model of two uniform strip sources is inadequate.

Therefore, a more detailed analysis was made of the intensity distributions of the lobe patterns given in Figs. 1(*c*) and 1(*f*), and it was found that in neither case can the pattern be fitted to that for a uniform strip source or a source with a gaussian brightness distribution. The 1,420-Mc/s observations of component *B* can be explained, however, by assuming that this source consists of a central bright core about 0·5″ wide contributing about 80 per cent of the total flux embedded in a halo of equivalent width of about 7″. Fig. 1(*b*), where component *A* predominates, suggests that this source has a similar structure

Table 1. EFFECTIVE WIDTH OF EQUIVALENT STRIP SOURCE
(Sec. of arc)

Frequency Mc/s	Component *A* Position angle 105°	313°	84°	Component *B* Position angle 105°	314°	83°
136	6·4	6·4	—	—	—	—

1,420	—	—	2·9	—	—	2·1 0·5 (7)*

* Estimated from an analysis of the whole diffraction pattern.
† Component *B* assumed to have width of 3″.

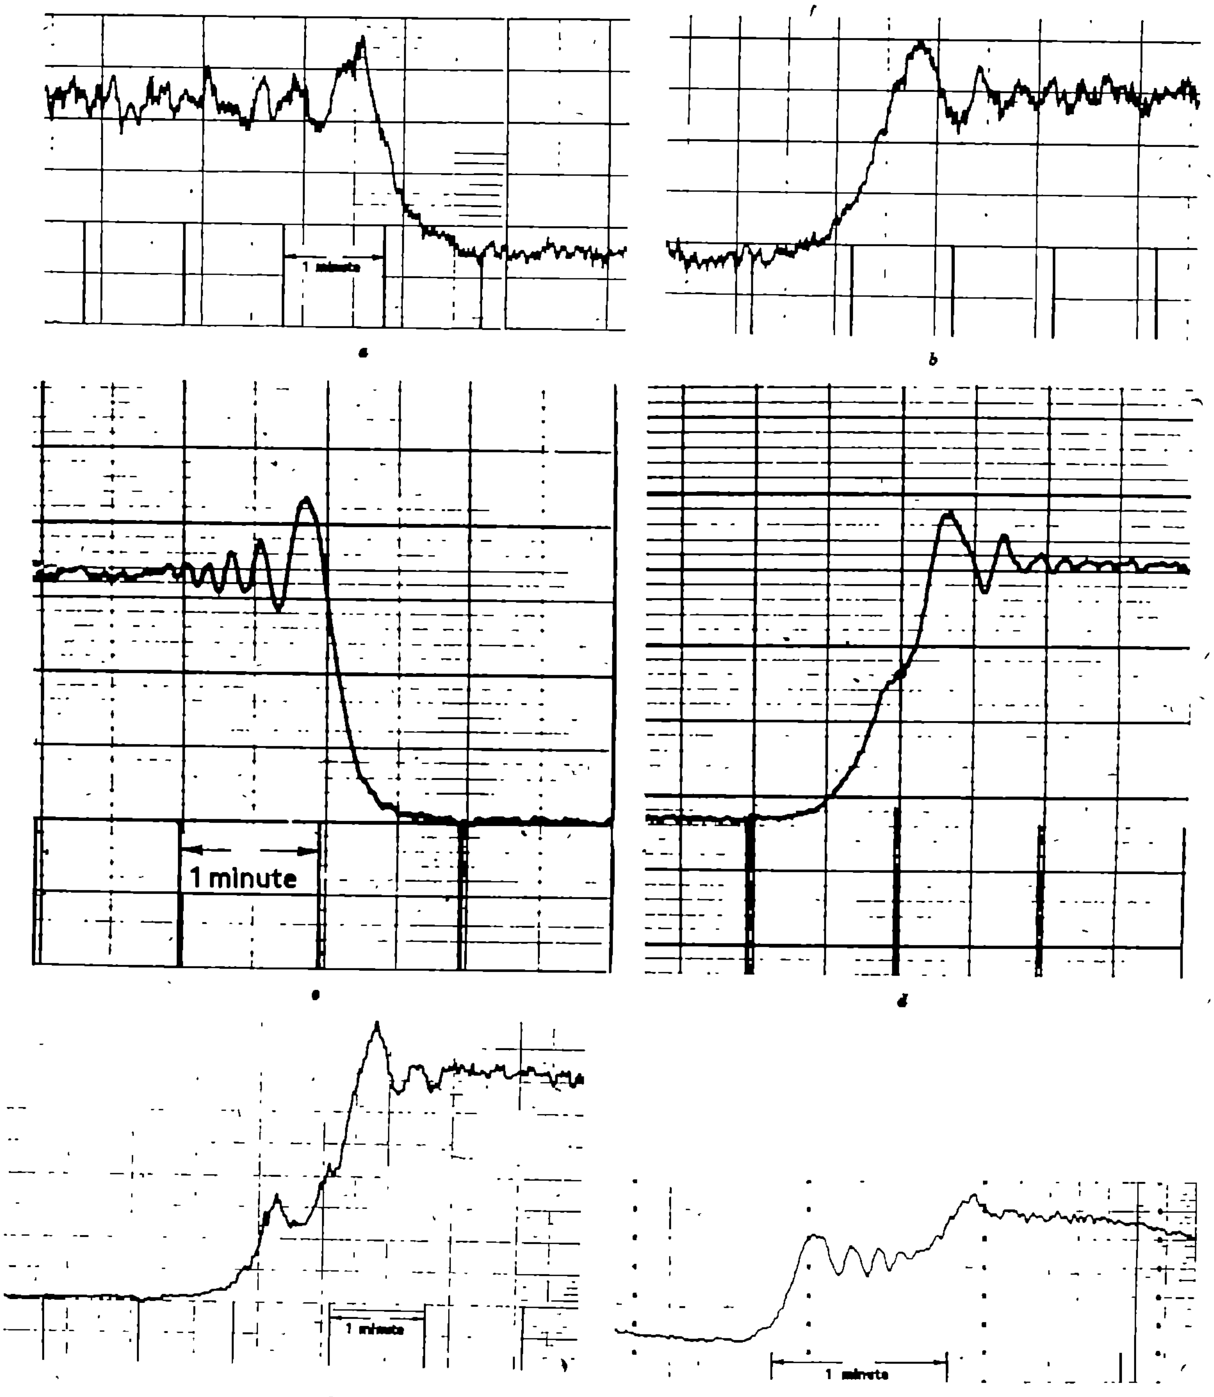

Fig. 1. Facsimiles of records showing occultations on August 5 and October 26, 1962, at different frequencies. (a) Emersion of August 5, 1962, at 136 Mc/s; (b) immersion of August 5, 1962, at 136 Mc/s; (c) emersion of August 5, 1962, at 410 Mc/s; (d) immersion of August 5, 1962, at 410 Mc/s; (e) immersion of October 26, 1962, at 410 Mc/s; (f) immersion of October 26, 1962, at 1,420 Mc/s. Abscissae, U.T.; ordinates, flux density

but with a core of effective width about 2″ at 410 Mc/s and a halo of width 6″. It therefore seems that the overall extent of both components are comparable but that the emission is more highly concentrated to the nucleus in *B* than in *A*. The close agreement between the halo size of *A* and its effective diameter at 136 Mc/s suggests that the observed variation of effective size with frequency may be due to a difference in the spectra of the halo and central regions. This would imply that the spectrum becomes steeper in the outer regions of the sources, that is, in the regions of lower emissivity. It is of interest that the integrated spectral indices of the two components show an analogous effect. Thus the spectrum of *B*, where most of the emission arises in a source about 0·5″ wide, is markedly flatter than that of *A*, where it arises in a source about 2″ wide.

The analysis is not sufficiently accurate to reach any reliable conclusions on the ellipticity of the individual components of *3C* 273, but allowing for the uncertainty in the estimated widths and position angle 314°, the 410-Mc/s observations indicate that both components may be elliptical with *A* elongated approximately along the axis joining the two components and *B* elongated perpendicular to this axis.

The position of each source was calculated from the observed times of disappearance and reappearance, which were estimated from the calculated flux density at the edge of the geometrical shadow and, where possible, from the positions of the diffraction lobes; these times are given in Table 2. In estimating the values of $T_D{}^A$ and $T_R{}^A$ from the 136-Mc/s records a small correction was applied for the effects of component *B*, this correction being estimated by comparison with the 410-Mc/s records. The corresponding times for *B* were estimated from the 410-Mc/s observations using the estimated position of component *A* and the known flux density ratio of the two components. For each component the times and associated errors given in Table 2 define three strips in each of which the source should lie; the centre lines of these strips represent the limb of the Moon at the time of observation and define in each case a triangular-shaped area. In principle, the position of the source lies in the area common to the three associated strips but it was found that for each component, and in particular for component *A*, that the size of the triangles defined by the Moon's limb was larger than would be expected from the estimated timing errors. This suggests that errors in the positions of the Moon's limb are more important than the estimated timing errors, and possibly that the effective position of the source varies slightly with frequency. The position of each source was therefore assumed to be given by the centre of the circle inscribed in the triangle defined by the Moon's limb at the relevant times. Dr. W. Nicholson of H.M. Nautical Almanac Office has kindly carried out these calculations and the estimated positions are as follows:

Component *A* (Epoch 1950)	R.A.	12h 26m 32·38s ± 0·03s
	Decl.	02° 19′ 27·8″ ± 1·5″
Component *B* (Epoch 1950)	R.A.	12h 26m 33·29s ± 0·02s
	Decl.	02° 19′ 42·0″ ± 0·5″

The average positions of the two sources given here represent the most accurate determination yet made of the position of a radio source. The quoted errors were estimated from the size of the triangles defined by the Moon's limb at the times of disappearance and reappearance, for the method is not subject to uncertainties introduced by refraction in the Earth's ionosphere or troposphere and is also free from the effects of confusion. A comparison of the times of disappearance and reappearance at different frequencies indicates that there is also no significant source of error due to refraction in either the solar corona or a possible lunar ionosphere; any refraction appears to be less than 0·3″ even at 136 Mc/s. This may be compared with the upper limit of 2″ at 237 Mc/s and 13″ at 81 Mc/s as estimated by Hazard[1] and Elsmore[6] respectively, and allows a new limit to be set to the density of the lunar ionosphere. Thus, from his observations at 81·5 Mc/s, Elsmore has set an upper limit to the electron density of 10^3 cm^{-3}; and it follows that the present measurements set a limit of about 10^2 cm^{-3}. Similarly, Buckingham[7] has estimated that at 50 Mc/s a ray passing at 50° to the Sun would be deviated by 1″ if the electron density in the solar corona at the Earth's distance from the Sun is 100 cm^{-3}. The present observations at 136 Mc/s and 410 Mc/s on August 5 indicate that at 50 Mc/s the deviation is less than 2″ at this angle, setting an upper limit to the electron density of about 200 cm^{-3}, which may be compared with an upper limit of 120 cm^{-3}, set by Blackwell and Ingham[8] from observations of the zodiacal light.

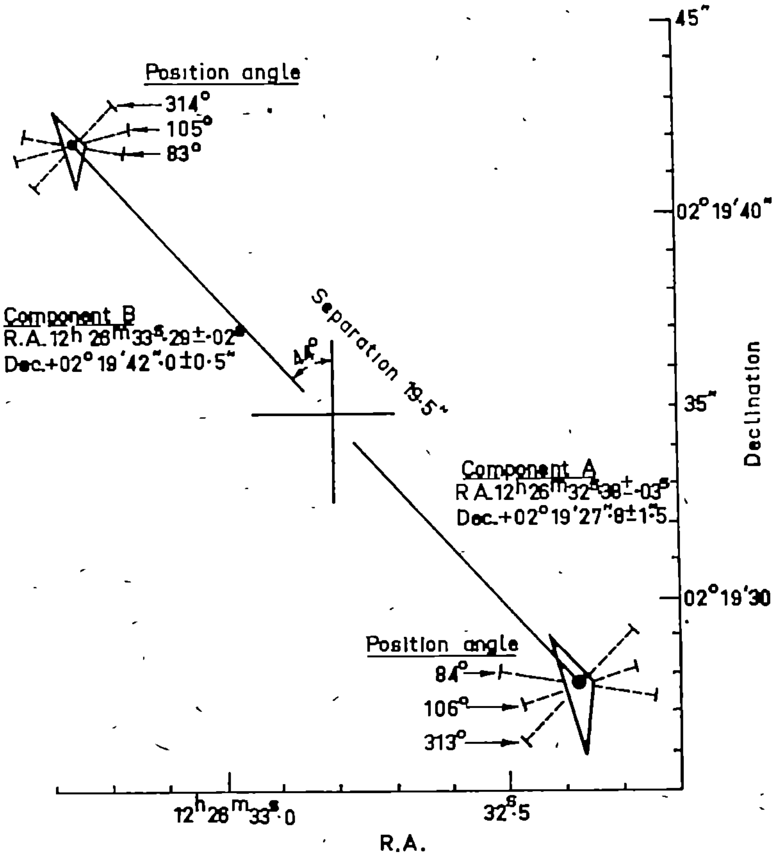

Fig. 2. Diagram of the radio source 3C 273. The sides of the full line triangles represent the positions of the limb of the Moon at the times of occultation. The broken lines represent the widths of the equivalent strip source as measured at 410 Mc/s for each of three position angles indicated

Table 2. OBSERVED OCCULTATION TIMES OF THE TWO COMPONENTS OF 3C 273

	Component *A* (U.T.)	Component *B* (U.T.)
Time of disappearance August 5, 1962	07h 46m 00s ± 1s	07h 46m 27·2s ± 0 5s
Time of reappearance August 5, 1962	09h 05m 45·5s ± 1s	09h 05m 45·7s ± 1 5s
Time of disappearance October 26, 1962	02h 55m 09·0s ± 1s	02h 56m 01·5s ± 0 4s

In a preliminary examination of a print from a 200″ plate it was noted that the position of component *B* agreed closely with that of a thirteenth magnitude star. We understand that the investigations by Drs. A. Sandage and M. Schmidt of the Mount Wilson and Palomar Observatories have revealed that this star and an associated nebulosity is very probably the source of the radio emission.

We thank Mr. J. G. Bolton for his interest in this work, and his assistance, with that of the staff at Parkes, in ensuring the success of these observations. We also thank Dr. W. Nicholson, who calculated the positions of the sources, for his valuable co-operation and interest in the occultation programme. One of us (C. H.) thanks Dr. E. G. Bowen for his invitation to continue occultation work at Parkes as a guest observer from the Narrabri Observatory of the School of Physics of the University of Sydney.

3C 273: A STAR-LIKE OBJECT WITH LARGE RED-SHIFT

By DR. M. SCHMIDT

Mount Wilson and Palomar Observatories, Carnegie Institution of Washington, California Institute of Technology, Pasadena

THE only objects seen on a 200-in. plate near the positions of the components of the radio source 3C 273 reported by Hazard, Mackey and Shimmins in the preceding article are a star of about thirteenth magnitude and a faint wisp or jet. The jet has a width of 1″–2″ and extends away from the star in position angle 43°. It is not visible within 11″ from the star and ends abruptly at 20″ from the star. The position of the star, kindly furnished by Dr. T. A. Matthews, is R.A. 12h 26m 33·35s ± 0·04s, Decl. +2° 19′ 42·0″ ± 0·5″ (1950), or 1″ east of component *B* of the radio source. The end of the jet is 1″ east of component *A*. The close correlation between the radio structure and the star with the jet is suggestive and intriguing.

Spectra of the star were taken with the prime-focus spectrograph at the 200-in. telescope with dispersions of 400 and 190 Å per mm. They show a number of broad emission features on a rather blue continuum. The most prominent features, which have widths around 50 Å, are, in order of strength, at 5632, 3239, 5792, 5032 Å. These and other weaker emission bands are listed in the first column of Table 1. For three faint bands with widths of 100–200 Å the total range of wave-length is indicated.

The only explanation found for the spectrum involves a considerable red-shift. A red-shift $\Delta\lambda/\lambda_0$ of 0·158 allows identification of four emission bands as Balmer lines, as indicated in Table 1. Their relative strengths are in agreement with this explanation. Other identifications based on the above red-shift involve the Mg II lines around 2798 Å, thus far only found in emission in the solar chromosphere, and a forbidden line of [O III] at 5007 Å. On this basis another [O III] line is expected at 4959 Å with a strength one-third of that of the line at 5007 Å. Its detectability in the spectrum would be marginal. A weak emission band suspected at 5705 Å, or 4927 Å reduced for red-shift, does not fit the wave-length. No explanation is offered for the three very wide emission bands.

It thus appears that six emission bands with widths around 50 Å can be explained with a red-shift of 0·158. The differences between the observed and the expected wave-lengths amount to 6 Å at the most and can be entirely understood in terms of the uncertainty of the measured wave-lengths. The present explanation is supported by observations of the infra-red spectrum communicated by Oke in a following article, and by the spectrum of another star-like object associated with the radio source 3C 48 discussed by Greenstein and Matthews in another communication.

Table 1. WAVE-LENGTHS AND IDENTIFICATIONS

λ	$\lambda/1{\cdot}158$	λ_0	
3239	2797	2798	Mg II
4595	3968	3970	Hϵ
4753	4104	4102	Hδ
5032	4345	4340	Hγ
5200–5415	4490–4675		
5632	4864	4861	Hβ
5792	5002	5007	[O III]
6005–6190	5186–5345		
6400–6510	5527–5622		

The unprecedented identification of the spectrum of an apparently stellar object in terms of a large red-shift suggests either of the two following explanations.

(1) The stellar object is a star with a large gravitational red-shift. Its radius would then be of the order of 10 km. Preliminary considerations show that it would be extremely difficult, if not impossible, to account for the occurrence of permitted lines and a forbidden line with the same red-shift, and with widths of only 1 or 2 per cent of the wave-length.

(2) The stellar object is the nuclear region of a galaxy with a cosmological red-shift of 0·158, corresponding to an apparent velocity of 47,400 km/sec. The distance would be around 500 megaparsecs, and the diameter of the nuclear region would have to be less than 1 kiloparsec. This nuclear region would be about 100 times brighter optically than the luminous galaxies which have been identified with radio sources thus far. If the optical jet and component *A* of the radio source are associated with the galaxy, they would be at a distance of 50 kiloparsecs, implying a time-scale in excess of 10^5 years. The total energy radiated in the optical range at constant luminosity would be of the order of 10^{59} ergs.

Only the detection of an irrefutable proper motion or parallax would definitively establish 3C 273 as an object within our Galaxy. At the present time, however, the explanation in terms of an extragalactic origin seems most direct and least objectionable.

I thank Dr. T. A. Matthews, who directed my attention to the radio source, and Drs. Greenstein and Oke for valuable discussions.

ABSOLUTE ENERGY DISTRIBUTION IN THE OPTICAL SPECTRUM OF 3C 273

By DR. J. B. OKE

Mount Wilson and Palomar Observatories, Carnegie Institution of Washington, California Institute of Technology, Pasadena

THE radio source 3C 273 has recently been identified with a thirteenth magnitude star-like object. The details are given by M. Schmidt in the preceding communication. Since 3C 273 is relatively bright, photoelectric spectrophotometric observations were made with the 100-in. telescope at Mount Wilson to determine the absolute distribution of energy in the optical region of the spectrum; such observations are useful for determining if synchrotron radiation is present. In the wave-length region between 3300 Å and 6000 Å measurements were made in 16 selected 50-Å bands. Continuous spectral scans with a resolution of 50 Å were also made. The measurements were placed on an absolute-energy system by also observing standard stars whose absolute energy distributions were known[1]. The accuracy of the 16 selected points is approximately 2 per cent. The strong emission features found by Schmidt were readily detected; other very faint features not apparent on Schmidt's spectra may be present.

The source 3C 273 is considerably bluer than the other known star-like objects 3C 48, 3C 196, and 3C 286 which have been studied in detail[2]. The absolute energy distribution of the apparent continuum can be accurately represented by the equation:

$$F_\nu \propto \nu^{+0{\cdot}28}$$

where F_ν is the flux per unit frequency interval and ν is the frequency. The apparent visual magnitude of 3C 273 is +12·6, which corresponds to an absolute flux at the Earth of $3{\cdot}5 \times 10^{-28}$ W m^{-2} (c/s)$^{-1}$ at 5600 Å. At radio frequencies[3] the spectral index is $-0{\cdot}25$ and the flux at 960 Mc/s is $5{\cdot}0 \times 10^{-26}$ W m^{-2} (c/s)$^{-1}$.

Between 6000 Å and 10,250 Å, eleven 120-Å bands were measured with an accuracy of 10 per cent. These measures indicate that the relatively flat energy distribution given in the equation here applies as far as 8400 Å. Beyond 8400 Å the flux may increase significantly. Between 3300 Å and 8400 Å the energy distribution cannot be represented, even approximately, by the flux from a black-body or a normal star. At least part of the optical continuum radiation must be synchrotron radiation.

During the course of the infra-red observations a strong emission feature was found near 7600 Å. Further observations with a 50-Å band-width placed the emission line at 7590 Å with a possible error of about 10 Å. The emission profile was found to be similar to that of the emission line at 5632 Å. Using this line and others in the visual spectrum Schmidt has shown that the most prominent emission features are Balmer lines and that the line at 7590 Å is *H*α. Using Schmidt's red-shift $\Delta\lambda/\lambda_0$ of 0·158, *H*α should appear at 7599 Å; this is in satisfactory agreement with observation, when it is recalled that the atmospheric *A* band absorbs strongly beyond 7594 Å. It is possible that the [*N*II] lines which have unshifted wave-lengths of 6548 Å and 6583 Å can contribute to the emission feature identified as *H*α. A large contribution, however, would shift the line significantly towards the red. The relative positions of *H*α, *H*β, *H*γ, and *H*δ cannot be produced by applying a red-shift to any other hydrogen-like ion spectrum.

Further observations, particularly in the infra-red, will be made in the near future.

RED-SHIFT OF THE UNUSUAL RADIO SOURCE: 3C 48

By Dr. JESSE L. GREENSTEIN

Mount Wilson and Palomar Observatories, Carnegie Institution of Washington, California Institute of Technology

AND

Dr. THOMAS A. MATTHEWS

Owens Valley Radio Observatory, California Institute of Technology

The radio source 3*C* 48 was announced to be a star[1] in our Galaxy on the basis of its extremely small radio diameter[2], stellar appearance on direct photographs and unusual spectrum. Detailed spectroscopic study at Palomar by Greenstein during the past year gave only partially successful identifications of its weak, broad emission lines; the possibility that they might be permitted transitions in high stages of ionization could not be proved or disproved. Hydrogen was absent but several approximate coincidences with He II and O VI were suggested.

The discovery by Schmidt (a preceding article) of much broader emission lines in the apparently stellar radio source, 3*C* 273, suggested a red-shift of 0·16 for 3*C* 273 if the lines were interpreted as the Balmer series. In 3*C* 48 no such series was apparent; measurable lines still do not coincide with the hydrogen series. However, the possibility of a very large red-shift, which had been considered many times, was re-explored successfully. 3*C* 48 has a spectrum containing one very strong emission feature near λ3832 which is 35 Å wide and about 10 other weaker features near 23 Å in width. The sharper lines are listed in Table 1 in order of decreasing intensity. Some broad lines or groups of lines between 50 and 100 Å width may be red-shifted hydrogen lines.

Table 1. IDENTIFICATIONS AND OBSERVED RED-SHIFTS

λ*	Wave-length λ lab.	Source	λ*/λ lab.
3832·3	2796 2803 } 2798	Mg II	1·3697:
4685·0	3426	[Ne V]	1·3676
5098	3729 3726 } 3727	[O II]	1·3679
4575	3346	[Ne V]	1·3673
5289	3868	[Ne III]	1·3671
4065·7	2975:	[Ne V]	1·3667:

The weighted mean red-shift $d\lambda/\lambda_0$ is $0{\cdot}3675 \pm 0{\cdot}0003$, an apparent velocity of +110,200 km/sec. The slightly discrepant value for λ2975 of [Ne V] is compatible with the uncertainty of ± 3 Å in the wave-length predicted by Bowen[3]. The Mg II permitted resonance doublet has a small additional displacement to longer wave-lengths, possibly caused by self-absorption in an expanding shell; it is the strongest emission line in the rocket-ultra-violet spectrum of the Sun. The forbidden lines are similar to those in other intense extragalactic radio sources.

So large a red-shift, second only to that of the intense radio source 3*C* 295, will have important implications in cosmological speculation. A very interesting alternative, that the source is a nearby ultra-dense star of radius near 10 km containing neutrons, hyperons, etc., has been explored and seems to meet insuperable objections from the spectroscopic point of view. The small volume for the shell required by the observed small gradient of the gravitational potential is incompatible with the strength of the forbidden lines.

The distance of 3*C* 48, interpreted as the central core of an explosion in a very abnormal galaxy, may be estimated as $1{\cdot}10 \times 10^{9}$ parsecs; the visual absolute magnitude is then $-24{\cdot}0$, or $-24{\cdot}5$ corrected for interstellar absorption. The minimum correction for the effect of red-shift is of the order of 2 *v*/*c* and a value between 4 and 5 times *v*/*c* is probable for a normal galaxy. The absolute visual magnitude of 3*C* 48 is then brighter than $-25{\cdot}2$ and possibly as bright as $-26{\cdot}3$, 10–30 times greater than that of the brightest giant ellipticals[4] hitherto recognized, which are near $-22{\cdot}7$ and another factor of five brighter than our own Galaxy, near $-21{\cdot}0$.

As a radio source at a distance of $1{\cdot}1 \times 10^{9}$ parsecs 3*C* 48 is not markedly different from other known strong radio sources like 3*C* 295 or Cygnus *A*. The one feature in which it does differ from most sources is in its high surface brightness. This is partially due to its extremely small radio size of $\leqslant$ 1 sec of arc[2]. The optical size is comparable, being also $\leqslant$ 1 sec of arc[5]. At the assumed distance such angular sizes indicate that both the optical and radio emission arise within a diameter of $\leqslant$ 5500 parsecs. The radio diameter might even be comparable with or less than that of 3*C* 71 (*NGC* 1068) the diameter of which is about 700 parsecs. However, 3*C* 71 has 5 orders of magnitude less radio emission.

If we determine the integrated radio emission of 3*C* 48 from the observed spectral index of the radio spectrum, and correct for the red-shift, we find that 3*C* 48 is comparable with 3*C* 295, emitting 4×10^{44} erg/sec of radio-frequency power. The cut-off frequencies were 7×10^{7} c/s and 10^{11} c/s. The lower limit is indicated by the observed radio spectrum and the upper limit is an assumed one.

The absolute magnitudes of the galaxies connected with 3*C* 295 and Cygnus *A*, corrected for interstellar absorption, are $M_v = -21{\cdot}0$ and $-21{\cdot}6$ (using a red-shift correction of 2 *v*/*c*) or $M_v = -22{\cdot}4$ and $-21{\cdot}8$ (using a correction of 5 *v/c*) respectively. Thus 3*C* 48 radiates about 50 times more powerfully in the optical region than other more normal but intense radio galaxies. In contrast, the absolute radio luminosity of 3*C* 48 is the same as that of Cygnus *A* and 3*C* 295. The unusually strong optical radiation may be synchrotron radiation as suggested (for other reasons) by Matthews and Sandage[5].

HUMAN CANCER: MENDELIAN INHERITANCE OR VERTICAL TRANSMISSION?

By DR. P. R. J. BURCH

Medical Research Council, Environmental Radiation Research Unit, Department of Medical Physics, University of Leeds,
The General Infirmary, Leeds 1

THE purpose of this article is to consider whether the familial tendency to malignant disease should be attributed to genetic inheritance or to the transmission of an oncogenic virus from either parent to offspring ('vertical' transmission[1]). It will be shown that this is one of those situations, rare in cancer research, where the available evidence is adequate to allow almost unambiguous conclusions to be drawn about an issue of fundamental importance.

Following many demonstrations of the vertical transmission of leukæmogenic viruses in mice, Gross[2] has recently stated: " . . . one could therefore regard the development of cancer, leukæmia, or that of any other [the printed form is not 'any other' but 'another': it is presumed that 'any other' is intended] malignant tumour, as the result of an activation, frequently merely accidental of an oncogenic agent, hitherto masked, and carried by the host since birth. . . . Oncogenic agents carried in descendants of certain families, in humans as well as in other species, may have a higher pathogenic potential and be more readily activated than those carried in other families. . . . Thus cancer, leukæmia, or other malignant tumours would develop more frequently in members of certain families than in others". Elsewhere it is made clear that the 'oncogenic agent' is a virus.

This authoritative and influential working hypothesis inspires much contemporary cancer research, and is supported by an enormous volume of experimental evidence obtained from chickens, mice and rats.

Nevertheless, it was claimed recently[3], in harmony with previous conclusions[4–6], that the 'inheritance factor' in human leukæmias usually takes the form of an apparent dominant 'predisposing' mutation of incomplete penetrance; furthermore, the several ætiologies of the various forms of this neoplastic disease are all polygenic in nature[3]. Haldane[7] in 1938 arrived at a similar conclusion with respect to cancer in general on the basis of Little's[8] statistical investigations of cancer inheritance. In rare families, but especially in those where the parents are consanguineous, childhood leukæmias and lymphomas can exhibit apparent recessive inheritance[9,10].

I have deduced[3,11] that malignancies in adult human beings generally develop from one or more cells containing a total of four specific (nuclear) gene mutations, one of which is often inherited, the remainder originating in one or more somatic cell lines.

The incompleteness of the penetrance of the inherited mutation arises because the probability of a somatic cell accumulating the fourth and final 'carcinogenic mutation' within the normal life-span is less than unity.

The evidence from families where the parents are consanguineous[9,10] indicates that two out of the four 'carcinogenic' mutations affect both homologous genes at a particular locus. More indirect evidence and arguments[12] are consistent with the view that the remaining two mutations affect both homologous genes at another locus. The ætiology of many childhood and adolescence malignancies[3] should involve a primarily non-genetic 'stress' factor such as (1) a hormonal stimulus; (2) a pyogenic infection (notably pneumonia[9,13]); or (3) infection, by 'horizontal' transmission, with an oncogenic virus. Direct epidemiological support for (3) has lately been obtained in the ætiology of a malignant lymphoma in children living in certain regions of Africa[14].

Familial Leukæmia and Mutation Frequency

By calculating (1) the size of (genetic) carrier subpopulations; (2) the 'penetrance' of an inherited mutation in the phenotypic form of a childhood leukæmia, the approximate frequency of childhood leukæmia in multiple sibs[9] can be accounted for[3]. Using Haldane's[15] "indirect method" for the calculation of mutation frequencies (where approximate genetic equilibrium is assumed) the derived values for the mutation frequencies of 'leukæmogenic' genes are closely comparable with known frequencies at other loci[3,11]. They lie at the upper end of the normal range[16] for dominant and sex-linked loci; but they include some effects attributable to gross chromosomal changes. Thus, trisomy for chromosome 21 (mongolism, or Down's syndrome) is associated with a very high leukæmia incidence in childhood[9,17,18], and the discovery of the *Ch*^{1} chromosome by Gunz *et al.*[19] shows that the inheritance of a chromosome 21 from which a portion of the short arm has been either deleted or translocated, predisposes to chronic lymphatic leukæmia.

There is another source of uncertainty that could introduce an overestimation of the mutation frequency. It is assumed that only two major 'leukæmogenic' loci are implicated with respect to each of the two groups of genetically related leukæmias[3]. Although immunological evidence indicates that one specific structural locus may be involved in the ætiology of many carcinomas[12], and although the phenomena of the *Ph*^{1} and *Ch*^{1} chromosomes[19,20] are consistent with specific loci being associated with leukæmogenesis, the possibility cannot be dismissed that there may be several loci of similar phenotypic expression. It is evident from the calculated mutation frequency that the number of major 'leukæmogenic' loci cannot be high, but it could be greater than two. (Other loci will undoubtedly affect the phenotypic expression of the major loci through their influence on factors such as growth, or growth-rate, but their net effect on the calculated mutation frequency should in general be small.)

The measure of agreement between established mutation frequencies and those calculated for the hypothetical major 'leukæmogenic' genes is obviously of considerable theoretical significance; it is rather unlikely that it represents a mere chance coincidence.

Direct Cytogenetic Evidence for an Inheritance Factor

With regard to the theoretical ætiology of chronic lymphatic leukæmia it was stated[3]: "Chronic lymphatic leukæmia in adults mostly arises from one or more cells containing one inherited and three somatic mutations". " . . . furthermore, a different set of common alleles may be involved in chronic lymphatic, chronic and acute myeloid, and some stem-cell leukæmias, together with certain pernicious anæmias and some cancers. . . . Given the predisposing dominant inheritance, the penetrance in the form of a specific leukæmia is typically of the order of 10 per cent for a normal life-span of 70 years".

The subsequent report of Gunz *et al.*[19] now offers considerable support for several of these predictions. Their findings show or suggest: (1) an association between a mutation of one chromosome of the pair 21 (the Ch^1 chromosome) and chronic lymphatic leukæmia in adults; (2) the inheritance of this defective chromosome yields a viable karyotype (there is as yet no indication that the Ph^1 chromosome[20] can be inherited); (3) the inherited Ch^1 chromosome is evidently a 'predisposing' factor—some adults are carriers of the defective chromosome without exhibiting any clinical signs of chronic lymphatic leukæmia; (4) if both chronic lymphatic and chronic myeloid leukæmias involve a common set of alleles, then the Ph^1 and Ch^1 chromosomes indicate that at least two loci (one on the long, and the other on the short arm of the acrocentric chromosome) are implicated in human leukæmogenesis; (5) a chromosomal deletion or translocation can again be phenotypically equivalent to a gene mutation[3]; (6) if the father of the 'C' family was a carrier, then the Ch^1 chromosome also predisposes to 'sarcoma of the mediastinum'; (7) if the sister (No. 5) of the propositus was a carrier, then the Ch^1 chromosome also predisposes to carcinoma of the uterus and to pernicious anæmia.

This cytogenetic evidence is probably relevant to rare families only. Out of eleven families Gunz *et al.*[19] have so far investigated in which there is at least one case of chronic lymphatic leukæmia, they have found only two where members exhibit the Ch^1 chromosome; it is therefore still possible that the normal mode of leukæmia and cancer 'inheritance' is neither a gross chromosomal-, nor a gene-mutation, but a vertically transmitted oncogenic virus.

To test this more general hypothesis it is necessary to examine evidence relating to large, for example, national populations.

Leukæmia Pedigree Evidence

Gross[3] points out " . . . However, transmission of certain oncogenic viruses *in utero*, or immediately after the birth of the hosts through the milk of nursing mothers, or by contact infection from parent to the new-born offspring, would also be included in the general pattern". We should expect, therefore, that transmission will occur with far greater frequency from the mother than from the father, and indeed it has been shown[21] that transmission of the Gross and Moloney viruses in mice occurs only via the mother. Videbaek[4] and Guasch[22] collected (independent) pedigrees of human "leukæmic families" from the literature and their own investigations. Videbaek's[4] collection (his Fig. 3) indicates that leukæmia was apparently 'transmitted' via the father in 16 instances and via the mother in 21. Guasch's[22] collection (his Tables 15–18) shows 18 examples of 'transmission' via the male, and 13 via the female. These small numbers therefore show equal frequencies of 'transmission' from the father and from the mother. This evidence is at variance with Gross's suggestions, but consistent with Mendelian autosomal inheritance to a remarkable (if somewhat fortuitous) degree.

A similar pattern of 'transmission' is found when all cancers are considered. Table 1 contains a summary of Little's[8] analysis of the incidence of cancer (all types) among the sons and daughters of cancerous fathers or mothers (four categories in all). The slight excess of 'transmission' from the mother is not statistically significant.

Table 1. INHERITANCE OR TRANSMISSION OF CANCER IN MAN*

Cancerous parent	Offspring investigated	No. investigated	No. cancerous	No. expected on chance basis	Ratio: No. observed / No. expected	
Father	Sons	453	14	0·85	16·5	12·6†
Father	Daughters	788	10	1·05	9·5	
Mother	Sons	565	12	1·19	10·1	14·0†
Mother	Daughters	504	27	1·59	17·1	

* Adapted from Little (ref. 8). The expected number of cases (column 5) was based on United States national statistics (1909–12). It is possible that case-finding in Little's sample (taken from the Eugenics Record Office) was better than the national average, and hence all ratios (last column) may be too high. There is no reason, however, to suspect a sex bias in the cancer statistics. Little gives no explanation of the sex-ratio for the offspring of cancerous fathers.

† Average for combined sons and daughters.

It could still be claimed that human oncogenic viruses are intimately associated with the genome, as in the phenomenon of lysogeny in bacteria. If such were the case, the 'lysogenic-type' of oncogenic virus could in principle be transmitted as readily via the sperm as the ovum. Evidently this is not the mechanism for transmitting the Gross and Moloney viruses in mice, and neither would this mechanism display normal Mendelian segregation—except by chance in rare instances. Nevertheless one may, for the sake of argument, disregard the indications of apparent dominant, and (very occasionally) recessive-inheritance, and consider instead certain broad features of cancer mortality.

Broad Aspects of Cancer Mortality

If age-specific total cancer mortality rates are plotted as a function of time, these are more or less steady in England and Wales among the lower age-groups, during the period 1915–53 [23]: a similar phenomenon is observed in the United States mortality statistics[24] over the period 1900–53. It must be admitted that it is difficult to know what significance can be attached to such statistics. They are complicated by advances in diagnosis and therapy, and the changing influence of environmental carcinogens. In the case of childhood leukæmias, other complexities have been demonstrated. Stewart and Barber[13] have directed attention to an impressive inverse correlation between mortality-rates from pneumonia and leukæmia in children during the period 1912–59. This phenomenon will be discussed at the end of this article.

Complications apart, a steady incidence-rate of pre-zygotic cancers over the years is to be expected on the basis of Mendelian inheritance. In situations of genetic equilibrium, the selective mortality among carriers before and during the reproductive phase is balanced by the introduction of new spontaneous mutations into the population. A general increase (decrease) in the mutation-rate would, of course, raise (lower) the incidence-rate of pre-zygotic malignancies until a new equilibrium would eventually be attained.

Consider in this context Gross's working hypothesis[3] of the vertical transmission of oncogenic viruses. To maintain an equilibrium incidence of cancer in the population by such a mechanism it is necessary for the virus host (mother or father) to transmit the oncogenic virus, on the average, to slightly more than half their offspring. (The selective mortality among recipients up to and during the reproductive age requires that more than half the offspring should be affected at birth—or during the period of infective contact with parents.) It is obviously impossible to achieve a stable equilibrium through vertical transmission. A slight average deviation upwards from the 'equilibrium transmission faction' would lead to an initially exponential increase in the proportion of hosts in the population until ultimately all members of the population would be affected. On the other hand, a slight departure downwards would lead to an exponential decrease in the proportion of hosts and their eventual disappearance. Any temporary equilibrium would be highly unstable.

Abandoning Gross's particular hypothesis, this leaves open the logical possibility that every individual is in fact a host to oncogenic viruses (of equal pathogenic potential from one individual to another) and that these are necessary to cancer development, but additional to all the genetic and other factors previously described[8]. On present evidence, this logical possibility is superfluous.

Evidence from Studies of Twins

On Mendelian theory, if one monozygotic twin is a genetic carrier the co-twin will also be a carrier. For the common case of apparent dominant autosomal inheritance of a single 'carcinogenic mutation', if one dizygotic twin is a carrier, the average chance of the co-twin being a carrier is 0·5. Neglecting post-zygotic cancers, the frequency of concordant cases of cancer in monozygotic twins should therefore be twice that in dizygotic twins. The phenomenon of post-zygotic cancers will, on the average, affect all non-carrier twins equally, and this will 'dilute' the ratio, to make it slightly less than 2. On Gross's vertical transmission hypothesis (*ad hoc* assumptions apart) the cancer concordance-rates should be identical in both types of twins. The results in a recent investigation[24] were combined with four previous investigations to show that the average (uncorrected) concordance-rates are 9·8 per cent for 255 monozygotic twins and 5·1 per cent for 704 dizygotic pairs; the difference is significant at the 0·01 level of confidence[25]. The nominal ratio of concordance-rates (1·9) provides further remarkable support for the hypothesis of Mendelian inheritance of 'cancer predisposition'. (It should be noted that in these studies the average penetrance of an inherited carcinogenic mutation in the phenotypic form of any cancer is $\sqrt{9{\cdot}8 \text{ per cent}} = 0{\cdot}3_1$.)

Conclusions

On the basis of all the foregoing evidence, Gross's working hypothesis of human carcinogenesis quoted at the beginning of this article is, as a general proposition, untenable. Nevertheless, the possibility cannot be excluded that it may be applicable in particular (but rare) instances. In a modified form of the vertical transmission hypothesis described here (with every individual a host to similar oncogenic viruses) the hypothesis is, on present evidence, superfluous, but not necessarily false. In this modified hypothesis, vertical transmission viruses could logically constitute familially neutral oncogenic factors additional to the genetic and other factors described here, previously[8] and in the next article[16].

Two outstanding enigmas remain.

(1) Why should the vertical transmission of oncogenic viruses be such a conspicuous feature of the ætiology of malignancies in small, short-lived animals, and so inconspicuous in man? It is suggested that the solution to this problem is an immunological one, and it will be discussed in an article to appear in the next issue of *Nature*.

(2) Although two large-scale statistical surveys[4,6,17] yield apparently unambiguous evidence of an abnormally high incidence of leukæmia in the relatives of leukæmic subjects, three other surveys[19,22,26] give no indication of familial leukæmia. Quite apart from theories of carcinogenesis, these apparent contradictions are disturbing in themselves, and the failure of three statistical investigations to reveal a familial tendency to leukæmia runs contrary to all the evidence relating to particular leukæmic families. Much of this latter evidence cannot be explained, even remotely, on a chance basis[27].

Videbaek's survey[4] was carried out in Denmark, and he found 17 confirmed cases of leukæmia in the families of 209 leukæmic patients, and only 1 in the families of 200 matched, healthy controls. Busk's[18] criticisms of this investigation have been answered by Videbaek[23]. According to the present theory, the maximum ratio of familial leukæmic incidence in the two groups should have been about 10, although the probable ratio is appreciably lower. However, even if the 'true' ratio is as low as 5, it is still consistent with Videbaek's small numbers. Steinberg[19], acting on Busk's[18] criticism, dispensed with controls, and compared the leukæmia mortality (assessed by interview and correspondence) in the families (grandparents, parents, aunts, uncles and sibs) of 249 children who had acute leukæmia with the 'expected mortality' based on 1940 and 1950 statistics. No significant difference was found (based on only 4 cases of familial leukæmia). However, the crude death-rate from leukæmia in the United States increased by more than a factor of 4 between 1921 and 1951[20], and little significance can be attached to Steinberg's conclusions regarding his statistical investigation. To minimize errors associated with cohort effects (however caused) and faulty memory recall, the use of a carefully matched control group as advocated by Videbaek[4] would appear to be indispensable to this type of investigation.

Morganti and Cresseri[26] carried out such an investigation, with controls, in Italy. In the families of 476 leukæmic probands, they found only 3 cases of leukæmia, as compared with 2 cases in the families of controls. In Guasch's[22] personal investigation in Spain, one case of leukæmia was found in the 2,290 members of the families of leukæmic patients and four in the 4,340 members of the families of controls. Both these surveys, therefore, give no indication of a familial tendency to leukæmia. However, a fascinating aspect of Morganti and Cresseri's study[26] is the demonstration of a significantly higher incidence of non-leukæmic malignancies in the families of leukæmic patients as compared with controls. The ratio they found was 1·3 (228/175 cases). Videbaek found a slightly higher ratio (1·4) and concluded "that there exists a relation between leukæmia and cancer".

In the terms of the present theory[8], a gene mutation that strongly predisposes to leukæmia development also markedly increases the susceptibility to certain other cancers. (As already mentioned, other genes will have some influence on the carcinogenic process. In mice, the agouti locus which affects growth-rate and total growth also influences the incidence of mammary tumours, the faster-growing, larger mice having, as would be expected, the higher incidence[21]. Furthermore, various hormones (especially the sex hormones) are known to modify the carcinogenic process, and it is obvious that these agents must be influenced by genes other than the major 'carcinogenic' ones.) Where the numbers of cases found were high enough to impart statistical significance, Morganti and Cresseri's data therefore indicate that the proportion of "leukæmogenic-carcinogenic genetic carriers" was higher in the families of leukæmic patients than in the families of controls. One of the principal reasons why Morganti and Cresseri[26] and Guasch[22] were unable to find statistical evidence for the genetic factor in leukæmias demonstrated by Videbaek[4] and by Stewart[6] is the low mortality from leukæmia in pre-1950 Italy and Spain, as contrasted with pre-1945 Denmark, and with England, Scotland and Wales during 1953–55. A low overall mortality rate, is, of course, equivalent to a lower expectation of mortality per individual. Hence in countries with a low overall incidence of leukæmia, the 'test' populations need to be much larger to demonstrate the existence of pre-zygotic leukæmias in the presence of a 'background' of post-zygotic leukæmias. The following discussion will amplify this point.

An interpretation of the marked differences in leukæmia mortality rates between different countries has been proposed[23]; but a brief recapitulation will be given here.

'Leukæmic mutations' in the malignant cell must abrogate the normal control of cellular differentiation and mitosis[12]. It is proposed that some degree of impairment exists in the pre-leukæmic genetic carrier and, as a consequence, the immune defence mechanism is weakened. This hypothesis readily accounts for the inverse correlation mentioned earlier between pneumonia and leukæmia mortality in children[18]; but it is proposed[32] that adult 'leukaemic genetic carriers' are likewise more prone than non-carriers to death from certain infectious and parasitic diseases. On this view, in countries where there is a high incidence of these diseases, there should be a low mortality from leukaemia and aleukaemia because of selective mortality from infectious disease among 'leukaemic genetic carriers'. The truth of this prediction is illustrated in Fig. 1. Furthermore, changes of mortality from infectious disease within a given country, over the years, should be followed by inverse changes in mortality from leukaemia. The truth of this second prediction is well known, and is illustrated in Fig. 2 with respect to statistics for England and Wales. (The mathematical form of these relationships will be exceedingly complicated.) In this context it is noteworthy that patients with diagnosed chronic lymphatic leukaemia generally exhibit hypogammaglobulinaemia[36,37] and frequent infectious complications[37].

Hence, in environments where mortality from infectious disease is high, mortality from pre-zygotic leukaemias should be low. Mortality from post-zygotic leukaemias, on the other hand, should be relatively unaffected—the immune defence system in non-carriers will not in general be impaired—consequently the ratio of pre-zygotic to post-zygotic leukaemias will be greatly diminished in countries where there is a high mortality from infectious disease. We now see why Videbaek[4] in Denmark—the country with the world's lowest recorded mortality rates from infectious disease and the world's highest mortality rates from leukaemia—was able to detect the familial tendency to leukaemia in a statistical survey, whereas in Italy and Spain, countries with a relatively high mortality from infectious disease, no such effect was detectable.

Nation-wide surveys are clearly necessary to elucidate the genetics of all forms of malignant disease through an analysis of pedigrees. It is very difficult to escape the conclusion that among the many aetiological factors in human carcinogenesis there exists a genetic basis.

Note added in proof. Dr. F. W. Gunz and his colleagues, Christchurch Hospital, New Zealand, have investigated 87 per cent of all cases of leukaemia arising in New Zealand during the period of their investigation. In a private communication to me, Dr. Gunz states: "Our figures for familial leukaemia support Videbaek, but our material is larger than his". Thus another large-scale survey in a country where there is a relatively low mortality from infectious disease (Fig. 1) confirms the existence of familial factors in leukaemogenesis.

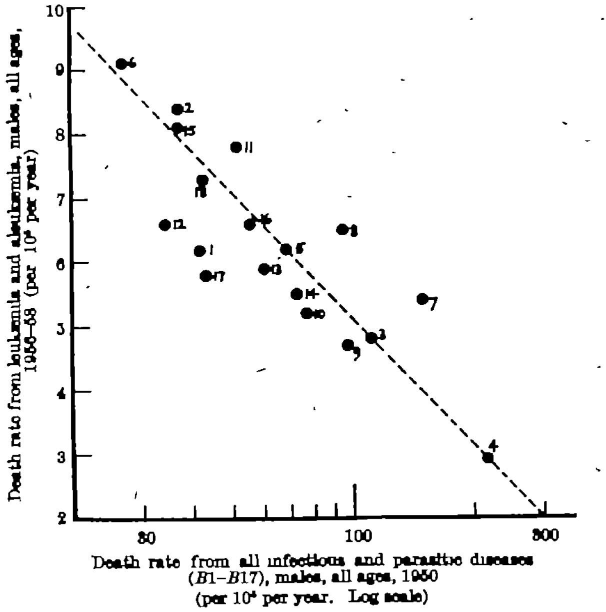

Fig. 1. Relation between gross mortality rates in males, from leukaemia and aleukaemia (ref. 33) (1956–58), and all infectious and parasitic diseases (ref. 34) (*B*1–*B*17 International Abridged List, 1948) for 1950, in different countries. (Changes in leukaemia mortality should lag behind changes in mortality from infectious diseases)

RELATIONS BETWEEN MOTHS AND PREDATORS

By DR. A. D. BLEST

Department of Zoology and Comparative Anatomy, University College, London

THE visual protective adaptations of the Lepidoptera, and the selection pressures which have given rise to them, have been the subject of intensive study in the course of the past ten years. On the whole, researches in these fields follow three main lines of attack. In the first place, it is necessary to provide evidence of more than anecdotal value for the actual efficacy of a supposed adaptation; in this respect, adequate experimentation has become possible largely through the combination of satisfactory experimental design with the precise observation of the behaviour of predators which modern ethology allows. Secondly, those features of the predators' behaviour which have forced the evolution of the protective adaptation need detailed behavioural analysis. Lastly, the evolutionary possibilities of the prey–predator interaction require a genetic analysis if they are to be sufficiently understood.

The field has recently been reviewed by P. M. Sheppard[1]: few investigations other than the well-known series by Dr. H. B. D. Kettlewell on industrial melanism in *Biston* have been able to pursue all three approaches simultaneously. Nevertheless, there is an impressive body of evidence to refute the scepticism of the generation of ecologists who followed Sir E. B. Poulton, and who doubted whether even the most obvious adaptations were more than the products of morphogenetic or evolutionary accident.

It is customary to classify visual adaptations in terms of the relationship between the visual appearance of the prey and that of its environment. Species with cryptic coloration resemble some features of their normal background; aposematic species stand out from it and are distasteful; the eyespot patterns of others have been assumed to mimic the appearance of their predators' own enemies, and so forth. The behaviour patterns which disturbance elicits from such insects are rather precisely adjusted to the patterns which they bear, and the presumption that behaviour and correlated visual pattern are mutually necessary to confer protective advantage has been demonstrated experimentally for each of the three categories listed here. In addition, it has been shown that the immobility and dispersion of many cryptic insects exploits the searching behaviour and limited learning capacity of avian predators, while the detailed accuracy of their procryptic resemblances corresponds to the precision of the visual discriminations which birds can achieve under ideal conditions of presentation. Eyespot patterns have been shown to parasitize the inborn responses of passerine birds to their predators; their concealment when their possessors are at rest, and sudden exposure during protective display, are required by the rapidity with which the passerine's responsiveness to them wanes with repeated presentation. Predators have been repeatedly shown to link bright aposematic patterns with distasteful properties, and to avoid insects so coloured, often under conditions of single trial learning. There is also a suggestion in recent work that some potential predators may be equipped with built-in responses to aposematic patterns.

In the last category of analysis, Kettlewell has determined that the melanic form of *Biston betularia* is controlled by an autosomal dominant, and has traced its rapid spread through the British population over the past hundred years. In this case, selective advantage is conferred by the procrypsis of the black form of the moth when resting on tree-trunks contaminated by industrial soot. There is an intriguing possibility that the supporting gene complex of the melanic dominant has also undergone selection to enable it to confer a physiological advantage over the typical form, but the evidence is inconclusive. There are also a number of recent studies by P. M. Sheppard and C. A. Clarke of the control of genetic polymorphism in mimetic butterflies.

At the present time, then, it would seem that the advantages conferred by visual adaptations have been amply demonstrated, and the fact of their existence sufficiently explained. Can work of this kind be made to yield further results of any great importance to evolutionary theory?

In fact, the more complex selective consequences of these prey–predator interactions have been ignored; yet they present some of the most interesting evolutionary and ecological problems. They are, broadly speaking, of two main types: (1) the effects of selection by predator populations are limited or directed by concurrent interactions between the prey population and its animate or inanimate environment; (2) the special features of the relationship between prey and predator impose widespread selective effects which are not obviously related to the protective devices which are their immediate result. It will be seen that these two types of action are somewhat arbitrarily defined.

Type (1) may be illustrated by two examples, the first of which can barely be differentiated from the simple kind of direct selection usually studied. Cryptic moths have evolved colour patterns which match the backgrounds against which they usually rest. In a tropical environment which presents a florid speciation and the opportunity to compare several closely related species grouped in different habitats, such matching may be critically observed. In Panama, lymantriids, notodontids and geometrids have been seen in seasonal evergreen tropical forest at sea-level, and at altitudes of 4,000–5,000 ft. in the Province of Chiriqui. The latter forest contains a particularly high density of lichens, mosses and epiphytes on the trees; not surprisingly, the species found in it have colour patterns which seem, from the frequency with which grey and green occur in them, to be specifically adapted to the altered background. At the same time, the examination of very large assemblies of cryptic species suggests that there may be selection for interspecific divergence in procryptic forms, and the adoption of very specialized cryptic niches by individual species. It is clear that the learning capacities of predators must limit the density of individuals which can occupy any one cryptic niche.

The same two habitats provide a second example. The diurnal temperature range of the lowland habitat is only removed by some 6° C from the lowest effective working temperature of the flight muscles of Lepidoptera (35° C for sphingids[2]). Consequently, even heavy bodied saturniids and sphingids are able to make fairly efficient escape flights from rest when they are disturbed. Correlated with this ability is a poor maintenance of protective display in all but the most aposematic species. Presumably a fast escape flight is more likely to succeed than a display which may or may not be effective. In aposematic small-bodied arctiids, these transient displays are usually held for no more than a few seconds. At the higher altitudes, with diurnal temperatures which are lower by some further 8° C, the saturniids and arctiids are found to have well-defined and sustained displays. This would appear to be a genuine and selectively determined difference, for cooling the lowland forms does not notably improve their display performance. The general range of environmental temperatures appear to be critical in determining the evolutionary course taken by protective display behaviour in flying insects.

The last category is, perhaps, more speculative, and also more difficult to analyse. It is a familiar fact, for example, that aposematic insects are commonly tough and heavily sclerotized in comparison with non-aposematic forms, and it is usually argued that aposematic species have to survive sampling by inexperienced predators. In order to achieve heavy sclerotization, selection must exert rather widespread effects on the ecology of the early stages; it might be expected to impose a relatively greater food-intake, and probably a longer larval history to accommodate it. These effects do not seem to have been searched for critically, and their confirmation would be of some interest. There are, too, more complex possibilities. One of them relates to the status of a non-feeding adult insect after it has completed a reproductive role in its population. If it is a procryptic species, its continued post-reproductive survival can only prejudice the safety of its fellows, for it remains available to train one individual predator to find them. For this reason, group selection might be predicted to shorten post-reproductive survival in procryptic forms, and, in addition, to concentrate reproductive behaviour near to the beginning of adult life. Conversely, a post-reproductive aposematic individual can only benefit its still reproducing fellows, for it can train more than one predator to ignore them. Selection in this case should lengthen post-reproductive survival, and allow more latitude in time to the reproductive process. Recent evidence from hemileucine saturniids observed in seasonal tropical evergreen forest has tended to confirm these predictions, and has suggested an extension of them: while the aposematic species have behaviour which is stable in time from emergence until death, procryptic species show great behavioural instability, and become progressively more excitable as they grow older. Since they also possess 'soft' scaling, the result tends to be a considerable degree of damage to their cryptic patterns rather early in their potential life-spans, and it seems likely that mechanical damage and increased vulnerability to predation remove them from their populations even earlier than their life-spans under ideal laboratory conditions would imply[3].

Effects of this kind require the operation of group selection, and the extent to which this is possible in Nature is still controversial. Clearly, certain obvious constraints (for example, lack of mobility in the populations concerned, and the synchronous emergence of siblings) are necessary conditions which are met for tropical saturniids. Whether other families of the Lepidoptera are as liable to group selection is not known. It might serve to explain the paradox of the general fragility of so many short-lived cryptic forms. In principle, since cryptic patterns have achieved a degree of precision which has been shown to be required by the discriminatory abilities of predators, direct selection might be expected to make their structure sufficiently tough to last the course of an average life-span. If, however, a counter-selective force, generated by the predators learning abilities, tends to reduce the availability of the pattern to reinforce recognition, the outcome could conceivably be that actually found: precision of colour pattern, coupled with fragility to confer a limited availability for learning processes, particularly during the act of prey-capture.

Such complex selective effects are probably widespread, and they may prove to underlie the elaborate structuring of actual populations of closely related aposematic forms in the tropics, where instead of the simple Müllerian convergence which might be predicted the investigator more commonly finds complicated systems of partial resemblance from which the cases of classical Müllerian mimicry stand out and invite, perhaps, too easy explanation.

The original field work which formed the basis of some of this article was supported by grants from the U.S. National Science Foundation, and from the U.S. Institutes of Health (*RG*–7109). It was carried out in the Canal Zone Biological Area, U.S. Canal Zone, Panama, during 1958, 1961 and 1962. The article summarizes a lunch-hour lecture delivered at University College, London, on January 22, 1963.

COMPUTERS AS BOTANISTS

Substance of a Friday Evening Discourse delivered at the Royal Institution on October 26

By Prof. W. T. WILLIAMS
University of Southampton

IN any day and age some scientific opinions have been less acceptable than others. Galileo found himself in difficulties as a result of holding currently unfashionable views on the manner in which the universe conducted itself; and in Galileo's day you suffered, if suffer you did, at the hands of the Church or State. Nowadays, it has been wisely remarked, if anybody burnt a scientist at the stake it would be his fellow-scientists; for the modern counterpart of the phenomenon is that some scientific activities are professionally less respectable than others. A recent example is the melancholy argument over extra-sensory perception, where the dispute seems to have been less over whether or not it actually happens, than as to whether a reputable scientist ought to investigate it at all.

Another scientific activity which is at present in some disrepute is that which involves the extraction, from a complex mass of data, of some form of underlying pattern or general principle—an activity which occupies the time of many of those engaged in examining living organisms, whether these be plants, animals, or even that special animal, the human being. There seem to be two reasons for the present denigration of this pursuit. First, it must be remembered that all sciences start like this, by the extrication of patterns from a welter of observations. If the resulting patterns are simple and clear, we may even call them 'laws'; but this is no more than a courtesy title—no Government has ever attempted to repeal the law of gravitation, and no magistrates' court has ever fined a scientist for breaking it. Whatever they may be called, these patterns, once extracted, can be used for predicting further phenomena. Now, the predictive stage of a science is immensely powerful, immensely useful, and remarkably lucrative; and the physical sciences, which are now largely in this stage, are inclined to look down on their own humble origins. Since the biological sciences are, because of the almost inconceivable complexity of the simplest of their material, still largely in the pattern-making stage, they tend to become looked down on *en bloc*.

The second cause of this present disrepute arises, I believe, out of our lack of understanding of the logical processes involved. The extrication of patterns is an entirely human activity, and those who are most gifted in this respect are far from clear as to how they do it, and are seldom able to teach the process to others. It is at this point that the myth that pattern-making is a second-class science is vulnerable; for if we can show that the process can be reduced to a set of rigorous mathematical transformations, we can make it objective, universally available and respectable. A computer may be regarded as a model of some aspects of the human brain. Can a programme be written for a computer which will enable it, when given a set of data, to extricate its underlying pattern?

Consider the problem of establishing the pattern in an area of vegetation, where what is required is a subdivision of the area into regions as different from each other as possible. A human ecologist will do this by walking over the area, using—not always consciously—many different items of information, and drawing extensively on his past experience. If the process is to be made objective, we must control the information reaching the ecologist; he must not be allowed to see the area himself. We will instead provide him with information concerning a series of small sample areas ('quadrats') arranged in a grid over the whole area, and this information will consist solely of the presence of named plants. His task will be more difficult, but not impossible; but he may still be able to draw on his experience by using his knowledge of the proclivities—the habitat preferences—of plants with which he is familiar. The information must therefore be still further reduced: the plant species must be given code numbers or letters, and their names not divulged. Is the problem still soluble?

The work of Nordhagen[1] and Goodall[2] showed that in principle it is. Nordhagen pointed out that the existence of heterogeneities would be manifested by the tendency of the different species to occur in groups which are, or tend to be, mutually exclusive; and that the existence of some degree of association or dissociation between any pair of species would be evidence of a discontinuity in the area. Goodall pointed out that if an appropriate statistical measure of association were calculated for every pair of species, the resulting symmetrical matrix of associations would summarize the available information concerning heterogeneity. His work implied that it should be possible to establish which of the columns or rows of the matrix, that is, which of the plant species, contained the most information; and he pointed out that a division of the area into those regions containing, and those not containing, this species should delimit those regions which, so far as a single species could provide the information, were most different. Our contribution at Southampton was to suggest a means by which this species could be identified[3], and the entire process of analysis could then be transferred to a computer, and was in fact programmed for the Ferranti *Pegasus* computer.

The process was tried out on three test areas. Details of the results can be found in the literature[4,5], and for the purpose of this article the briefest summary will suffice. In the first of these areas—a strip of New Forest heathland near Beaulieu Road Station—my colleague and I hoped that the computer would extract and delimit patches of ground burnt by sparks from passing trains. It did so, stigmatizing these as of only minor importance, but first indicated that the area should be divided neatly into two. More detailed examination of the site showed that the computer had defined a soil difference—the boundary between Barton Sand and Plateau Gravel—which was far from obvious on the surface. The computer was, of course, perfectly right in assigning to this the greater importance; for it is a permanent difference, whereas the burning changes, though more spectacular, are transitory. Chastened by this experience, Dr. Lambert and I selected a very strikingly zoned area of the heath, ranging from dry heath to bog. Here we were reasonably confident that not even the most fallible botanist could err; and we were comforted when the computer produced precisely the same results as our own.

The last of the test areas was the now classic Rockland–Claxton level, in the Norfolk Broads. This had been surveyed some years earlier by Dr. Lambert with the help of a group of students, and her published maps—which were fully accepted by ecologists—related the major heterogeneities to differences in soil and grazing[6]. The computer accepted the soil, paid no attention to the grazing, and again firmly divided the area along an unexpected line—which this time was manifestly the parish boundary. Historical investigation provided the reason for this ecclesiastical interest: the 1840 tithe-maps show that by that date one of the parishes had drained its land, the other had not. The difference was still detectable in the vegetation. For good measure the computer made a further division, between different pairs of students; there had been, it appeared, some uncertainty about the identification of grasses.

All in all, the results fulfilled, and even exceeded, our expectations. In two of the cases the computer did better than the human beings, in the sense that it revealed discontinuities which had been overlooked by its human colleagues, but which on investigation proved to be of major importance. There is, then, no doubt that patterns can be extricated by computers by mathematical operations on the data; this should be a great relief to biologists, since it is to-day regarded as a mark of prestige if one's scientific activities, whatever they may look like to the casual observer, can be claimed to be, in reality, a slightly recondite branch of mathematics.

But does the fact that a computer can beat a human being at an essentially human activity carry any sinister long-term implications? In science fiction, which is the literature of extrapolation, there is to be found the recurrent theme of the omniscient computer which ultimately takes over the ordering of human life and affairs. Is this possible? I believe it is not; but I also believe that the arguments commonly advanced to refute this possibility are the wrong ones. First, it is often said that computers 'do not really think'. This, I submit, is nonsense; if computers do not think, then nor do human beings. For how do I detect the process of thinking? I present data—say, an examination paper—to a student, which he scans with a photoelectric organ we call an 'eye'; the computer scans its data with a photoelectric organ we call a 'tape-reader'. There is then a period when nothing obvious happens, though electrical changes can be demonstrated on the monitor-tube of a computer or on the corresponding device—an electroencephalogram—for the student. Lastly, information based on the data is transcribed by means of a mechanical organ called a 'hand' by the student and a 'teleprinter' by the computer. In other words, as Gilbert Ryle[7] pointed out, the only evidence we have that people think is what they do, our observations of their actions; and the actions of man and machine differ only in the appliances they use.

Secondly, it is said that computers 'only do what they are told', that they have to be programmed for every computation they undertake. But I do not believe that I was born with an innate ability to solve quadratic equations or to identify common members of the British flora; I, too, had to be programmed for these activities, but I happened to call my programmers by different names, such as 'schoolteacher', 'lecturer' or 'professor'.

Lastly, we are told that computers, unlike human beings, cannot interpret their own results. But interpretation is always of one set of information in the light of another set of information; it consists simply of finding the joint pattern in two sets of data. The mathematics of doing this is cumbersome, but well known; the computer would be perfectly willing to do the job if asked.

There are, of course, real differences. The memory store of the human brain, though slow and uncertain of access, is vastly larger than that of any computer yet built or conceived; but this is not a fundamental difference, and will become less important as computers get larger. Moreover, computers tend to think in straight lines, like the signal reaching a television tube; they do not immediately apprehend it, as the human brain can, as a two-dimensional pattern of moving images. This is merely because the human brain contains many separate thinking paths, all elaborately cross-connected; whereas even the largest computers have few distinct paths, with little cross-connexion. This is purely a matter of computer design, and could be overcome if we so desired.

Clearly, then, these well-worn arguments will provide no comfort for those who fear domination by computers. One vital distinction between computers and men, hitherto completely overlooked, does nevertheless remain. It was first pointed out by my colleague Mr. A. R. Manser, to whom I am indebted for permission to reproduce the substance of his argument in this communication. Briefly, human beings *want* to compute; and the reasons for their wanting are unrelated to the things they compute. For human beings are provided with more than brains; they have reproductive systems, digestive systems and the like. These supply them with drives, impulses, needs, wants, desires—and some of these may be satisfied by mental activity. I do not intend any reference to some sort of psychological 'compensation'; I mean only that I may undertake additional mental activity—more work—in order to obtain money to buy a refrigerator, because I enjoy food; or to buy a mink coat, to clothe someone I wish to please. Computers, being only brains, live in a cold world, free from all such desires and free, therefore, from the desire to think; and we shall be safe from their domination so long as we continue to build them solely as brains. If we go further—if we aspire to give them reproductive systems, digestive systems and all the facilities for sensuous enjoyment, then they will no longer be computers but genuine robots; and the world of Karel Čapek, Isaac Asimov and Arthur Clarke will be around us at last.

But even if we do not make this mistake, one danger remains. Computers, even in the very human field of pattern-making, are so much faster and more reliable than human beings that we may be tempted to delegate to them all our computational activities; computation would then become something that men never do. But something men never do soon becomes something men never teach; and all our knowledge of the manifold skills of computing could be lost within a few generations. So one vital question remains: has the human computer, *qua* computer, any advantages over his electronic counterpart? The answer to this question has long been current in computer circles, though I have been unable to trace its original author.

Man has indeed three advantages—advantages which he may well retain even into the far-distant future. First, given his abilities, he weighs less than any computer yet designed or even envisaged: there seems no likelihood that an electronic computer capable of so great a variety of computational facilities can be encompassed within 150 lb., even though the human computer increases somewhat in size and weight after the first fifty years' operation. Secondly, man needs far less energy; his energy requirements, being in the form of food and drink, are intensely inconvenient and clumsy, but they are collectively minute when compared with those of an electronic computer. Thirdly, and lastly, and perhaps most important of all, man is the only computer yet designed which can be produced entirely by unskilled labour.

TEACHERS OF ENGLISH AND THE LITERACY OF SCIENTISTS

By Prof. R. S. SCORER

Department of Mathematics, Imperial College of Science and Technology, University of London

MR. A. J. KIRKMAN has recently argued in *Nature*[1] that it was mainly up to teachers of science and technology to give the guidance and impose the standards necessary for their students to improve their written English. He gave examples of errors of grammar typical of their writings, mostly indicating rather trivial effects of carelessness: sentences incomplete or tenses changed in the middle, bad punctuation and spelling, and so on.

All the errors he mentioned were fairly easy to spot, easy to correct, and of a kind which the teacher could easily mark; but they were all irrelevant to the main problem of helping scientists to write better English and express themselves more fluently.

The damage is done in the classes called 'English', and is not the fault of science teachers who accept low standards. I can best illustrate from my own experience as a schoolboy one of the ways in which respect for English as a subject is destroyed; and I should say, lest a counter argument be sought, that there is no analogy in the lack of enthusiasm some students have for mathematics (which may, perhaps, be compared with Latin), for English is my language just as much as the English teacher's. One essay I wrote was criticized as being "too much like a *Daily Herald* leader". I was given no help in how to express views which, in those days of the 'Hunger Marchers', my generation held very strongly indeed. I was even criticized for my vehemence.

The subject set the following week was "The English Sunday". In response to my teacher, and drawing on my upbringing in a cathedral city, I concocted an inconsequential blather about cake, church bells, and chimneys, contrasting them with Continental commercialism. Without conviction about the sentiments expressed nor believing that the topic was important, I was awarded a prize for this performance in hypocrisy and, by some standards, banality.

Now science is about veracity and understanding. Scientists are not barristers, though they sometimes rather foolishly allow their emotions to get them into the position of advocate when their own ideas are attacked. To be rewarded by my teacher for my exercise without conviction had not helped me to sort out in words on paper the complicated ideas boiling up and the ideals growing inside me. It illustrates how easily teachers can kill 'English' as a subject by setting subjects in which the pupil cannot involve himself. They imagine that it is better to think up than think out ideas. They encourage padding, for it is commonly accepted that on reaching the top of the fourth page of an essay the pupil has at least done what he is allowed to call enough, whatever its quality. This takes all, yes all, the poetry from writing.

The teacher's task is to get the students to set down live theses (live, of course, to the pupil, not necessarily to the teacher), to polish until it cuts cleanly into the reader's imagination. They should invite descriptions of experiments in the science laboratory or of a football game just played, comment on an outrageous piece of current news or an imaginary case of moral injustice within the law, inquiries into the causes of accidents, advice on choosing a camera, accounts of almost anything for which the writer has some genuine feeling. Any pupil who responds will find occasion enough for drudgery when later he aspires to achievements which will require it, and he need never be assigned to it. The teacher should get the whole class to consider how to improve the effectiveness of each pupil's effort. What a change this would be from essays on characters in Shakespeare with marks for spelling, punctuation and all the other corrigenda of the grammarian.

Driven to cynicism for the fun of it, I occasionally made discoveries. On one occasion, in answer to the invitation to write on "The Best Time of Life", I opted for old age. (My views were recently endorsed in a B.B.C. sound programme on growing old.) Conviction was evolved in a mood of rebellion against the usual tedious story: the essay had many shortcomings, but apart from grammar, it was criticized for insincerity. Instead of investigating better ways of expressing my chosen thesis I was reprimanded for "trying to be clever", which convinced me that I had succeeded, wherefore I could not at the time see the shortcomings of the essay.

An interesting point about Mr. Kirkman's examples is that in each case it was immediately clear what the writer meant, though a moment's thought was necessary to spot the error for which it was quoted. The outrage against the rules of grammar evidently annoyed Mr. Kirkman who, being himself unable to understand the intended meaning, blamed the bad grammar rather than his own lack of knowledge of the subject-matter for the failure of communication. He should not suppose that the writing ought to be intelligible if the grammar is correct. Thus Carlyle writes, "The man so nourished and decorated, thenceforth named royal, does verily bear rule; and is said, and even thought to be, for example, 'prosecuting conquests in Flanders', when he lets himself like luggage be carried thither: and no light luggage; covering miles of road". Full of thought, concentrated and delightful to one who understands, but certainly obscure and of questionable grammar to one who does not. Imagine Mr. Kirkman's reaction to a laboratory experiment described in this style. Correction of the grammar in the cases quoted by him would only ensure that so far as the grammarian was concerned the words could have meaning; but grammatical correctness does not guarantee meaning, still less significance. Nonsense can be made grammatically correct; and grammatical correctness has even caused meaning to be sought in words which contained none, as in the example from ***Ezekiel*** given later in this essay.

Any ordinarily educated person can easily learn the habit of correct grammar with practice. Some errors remain only because students have not been taught how to re-read what they have written. This has nothing to do with the problem of becoming articulate on paper. In mathematics and science the pupil is encouraged to say what he needs in the least possible space. In mathematics particularly, provided the logic is correct, the briefest formulation is often the best. We have no sympathy for padding, or "leisurely periphrasis" as Mr. Kirkman approvingly calls it. We have symbols for whole sentences the intelligibility of which depends on hard-learned familiarity: it is not merely a language but a shorthand which cannot be translated into ordinary language because many other symbols and sophisticated ideas stand between it and its origins in the commonplace world. The mathematics student is therefore used to having a whole series of steps in an argument presented in half a page. Equal logical content in a political, religious, or legal argument would occupy perhaps several pages which would take an hour or more to write.

The unpractised writer has great difficulty in visualizing all the steps in a long verbal sequence as clearly and simultaneously as he can see them in a mathematical argument contained physically on one piece of paper. It takes such a long time to write out that he cannot easily keep clear in his mind where he has got to at each moment; he easily forgets the intended asides and reinforcements. It is probable that most teachers suggest the making of rough notes; but which of them dissects the pupil's final essay, reshaping it sympathetically over and over again until all unnecessary content is removed? More important —which of them does this with essays on subjects they know the pupils feel strongly about?

Experienced authors often cannot see mistakes in printers' proofs because they know too well what was intended, and it is only worth a student's while checking for grammar if some considerable time is allowed to elapse since the writing was done. In tutoring mathematics students, I have, from time to time, asked them to write essays on non-mathematical topics in order to give them practice in writing. They make plenty of trivial grammatical mistakes, but these should be tolerated with a smile: they can easily see them if I keep their work from them for a week or two. But often what was in their minds lies only between the lines and is only fully exposed by discussion of the essays. One idea is expressed two or three times while another is forgotten. Obviously the hand and the mind have not learned to move at the same speed, and the mind sees implications in the written words which are not apparent to a reader new to the matter.

English teachers have no easy task in training pupils to express their intended meaning clearly and unequivocally. Except in mathematics the meaning evoked in the reader's mind depends not only on what is written but also on the reader. The extreme example of this occurs when reviewers accuse authors of advocating points of view which they have actually expressly rejected. The reviewer is anxious to categorize the author as hastily as he can (we all do this, but are not usually in such a hurry as a reviewer) and his eyes and mind become fixed on sentences which seem to label the author with one or two '-isms' well known to the reviewer. The author has probably written the book in the first place because he finds these very '-isms' unsatisfactory; but it it is easier to read a new book and write it off as being a good or bad exposition of familiar theses than to search the depths of the writer's mind.

Some things are indescribable however good one's control of language. It is a common experience of scientists who have have been intimately concerned with a matter which has become news to see nonsense made of it by 'Our Science Correspondent' who, in the profession of journalism, has learned fluently to form sentences according to the rule of grammar which are only seen to be meaningless by those who know what he was trying to understand. Occasionally meaning gets through to those with sufficient knowledge of the topic. Thus Ezekiel, believing the Lord to be descending from heaven in a cloud to summon him, describes a thunderstorm with a tornado:

". . . Now as I beheld the living creatures, behold one wheel upon the earth beside the living creatures, for each of the four faces thereof. The appearance of the wheels and their work was like unto the colour of beryl: and they four had one likeness: and their appearance and their work was as it were a wheel within a wheel. When they went, they went upon their four sides: they turned not when they went. As for their rings, they were high and dreadful; and they four had their rings full of eyes round about . . ." and so on. This kind of writing is described by loyal theologians as "obscure", the implication being that we cannot penetrate the depth of Ezekiel's vision. One could alternatively say that the vision was very shallow: How could it be otherwise for an observer who understood neither rotation, nor condensation, nor electricity, nor wind? Moreover, how impossible for a translator who himself does not understand a tornado, nor even suspects that this was the basis of the vision, to render meaningfully into English!

One is led to suspect that a teacher of English can hope to find only the superficial deficiencies in scientific English unless he learns more about the subject-matter. Perhaps Mr. Kirkman is right after all in passing responsibility to the science teachers because most English teachers cannot bear it. But the scientist's task is so often rendered well-nigh impossible by English teachers who inoculate pupils interested in science with a distaste, or at least a disdain, for the subject known as 'English'.

---

OBITUARIES

Dr. P. Rosbaud

With the death on January 28 of Dr. Paul Rosbaud, at the age of sixty-six, one of the most lovable personalities in the world of science has passed away. He was not an active research scientist but was engaged in scientific publication. There cannot be many contemporary authors of scientific books who have not met him some time. He was friends with many leading scientists, mainly physicists and chemists, and to some of them he was very close.

Born in Austria, he studied chemistry in Germany. Early in the 1930's he joined the big scientific publishing firm of Springer in Berlin as scientific editor, and there he began his fruitful publishing activities. Most of the important standard works in physics and chemistry published by this firm at the time must have passed through his hands, and he was undoubtedly responsible for the writing of many. One of his most fateful activities was in 1938 when, after a telephone call from Prof. O. Hahn, he decided to have a paper published in *Die Naturwissenschaften* describing Hahn's discovery of nuclear fission. Thus this important fact was made known to the world shortly before the War.

In 1933, the Nazi period began, which he loathed from the very beginning. Shortly before the Second World War he had to send his wife out of Germany—she went to England as a refugee—but Rosbaud stayed in Berlin. He did not want to take one of the few posts then available to refugees. His office in Berlin became a meeting place for dissident scientists. He was always ready to help as much as he could those in trouble. During the War he was in constant danger of his life, owing to his manifold anti-Nazi activities; but he judged the Nazi police correctly: it was more cruel than intelligent. In the middle of the War he secured the release of two French scientists from a prisoner of war camp for "the purpose of translating a scientific book into French" (after obtaining Joliot-Curie's consent that they would not be accused of collaboration after the War).

When the War ended, all the Allies knew his worth, and several Powers tried to get him. He wanted to go to England and was flown there. England became the country of his adoption and he loved it. Soon he began his publishing activities again. First, he was partner of a new scientific publishing house but later he made himself independent, working as a free lance. He was scientific adviser to many big publishing firms throughout the world, mediating between author and publisher. His contact with prospective authors was always personal and this enabled him to be uniquely up to date in the developments of science. In his small unpretentious office in London, S.W.1, with the kind landlady who was always ready with a cup of tea for the visitor, everyone must have felt at ease. His intelligence, vividness and dry humour won the heart of everyone of good will. He was tolerant of every honest opinion but very intolerant of injustice, underhandedness and so on.

In 1961 he was awarded the Tate Medal of the American Institute of Physics for his services to science.

The post-war development of science was not entirely to his liking, and he worried a lot about it. He did not like the alliance science had made with military authorities. Nor was the pretentious scale on which science was to be furthered quite to his taste, and he disliked the attitude that sponsored it. He saw the danger involved when science became too much mixed up with the interest of power or mere material advantage.

In September 1962 he was frequently seen at the Pugwash Conferences in London (in which he nominally did not participate) discussing the world's problems with the delegates—lively as ever. He fell ill in November. It turned out to be leukaemia. Up to the last he thought of his friends. He died peacefully on January 28.

W. Heitler

Prof. N. R. Sen

Nikhil Ranjan Sen, who retired in 1959 as Ghosh professor of applied mathematics at the University of Calcutta, after holding the chair for thirty-five years, died on January 13. He was honorary research professor at the Indian Association for the Cultivation of Science, Calcutta, at the time of his death.

Son of Shri Kalimohan Sen and Shrimati Bidhumukhi Devi, he was born on May 23, 1894. He was educated at Dacca Collegiate School, Rajshahi School and Rajshahi College. Later he studied in Presidency College, Calcutta, and at the University of Calcutta, and he took his M.Sc. degree in 1916, and D.Sc. in 1921. Afterwards he proceeded to Germany, where he worked with Prof. Max Von Laue. Shortly after returning to India he was appointed Ghosh professor in the University of Calcutta, where he worked ceaselessly to create a school of research in applied mathematics which in the course of years spread its influence in all parts of India.

His researches embraced several fields. He did interesting work on some intricate problems on spherical harmonics early in his career. In the early 'thirties he worked on wave mechanics, including Dirac's relativistic equations. He also worked on cosmological problems. Later he turned to relativistic effects in stellar bodies and also (a little after the advent of Bethe's law of energy generation) to the problems of stellar constitution. During the 'fifties he started working on turbulence and other problems of fluid mechanics.

To his students and colleagues Sen was a model of single-minded devotion to work, and the team of enthusiastic teachers which he built up in his department in Calcutta was inspired by his exemplary character. His weekly seminars, which attracted persons from different institutions, worked as a powerful force and pioneered a new spirit of research and study. One would also often see him on holidays holding small study groups in his house, squatting on a mat, reminiscent of an ancient Indian teacher with his disciples.

He was greatly interested in the problems of teaching mathematics at school-level, especially in relation to the teaching of higher mathematics. In the 'thirties he started a small laboratory for numerical computation for his M.Sc. students. For some years before his retirement he was working to set up a small hydrodynamic laboratory with a flume and a wind tunnel.

He was the fountain-head of inspiration of the Calcutta Mathematical Society. With the help of hard-working editorial secretaries he did his best to raise the standard of the *Bulletin* of the Society.

Though essentially of retiring temperament and averse to committee work, he responded to the demands of the country and served on various committees and advisory bodies all over India.

S. N. Bose

NEWS and VIEWS

The Royal Society of Edinburgh: New Fellows

THE following have been elected Fellows of the Royal Society of Edinburgh: Mr. A. J. Aglen, fisheries secretary, Department of Agriculture and Fisheries for Scotland; Sir William Arbuckle, secretary of the Scottish Education Department; Mr. J. W. Atwell, managing director, G. and J. Weir Holdings, Ltd., Glasgow; Prof. J. Baddiley, professor of organic chemistry, King's College, University of Durham, Newcastle upon Tyne; Dr. R. A. Beatty, senior principal scientific officer, Agricultural Research Council Unit of Animal Genetics, Edinburgh; Mr. A. J. Brook, lecturer in botany, University of Edinburgh; Prof. J. Bruce, Regius professor of clinical surgery, University of Edinburgh; Mr. J. D. S. Cameron, president of the Royal College of Physicians, Edinburgh; Mr. W. Dickson, senior science master, George Watson's Boys' College, Edinburgh; Dr. A. J. Hale, senior lecturer in pathology, St. Thomas's Hospital Medical School, London; Prof. J. Hawthorn, professor of food science, Royal College of Science and Technology, Glasgow; Dr. J. B. Helliwell, senior lecturer in mathematics, Royal College of Science and Technology, Glasgow; Dr. P. N. Hobson, head of Microbiology Department, Rowett Research Institute; Prof. A. Iggo, professor of veterinary physiology, Royal Dick Veterinary School, Edinburgh; Mr. G. S. Johnstone, principal geologist, H.M. Geological Survey (Scotland); Mr. P. P. Love, director of research and development, Glacier Metal Co., Wembley; Prof. W. T. Marshall, Regius professor of civil engineering in the University of Glasgow; Dr. D. Martin, senior lecturer in mathematics, University of Glasgow; Dr. W. G. Siller, principal scientific officer, Agricultural Research Council, Poultry Research Centre, Edinburgh; Mr. D. G. Sopwith, director of the National Engineering Laboratory (Department of Scientific and Industrial Research), East Kilbride; Mr. T. A. Stuart, principal scientific officer, Department of Agriculture and Fisheries for Scotland, Freshwater Fisheries Laboratory, Faskally, Pitlochry; Dr. R. L. M. Synge, biochemist, Rowett Research Institute, Bucksburn, Aberdeen; Dr. C. J. Taylor, acting head of the Forestry Department, University of Edinburgh; Dr. J. Tinsley, reader in soil science and head of department, University of Aberdeen; Dr. H. W. Wilson, director of the Scottish Reactor Centre.

The 1961 Corday Morgan Medal and Prize: Prof. F. Sondheimer

PROF. FRANZ SONDHEIMER, professor and head of the Organic Chemistry Department at the Weizmann Institute of Science, Rehovoth, has been awarded the Chemical Society's 1961 Corday–Morgan Medal and Prize, in consideration of his contribution to the chemistry of natural products, including his notable synthesis of the steroidal sapogenins and his studies of the synthesis and properties of unsaturated macrocyclic compounds. This award, consisting of a silver medal and a monetary prize, is made annually to the chemist of either sex and of British nationality who, in the judgment of the Council of the Chemical Society, has published during the year in question, and in the immediately preceding five years, the most meritorious contribution to experimental chemistry, and who has not, at the date of publication, attained the age of thirty-six years.

The International Commission on Radiological Protection

THE following have been elected officers and members of the International Commission on Radiological Protection for the period 1962–65: *Chairman*, Dr. E. Eric Pochin (U.K.); *Vice-Chairman*, Prof. L. Bugnard (France); *Members*, Mr. W. Binks (U.K.), Prof. Otto Hug (Germany), Dr. H. Jammet (France), Dr. Bo Lindell (Sweden), Dr. John F. Loutit (U.K.), Dr. K. Z. Morgan (United States), Dr. H. J. Muller (United States), Prof. Rolf M. Sievert (Sweden), Dr. C. Gordon Stewart (Canada), Prof. R. S. Stone (United States), Dr. Lauriston S. Taylor (United States); *Scientific Secretary*, F. D. Sowby. The Commission's secretariat has recently been transferred from Stockholm to Clifton Avenue, Sutton, Surrey, England.

The Water Resources Bill

TOWARDS the end of the report stage of the Water Resources Bill in the House of Lords, the claims of amenity were strongly pressed in discussion of an amendment moved by Lord Henley in favour of a Lakeland River Authority. The Bishop of Carlisle, Lord Chorley, Lord Conesford and Lord Hurcomb all referred to widespread concern that the amenity interests of the Lake District would not be sufficiently respected by Lancashire and Cumberland River Boards on which the dominant interest represented was that of interest as consumers. Earl Jellicoe, while unable to accept the amendment, was at pains on behalf of the Government to reassure the House that the Government was really determined that the amenity interest should be adequately protected and that this was better served by treating areas concerned as a single unit as proposed in the Bill. He further pointed out that since Clause 13 provided for the appointment of an amenity member to the Water Resources Board, it was almost certain that the Board would be alerted of all important schemes and that the amenity member of the Board would watch such schemes in the interest of amenity. Special references to natural beauty were to be found in Clause 19 dealing with minimum acceptable flaws, and there was a new sub-section in Clause 52 dealing with the transmission of applications for licences to the National Park Planning Authorities. Besides the amenity clause itself (93), there was the saving for the town and country planning legislation in Clause 63 (3) and there was a new clause recognizing the special responsibility in this field of the Nature Conservancy. Earl Jellicoe said that he himself had proposed an amendment making the Water Resources Board, in addition to the river authorities, responsible for securing economy, and he thought that all these enactments would ensure that amenity was always in mind at all stages of the river authorities' work and in the counsels of the Water Resources Board. They would ensure that the views of the local National Park Planning Authority were made known to the river authority and taken into consideration by that authority. They secured that decisions on planning permission for the construction of works were not taken by the river authorities but either by the planning board or the Minister himself, and on a controversial application the final decision would rest with the Minister. He claimed that it was impossible for any river authority to ride roughshod over local opinion in this question of natural beauty and amenity.

Working Party on Materials Science and Technology

A WORKING Party on Materials Science and Technology has been formed under the auspices of the Institution of Chemical Engineers and the inaugural meeting has been held. The interests represented included paper, concrete, rubber and plastics, in addition to metals, ceramics and glass. It was unanimously decided that every attempt should be made to co-operate with other groups concerned with materials. It is hoped that, at a later stage, conferences will be held, in conjunction with other learned and professional societies, on a series of themes, each of which involves consideration of a wide variety of materials, to stimulate the exchange of ideas and techniques between what are at present considered different disciplines. The Working Party is constituted as follows: *Chairman*, Mr. L. Holliday (Shell Chemical Co., Ltd.); *Honorary Secretary*, Dr. P. E. Evans (Manchester College of Science and Technology); *Members*, Dr. N. F. Astbury (British Ceramic Research Association), Prof. J. G. Ball (Imperial College of Science and Technology), Dr. T. H. Blakeley (The Morgan Crucible Co., Ltd.), Prof. R. W. Cahn (University College, Bangor), Dr. A. R. Collins (Cement and Concrete Research Association), Prof. A. H. Cottrell and Mr. J. A. Charles (University of Cambridge), Dr. J. I. Cox (A. Boake, Roberts and Co., Ltd.), Prof. R. W. Douglas (University of Sheffield), Dr. E. Eastwood (English Electric Co., Ltd.), Dr. G. A. R. Hartley (Courtaulds, Ltd.), Dr. J. M. Hutcheon (U.K. Atomic Energy Authority), Dr. N. P. Inglis (Imperial Metal Industries (Kynoch), Ltd.), Prof. R. Edgeworth Johnstone (University of Nottingham), Mr. A. Kennaway (B.T.R. Industries, Ltd.), Prof. A. J. Kennedy (College of Aeronautics, Cranfield), Mr. J. Luckins (British Paper and Board Industry Research Association), Mr. D. S. Mahon (Plastics Institute), Dr. J. W. Martin (University of Oxford), Prof. E. W. J. Mitchell (University of Reading), Mr. N. C. Moore (Plessey, Ltd.), Dr. P. Murray (U.K. Atomic Energy Research Establishment), Dr. J. F. Nye (University of Bristol), Mr. C. E. Phillips (National Engineering Laboratory), Dr. L. H. A. Pilkington (Pilkington Brothers, Ltd.), Dr. J. A. Pople (National Physical Laboratory), Mr. R. Llewellyn Rees (Central Electricity Generating Board), Prof. E. Rhoderick (Manchester College of Science and Technology), Mr. F. Roberts (U.K. Atomic Energy Research Establishment), Prof. T. K. Ross (Manchester College of Science and Technology), Dr. G. C. Shipp (Brunel College of Technology), Dr. E. G. Stanford (Aluminium Laboratories, Ltd.), Dr. W. F. Watson (Rubber and Plastics Research Association), and Dr. J. G. Wistreich (British Iron and Steel Research Association).

Economic Planning in France

French Economic Planning describes briefly and clearly the origin and development of economic planning in France from the First (Monnet) Plan for modernization and equipment, 1946–53, to the final approval of the Fourth Plan (Pp. 12. London: Ambassade de France, Service de Presse et d'Information, 1963). It covers economic and social development 1962–65, visualizing a 24 per cent growth in gross internal production, an increased export drive, appreciable increase in collective equipment for schools, hospitals, scientific research, town planning and country equipment and a policy of regional development. The Second Plan, 1954–57, set production and investment targets for most sectors of the national economy, particularly the processing industries, agriculture and housing. The Third Plan, 1958–61, set out to restore the balance of the economy, which had been upset by over-rapid progress under the Second Plan. The pamphlet also describes briefly the bodies responsible for planning, including the Commissariat Général du Plan and the Modernization Commissions, the procedure adopted in drawing up the Plans and the psychological and other factors which contribute to the effectiveness of the Plans.

U.S. National Institute of General Medical Sciences

The National Institute of General Medical Sciences, with Dr. Clinton C. Powell as its director, has been founded. This brings the total of the National Institutes of Health, U.S. Public Health Service, Bethesda, to nine. The new Institute was formerly the Division of General Medical Sciences of the National Institutes of Health. The Division was established in 1958 to help meet the increasing requirements of the Institutes' programmes of grants to non-federal medical schools, universities, and other medical institutions. The new Institute will be responsible for administering, fostering and co-ordinating research in the sciences basic to medicine and biology, to public health, and to certain clinical sciences and biomedical studies not within the responsibility of the other institutes.

National Science Foundation Support for Research on Information Retrieval

According to *Scientific Information Notes*, December 1962–January 1963 (No. 6, Vol. 4), an experimental study supported by the National Science Foundation showed that it is both practicable and desirable to convert the terminology used in some information systems to that being used by another and that the methodology developed can be applied to the preparation of a practical tool for the necessary conversion. Under a Foundation contract, the Datatrol Corporation, Maryland, is now developing a structured composite listing of the vocabularies used by the Atomic Energy Commission, the Armed Services Technical Information Agency and National Aeronautics and Space Administration with the view of compiling a dictionary of equivalents. Under another Foundation contract the character and degree of use of the *Chemical Engineering Thesaurus* and the index data provided for articles in *Chemical Engineering Progress*—both published by the American Institute of Chemical Engineering—are also being studied by Harner and Co., Washington, D.C., partly with the view of providing insight into the construction of thesauri and their efficiency as retrieval tools. The American Anthropological Association is conducting a rapid but thorough investigation of its publishing situation: (1) to determine the extent and nature of existing stockpiles of data and manuscripts in anthropology and the reasons why they have not been published; (2) to explore means for distributing such unpublished material; and (3) to suggest ways of integrating and organizing the flow of anthropological materials, whether published or not.

The British Library of Political and Economic Science

The annual report, 1961–62, of the British Library of Political and Economic Science records progress in the transfer of books to the Library Depository established at Egham by the University, but staffing difficulties badly handicapped the work of the cataloguing department at senior and junior levels (Pp. 15. London: British Library of Political and Economic Science, 1962). Acquisitions during the year totalled 7,353 treatises, 1,450 pamphlets, 3,551 non-serial Government publications (excluding British Parliamentary Papers and United States Public Documents) and 8,711 current serials. Bound volumes acquired totalled 11,405, 241 volumes of pamphlets bound bringing the total to 11,646, from which 252 were withdrawn or transferred to the Lending Library. Some 5,000 volumes of current acquisition were bound and 5,594 were bound, re-bound or repaired. The total of bound volumes in all libraries at July 31, 1962, was 432,208 of which 11,348 are in the Lending Library, 9,253 in study rooms, and 5,019 in the Shaw Library. Expenditure on treatises amounted to £8,135 with £1,157 on binding, on pamphlets £148, on non-serial Government publications £512, on periodicals and other serials £8,357 (including £3,498 on binding), while £5,507 was spent on current binding, and binding of arrears, repairs and rebinding. The Lending Library issued 39,314 treatises, 1,371 works were lent to other libraries, and, of 862 readers' permits (262 for overseas), 327 were in force on July 31, 1962.

Volatile Fruit Flavours

THE report of a symposium held in Berne during 1962, one of a series organized by the Scientific and Technical Commission of the International Federation of Fruit Juice Producers, summarizes the great advances made in the chemistry and technology of fruit aromas since the advent of gas–liquid chromatography (*Volatile Fruit Flavours*. Pp. 449. Zurich: Juris-Verlag, 1962. Obtainable from International Fruit Juice Union, Eschenz TG, Switzerland. 40 Sw. Fr.). The papers presented, reviews or original papers, are in English, French or German with tri-lingual summaries. Of the 38 articles, 28 deal with the chemistry of aroma components or with their commercial recovery from fruits and juices. The developments so far have already led to significant improvements in the quality of juice products; the more detailed examination of aroma components is now beginning to make possible a more quantitative assessment of quality, though sensory tests still remain the final criteria.

Investigations of Infra-red Spectra

DR. R. N. JONES, president of the Coblentz Society, has written to the Editor saying that, with the permission of the Carnegie Institution of Washington, the Coblentz Society has arranged for the re-publication of the Carnegie Institution Monograph No. 35, *Investigations of Infrared Spectra*. In this is published the original research work of Dr. W. W. Coblentz, who first established the potentialities of infra-red spectroscopy as a tool in organic chemical research, and who died in Washington last September at the age of eighty-eight. The Monograph, which was originally published in 1905, has long been out of print; it is believed that it will be of interest to many molecular spectroscopists outside the immediate circle of the Society members. A limited number of copies are still available at a price of 3.5 dollars, and can be obtained from Dr. H. B. Kessler, secretary of the Coblentz Society, the Perkin-Elmer Corporation, Norwalk, Connecticut.

The Coblentz Society was formed in 1954 with the view of bringing together physicists and chemists concerned with the development and application of infra-red spectroscopy and has its headquarters in the United States.

The Sun during the International Geophysical Year

DR. M. A. ELLISON, senior professor in the School of Cosmic Physics at the Dublin Institute for Advanced Studies and editor of Volumes 21 and 22 of the *Annals of the International Geophysical Year* (*I.G.Y. Solar Activity Maps, DI and DII*), which were reviewed on p. 1237 of the September 29, 1962, issue of *Nature*, has written to the Editor of *Nature* as follows: "In the review . . . there was no mention of the greatly reduced price available to individuals who certify that the *Maps* are for their own personal use (£18 as against £54 to Institutions). . . . Such orders must be addressed to IGY Solar Maps, Pergamon Press, Headington Hill Hall, Oxford, England".

Course in Nuclear Magnetic Resonance Techniques

A SPECIAL advanced course on "Nuclear Magnetic Resonance in Molecules of Moderate and High Molecular Weight" will be held during April 25–26. The speakers include Prof. A. R. Katritzky, and Drs. R. Freeman, D. W. Jones, J. A. S. Smith and I. M. Ward. Applications in inorganic, organic and polymer chemistry will be considered, and there will be a short session on commercial equipment. The fee for the course is 30*s*. Further details and registration forms can be obtained from the Registrar, Institute of Technology, Bradford 7.

The Night Sky in April

FULL moon occurs on April 9d. 00h. 57m. U.T. and new moon on April 23d. 20h. 29m. The following conjunctions with the Moon take place: April 3d. 05h., Mars 2° N.; April 18d. 23h., Saturn 1° N.; April 21d. 09h., Venus 3° N. In addition to these conjunctions with the Moon, Venus is in conjunction with Jupiter on April 28d. 17h., Venus being 0·6° S. Mercury is an evening star, and is conveniently placed for observation during the last week of the month, when it sets about two hours after the Sun. Venus is a morning star, rising about an hour before the Sun. Mars sets at 4h. 10m., 3h. 20m. and 2h. 30m. on April 1, 15 and 30, respectively. It is at a distance of 101 million miles on April 15, when its stellar magnitude is +0·5 and it is in Cancer. Jupiter and Saturn are too close to the Sun for easy observation. There are no occultations of stars brighter than magnitude 6 visible at Greenwich. The Lyrid meteors are active during April 19–22, the radiant being at R.A. 18h. 04m., Dec. +33°; conditions for observation are favourable.

Announcements

PROF. BERND T. MATTHIAS, professor of physics at the University of California, San Diego, has been awarded the twenty-seventh Research Corporation Award for his outstanding contributions in the fields of superconductivity and ferroelectricity. The Award includes an honorarium of 10,000 dollars.

AN international starch conference will be held in Detmold during April 24–26. Further information can be obtained from Wolfgang Kempf, Arbeitsgemeinschaft Getreideforschung E.V., Detmold, Am Schützenberg 9.

THE 1963 Central African Scientific and Medical Congress will be held at the College of Further Education, Church Road, Lusaka, during August 26–30. Further information can be obtained from the Honorary Secretary, P.O. Box 844, Lusaka, Northern Rhodesia.

THE third European Mycological Congress will be held in Glasgow during August 31–September 7. The programme will include a symposium on "Gasteromycetes". Further information can be obtained from the Local Secretary, Third European Mycological Congress, Botany Department, the University, Glasgow, Scotland.

THE British Institution of Radio Engineers and the Institution of Electrical Engineers are organizing a joint symposium on "Automatic Control", which will be held at the University of Birmingham on March 28. Further information can be obtained from Mr. G. K. Steel, Department of Electrical Engineering, College of Advanced Technology, Gosta Green, Birmingham 4.

THE Third International Meeting in Forensic Immunology, Medicine, Pathology and Toxicology will be held in London during April 16–24. Among the subjects to be discussed will be the problems in relation to: aviation; odontology; horse doping; stains by human tissues; drug addiction; psychiatry; industrial toxicology; clinical toxicology; plant and animal poisons; poisoning by therapeutic substances; questioned documents. Further information can be obtained from the Secretariat, Third International Meeting in Forensic Immunology, Medicine, Pathology and Toxicology, 28 Portland Place, London, W.1.

A SYMPOSIUM on "Aspects of Chemical Change during the Processing and Storage of Foods", arranged by the Nutrition Society (Scottish Group), will be held in the Royal College of Science and Technology, Glasgow, on April 20. The programme will include: foodstuffs as unstable chemical systems; catalytic destruction of vitamin A and carotene; chemical change in fish muscle during storage; flavour changes in potatoes; the environment for chemical change in dried and frozen foods. Further information can be obtained from Dr. D. G. Armstrong, Department of Agricultural Biochemistry, King's College, Newcastle upon Tyne 1.

THE INTERNATIONAL COMMITTEE ON WEIGHTS AND MEASURES

At the October 1962 meetings in Paris of the International Committee on Weights and Measures (Bureau International des Poids et Mesures, Pavillon de Breteuil, Sèvres, France), and its specialist sub-committees, proposals were made which, when formally adopted, will result in improved or extended bases for the measurement of length and temperature. Included were 12 new secondary wave-length standards of length, and 6 proposals to modify the International Practical Temperature Scale.

It was recognized nearly a century ago, in light of increasing industrialization and the expansion of foreign trade, that some sort of international agreement was necessary in the area of physical measurements. After considerable preliminary work, both scientific and diplomatic, the Treaty of the Metre[1] was signed in 1875 by representatives of 17 nations (there are now 38 member nations). This treaty provided international agreement on the bases for the metric system, and established the International Bureau of Weights and Measures on the outskirts of Paris, France. The International Bureau, funded by assessments of the member nations, conducts research in many areas of measurement, maintains physical prototype standards, and co-operates with the national standards laboratories in promoting measurement accuracy and agreement.

Representatives of the nations adhering to the Treaty of the Metre normally meet in Paris every 6 years at what is called a General Conference on Weights and Measures. Official actions, such as the adoption of new or improved standards, are voted on by the General Conference. Details of administration, and responsibility for recommending proposed actions to the General Conference, fall in the province of the executive body or International Committee, composed of 18 individuals, each from a different nation. The International Committee, which has advisory committees in 6 areas of measurement, meets annually. The actions of the advisory committees on length and temperature at the recent meeting are outlined here.

Secondary Wave-length Standard of Length

The metre was officially defined by the 1960 General Conference[2] as equal to 1650763·73 wave-lengths in vacuum of the orange-red wave-length of krypton-86, making the wave-length of that line about 6057·8021 ... × 10^{-10} m. This action abrogated the platinum–iridium metre bar as the standard of length, and resulted in a more accurate standard of widespread availability. At the October 1962 meeting the Consultative Committee for the Definition of the Metre recommended to the International Committee 12 secondary wave-length standards of length. These are:

A	Wave-lengths in vacuum of krypton-86
	6458·0720 × 10^{-10} m
	6422·8006 ,,
	5651·1286 ,,
	4503·6162 ,,
B	Wave-lengths in vacuum of mercury-198
	5792·2683 × 10^{-10} m
	5771·1983 ,,
	5462·2705 ,,
	4359·5624 ,,
C	Wave-lengths in vacuum of cadmium-114
	6440·2480 × 10^{-10} m
	5087·2379 ,,
	4801·2521 ,,
	4679·4581 ,,

The values for krypton are within 2 × 10^{-8}, those for mercury 5 × 10^{-8}, and those for cadmium 7 × 10^{-8} of the true values, respectively. These figures represent a consensus of view of all the national laboratories. It should be noted that these values have not as yet been accepted as international secondary standards of length, but that such action is expected probably late in 1963.

The Consultative Committee, recognizing that further work remains to be accomplished in the measurement of length, is encouraging the development of secondary standards in the ultra-violet and infra-red regions, and examination of the use of masers, Zeeman filters, atomic beams and interference filters in the measurement of length.

Proposed Changes in the International Practical Temperature Scale

The International Practical Temperature Scale[3], established in 1927, is defined in terms of a series of fixed points and of interpolation formulæ for the instruments used to realize the scale. Advances in the science of temperature measurement have made it possible to consider changes to make the International Practical Temperature Scale agree more nearly with the thermodynamic temperature scale, and to cover a more extended range of temperatures.

The Advisory Committee on Thermometry of the International Committee has made 6 tentative proposals for presentation at the 1966 General Conference of Weights and Measures. These tentative proposals, which would both extend the scale and improve its accuracy, are:

(1) Incorporate the T_{58} (^{4}He) and T_{62} (^{3}He) scales into the International Practical Temperature Scale. At present, the International Practical Temperature Scale is undefined below the oxygen point (90·18° K), and the inclusion of these two scales will provide a basis on the International Practical Temperature Scale for measurements in the range 0·25°–5° K. The T_{58} (^{4}He) scale has been recognized by the International Committee on Weights and Measures since 1958, but it has not been incorporated in the International Practical Temperature Scale. The ^{3}He vapour pressure scale, developed by the Los Alamos Scientific Laboratory, was this year recommended by the International Committee of Weights and Measures for interim use with the designation T_{62} (^{3}He).

(2) Define for the practical scale the equilibrium boiling point of hydrogen to be about 20·267° K and the boiling point of oxygen to be about 90·17 °K. The current value for the boiling point of oxygen is 90·18° K. No value for the boiling point of hydrogen is given on the International Practical Temperature Scale at present. The term 'about' is included in the wording of these proposals to indicate that new results or re-evaluation of existing data may change these values between now and 1966.

(3) Incorporate a platinum resistance thermometer scale in the region between the hydrogen and oxygen points. This step would extend the scale from its present limit of the oxygen point. Platinum resistance thermometers have been used for some time in this region, and there appears to be sufficient data on which to base this extension. However, work on the proper interpolation method, including the choice of the resistance-temperature relation, is needed in order to make this extension practical.

(4) Eliminate the sulphur (444·6° C) and replace it with the zinc point (at present 419·505° C, but see proposal (5)). This action is recommended because the zinc point is more reproducible than the sulphur point.

(5) Change the values of the zinc (419·505° C), silver (960·8° C), and the gold (1063° C) points on the Inter-

national Practical Temperature Scale by about +0·07, +1·1 and +1·5 degrees, respectively.

(6) Replace the standard thermocouple on the scale with the platinum resistance thermometer. The scale is at present defined in terms of the thermocouple from the gold point down to 630·5° C, and the platinum resistance thermometer from the oxygen point to 630·5° C. As the platinum resistance thermometer is more precise than the thermocouple, this action will yield more accurate determinations of temperature, and will result (along with proposal 3) in the definition of the scale from the hydrogen point to the gold point with platinum resistance thermometers.

The U.S. National Bureau of Standards has contributed strongly in the past to the foundations of the International Practical Temperature Scale, and is now working on two major projects which may affect these tentative proposals before submission in 1966. One concerns the gap that would exist in the scale between about 5° K and the hydrogen point even if provisions (1) and (3) are adopted. The Bureau is developing the ultrasonic thermometer as an absolute device to provide a scale in this region. Preliminary results with this thermometer, which is based on the determination of the speed of sound in helium gas, indicate a precision of ±0·007 deg. at 20° K and 0·002 at 2° K (ref. 4). Also, a major programme under way in gas thermometry may result in more accurate values for certain defining points on the scale before the 1966 meeting.

New Prefixes

The International Committee also adopted two new prefixes for denoting sub-multiples of units. They are: femto, 10^{-15}, symbol 'f', and atto, 10^{-18}, symbol 'a'. The Bureau will follow this action of the Committee, which brings the list of numerical prefixes to a total of 14. The full list is given in Table 1.

Administrative

The International Committee on Weights and Measures met this year for the first time with the new director of the International Bureau of Weights and Measures, Dr. Jean Terrien. Dr. Terrien is a distinguished French metrologist who had been at the International Bureau for several years. The Committee reluctantly accepted the resignation of its secretary, Prof. G. Cassinis, rector of the Polytechnical School of Milan, who had recently become the Mayor of Milan and therefore felt compelled to relinquish international committee responsibilities. Prof. J. de Boer, director of the Theoretical Institute of the University of Amsterdam, was elected the new secretary. Other officers, elected in 1960, are chairman, Prof. Richard Vieweg, recently retired as president of the Physikalisch-Technische Bundesanstalt, Germany, and vice-chairman, Dr. L. E. Howlett, director of the Applied Physics Division of the National Research Council, Canada.

Table 1

Multiples and Sub-multiples	Prefixes	Symbols	Pronunciations
10^{12}	tera	T	tĕr′ ȧ
10^{9}	giga	G	jĭ′ gȧ*
10^{6}	mega	M	mĕg′ ȧ
10^{3}	kilo	k	kĭl′ ō
10^{2}	hecto	h	hĕk′ tō
10	deka†	da	dĕk′ ȧ
10^{-1}	deci	d	dĕs′ ĭ
10^{-2}	centi	c	sĕn′ tĭ
10^{-3}	milli	m	mĭl′ ĭ
10^{-6}	micro	μ	mī′ krō
10^{-9}	nano	n	năn′ ō*
10^{-12}	pico	p	pē′ cō*
10^{-15}	femto	f	fĕm′ tō
10^{-18}	atto	a	ăt′ tō

* These pronunciations differ from those previously given, and are the result of international discussions to promote uniformity of pronunciation in various languages.

† The official French spelling for the prefix representing the multiple ten is deca. This prefix has long been spelled deka in the United States, Great Britain, Germany, and a few other countries. The continued use of this spelling is consistent with the American use of gram for the French gramme and meter for metre. The symbol, however, should be universal and even though dk has long been used in the United States for the symbol for deka, the National Bureau of Standards will from now on adhere to the official international symbol da for the prefix representing the multiple ten and recommends that this practice be followed throughout the United States.

One of the most important actions of the 1962 meeting was the completion of negotiations with the French Government for land to house a new laboratory for the recently activated programme on standards for measuring ionizing radiations. Plans for the Laboratory were reviewed and approved and construction is expected to begin early in 1963. The new laboratory will be on land until recently part of the Parc de St. Cloud, immediately adjacent to the present building of the International Bureau of Weights and Measures.

THE NATIONAL RESEARCH DEVELOPMENT CORPORATION

The *Bulletin of the National Research Development Corporation* is issued twice-yearly and the twenty-first issue (October 1962) appears with a new cover and in a revised modern format. The main articles are devoted to descriptions of the "Perbury Gear" and "The Piezo-magnetic Analogue Multiplier", both of which are the subject of patents, and the development of which is being supported by the Corporation. An improved unit utilizing the Perbury gear has been designed for the transmission of an input torque of 100 ft. lb. over a ratio range of 4·7 : 1 and six of these units have been built for trials on two re-circulating power test rigs at Plint and Partners, Ltd., of Wargrave. The results so far attained indicate that the possible industrial uses of the Perbury gear cover a wide range, from machine tools to test-house equipment and vehicle transmissions. The particular advantages are simplicity, compactness, high efficiency, and the ability to work at high rotational speeds. It is known from nearly 25,000 miles running experience with the *Hillman Minx* motor-car that the transmission is quiet at all speeds and, under normal motoring conditions, gives a lower fuel consumption than a car fitted with a standard gear-box.

The piezo-magnetic analogue multiplier utilizes the expression $XY = \frac{1}{4}[(X + Y)^2 - (X - Y)^2]$ and makes use of the fact that the force in a magnetic circuit is proportional to the square of the magnetic flux. A bender type piezo-electric crystal carries two soft iron armatures at one end, one on each side of the crystal. Opposite each of the armatures, and separated from it by an air gap, is a laminated silicon iron C-core. The two C-cores carry four identical coils, one on each limb. The input quantities to be multiplied are represented by currents X and Y. On one C-core the coils are connected in the same sense and the magnetic force exerted on the armature is thus proportional to $(X + Y)^2$. On the other C-core the coils oppose and the magnetic force exerted is proportional to $(X - Y)^2$. The two forces act in opposite directions so that the voltage output from the piezo-electric crystal is therefore proportional to XY. Small multipliers measuring 1 in. diameter by $1\frac{1}{4}$ in. long have been made and with improved materials multipliers of even smaller size with greater temperature stability, sensitivity and resonant frequency can be made. The applications of multipliers up to the present time have been limited, but the trend in electronics is towards extremely complex pattern recognition systems which utilize auto-correlation and cross-correlation of wave shapes, operations which require the use of an analogue multiplier. The computational power of a multiplier compares well with that of a fast digital computer, for with a bandwidth of 5 kc/s and an accuracy of $\frac{1}{2}$ per cent it can effectively multiply two 7-bit numbers 10,000 times per sec and a network containing 100 multipliers could easily do more arithmetic per sec than the fastest digital computer yet built.

THE IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY

THE fifty-fifth annual report of the Governing Body of the Imperial College of Science and Technology* covers the year ended July 31, 1962, in which the number of full-time students increased by 53 to 2,735, with a decrease of 4 in postgraduate students, and the academic staff increased by 25 to 444 full-time members. The report refers to the difficulty in recruiting and retaining staff of the right calibre, mainly because of the disparity between academic salaries and the inducements offered by industry. This may seriously affect the implementation of the integrated academic plan; but great concern is also expressed as to the effect of the restricted grants to be made available in the next quinquennium, as announced in June 1962. From October 1963 the undergraduate tuition fee has been increased to £85, inclusive of College and University examination and registration fees, the postgraduate fee remaining at £75 exclusive of those charges. Discussions are proceeding with the Architectural Association on the possible incorporation of the Architectural Association School within the College. The Governing Body considers that a close connexion between leading schools of engineering, particularly civil and structural engineering, and of architecture could be of great value. The £17·5 million 'ceiling' imposed on the overall cost of the Jubilee Expansion Scheme has necessitated postponing the start of two of the major buildings, with adverse effects on the Departments of Mathematics, Meteorology and Chemistry concerned.

The Rector's report notes that, during the year, students obtained 200 higher and 498 first degrees, science degrees accounting for 46 per cent of the total, and the 400 students awarded the D.I.C. included 296 technologists. Of the 653 overseas students, 406 were from the Commonwealth and four-fifths were postgraduates. Of the United Kingdom students, 27 per cent came from within 30 miles of the College. The academic staff now includes 50 professors and 73 readers, and developments in fields lying on the borderline between important disciplines include the introduction of a course on the application of engineering to medicine and biology and the institution of a chair in the history of science and technology. Library facilities were greatly improved during the year and, referring to research, Sir Patrick Linstead notes that of 37 research projects at present listed by the National Research Development Corporation, 6 originated at the College. Grants for research and income from research contracts totalled £523,000, the Department of Scientific and Industrial Research supporting 77 projects with an annual value of £235,000. Some notes on recent research are included in the Rector's report, and a list of publications during the year, arranged by departments, is appended, together with a list of special lectures.

---

ENVIRONMENTAL PHYSIOLOGY AND PSYCHOLOGY IN ARID CONDITIONS

A SYMPOSIUM on "Environmental Physiology and Psychology in Arid Conditions" was held recently at the Central Drug Research Institute in Lucknow, under the auspices of Unesco and the Government of India. The arrangements were made by Dr. M. Batisse of the Department of Natural Sciences of Unesco, and locally by Dr. B. Mukerji, director of the Institute and chairman of the symposium, with Dr. J. Swarbrick of the Unesco South Asia Science Co-operation Office at Delhi. Thirteen countries were represented by approximately fifty delegates.

The scientific papers and discussion were divided into nine sections, as follows: the neurophysiology of heat exposure, psychological aspects, human performance and comfort standards, comparative heat physiology, the significance of solar radiation in heat balance, water and electrolyte problems, nutrition and heat, medical climatology, and physiological anthropology. The proceedings, which will be published by Unesco, drew strength principally from two sources: first, from a number of pre-circulated reviews of the topics chosen for discussion, and secondly, from recent fundamental and field research, particularly in Israel and the French Sahara.

Unesco will publish these reviews separately and within the next few months. They range in subject-matter from physiological adjustments to heat, to the somewhat vexed definition of tropical neurasthenia. The authors include F. A. Fuhrman (United States, effects of heat on the action of drugs), E. M. Glaser (Great Britain, circulatory adjustments to heat), A. Henschel (United States, field test methods), R. A. Kenney (Great Britain, renal adjustments), G. E. Lambert (France, thermal comfort), D. H. K. Lee (United States, arid zone physiology), W. V. Macfarlane (Australia, endocrine adjustments), J. Mayer (United States, arid zone nutrition), E. Schreider (France, physiological anthropology), and F. Sargent (United States, tropical neurasthenia). Available also to the symposium participants was a review of the works of Soviet scientists on arid zone problems (prepared by the U.S.S.R. Academy of Medical Sciences and translated from the Russian). These documents are listed here because they were the background to many of the short papers read at the symposium, but there were also unrelated communications of value, notably by O. von Euler (Sweden) on the body thermostat and its setting, and by K. Schmidt-Nielsen (United States) on comparative physiology in arid climates.

The papers relating to recent studies in Israel and the French Sahara, along with similar contributions from Indian and Australian scientists, provided most of the participants with fresh and stimulating information. The Institute of Technology at Haifa, the Negev Institute in Beersheba, the climatic unit at the Tel Hashomer hospital in Tel Aviv, and the French centre for study and information on human problems in arid zones (PROHUZA), have all contributed significantly to our knowledge of heat physiology; and Unesco has done well to foster, throughout its major project on scientific research on arid lands, studies which are carried out in the field rather than in climatic chambers in temperate countries. Developing communities in arid regions, given a new way of life and new standards of hygiene, must sooner or later face the issues of how the local climate affects health and industrial programmes; and the studies which have been made so far, principally on expatriate European and American communities, are not altogether relevant. In this respect the work of W. V. Macfarlane (Australia) on long-term heat adaptations in domestic stock animals is particularly valuable, and it is encouraging to learn that similar comparative research is carried out in Egypt and at the Central Indian Arid Zone Research Institute in Jodhpur, and that the PROHUZA team has examined the industrial-employment aptitude and long-term adaptations of nomadic tribes in the Sahara.

The visiting participants at the Lucknow symposium are indebted to Unesco and the Government of India, and to Dr. B. Mukerji for his hospitality at the Central Drug Research Institute. The published Proceedings will contain much valuable information and should stimulate continued interest in the subject in the Middle East and in South-East Asia.

C. S. LEITHEAD

CARDIOVASCULAR ANATOMY AND PATHOLOGY

A SYMPOSIUM on 'Cardiovascular Anatomy and Pathology', organized by Prof. R. G. Harrison and Prof. K. R. Hill, was held in the meeting room of the Zoological Society of London during November 28–29, 1962. This symposium, which was attended by more than 100 research workers from a wide variety of medical and veterinary departments, reflected the growing interest in the functional anatomy and pathology of the cardiovascular system.

During the first morning session, under the chairmanship of Prof. E. W. Walls, Prof. F. Navarrina Gamez (Santiago de Compostela, Spain) described researches conducted in collaboration with Prof. R. G. Harrison on the effect of cortisone on the vascularization of bone in normal and ovariectomized female rats. These researches, like others during the symposium, demonstrated the need for a detailed analysis of the functional anatomy of organs and tissues when investigating their vascularization. During the first four weeks after ovariectomy there is a reduction in the extent of vascularization of the metaphyses and vertebral bodies. This is not as extensive as in cortisone-treated rats, however, and is followed, within ten weeks, by an increased vascularization. The primary metaphyseal ischæmia can be correlated with a disorganization of cell columns in the epiphyseal cartilages of long bones, which persisted in cortisone-treated rats. These alterations in vascular pattern are accompanied by changes in the pattern and density of trabeculæ in metaphyses and vertebræ; in some animals there is an obvious fragmentation of trabeculæ in vertebral spines.

Dr. Helen N. Duke (London) summarized her investigations on the hæmodynamics of the pulmonary circulation. Factors concerned with the pressure and flow and change of blood volume in the circulation were discussed. The pressure flow is concave to the flow axis. The curve is affected by changes of left atrial pressure and by vasomotor reactions of the pulmonary blood vessels. Increase of pulmonary arterial inflow rate or left atrial pressure increases the volume of blood in the pulmonary blood vessels; some of the increased blood volume is the result of capillary dilatation. It is probable that those vessels responsible for pulmonary vascular resistance are not those responsible for changes in lung blood volume.

The functional anatomy of the vertebral venous system was described by Dr. J. D. W. Tomlinson (London). The variability of the posterior vena cava, particularly among aquatic mammals, was clearly and beautifully demonstrated. The value of the azygos venous system as a collateral circulation for drainage of structures below the level of the diaphragm was also discussed.

Dr. R. L. Holmes (Birmingham) reviewed present-day knowledge on the anatomy of the hypothalamo-hypophyseal vascular system, with particular relation to the hedgehog and ferret, and showed that there is no isolation of the vascular supply of one part of the gland from that of another or from the hypothalamus. The portal vessels are responsible for carrying the greater part of the normal blood supply to the pars distalis, and play a major part in the mediation of hypothalamic control over the pituitary.

In the afternoon session on November 28, under the chairmanship of Prof. Harrison, Mr. D. Sykes (Liverpool) reviewed some of his work on the blood supply of the human kidney. There is a segmental pattern of branching of the renal artery within the substance of the kidney which is, however, subject to some variation. A continuous arcuate artery does not exist. The venous pattern does not correspond with the arterial supply, and evidence was presented to suggest that blood vessels which penetrate the kidney capsule are carrying blood which is passing centripetally into the substance of the kidney. The longitudinal sulcus, when it exists, does not correspond with Brodel's line, which is neither linear nor avascular.

Mr. D. B. Moffat (Cardiff) summarized the research work which he had been conducting with Dr. Julia Fourman on the fine vascularization of the mammalian kidney; he demonstrated the difference to be found in various mammalian species, and clarified the nature of the vasa recta, which he found to be mostly composed of capillaries.

Prof. D. F. M. Bunce II (Des Moines, Iowa) read a paper on the architecture of the distended arterial wall, and stressed the differences in histological appearance of arteries in the collapsed and distended state, and between arteries from various sites in the body. In the teaching of students he had found the use of casts of the renal vascular tree of great value for their appreciation of the true nature of glomerular structure.

Dr. J. L. Braithwaite (Liverpool) described experiments he had been conducting with Dr. C. J. Fairhurst on collateral venous drainage of the spleen. Pursuing his original investigations on the regional distribution of the splenic vessels and their branches to the rat spleen, he had shown that the venous drainage of a region of the spleen the hilar vein of which had been occluded was effected through a plexus of newly formed veins encircling the site of ligature. Following interruption of the main splenic vein, collateral channels, consisting of preformed anastomoses (evident at 24 h) newly formed vessels (visible at 7 days) and portal-systemic anastomoses (which developed 3 weeks later), became established.

Dr. J. E. Wright (Liverpool) concluded the afternoon session by describing the effects of interruption of the vascular pedicles of the liver in the experimental animal, and compared the effects of ligation of the hepatic artery with those of interruption of the portal vein. Arterial ligation was not followed by either atrophy or necrosis, and was accompanied by the enlargement of œsophageal and omental anastomoses, and a peribiliary plexus of vessels coursing along the wall of the bile duct. Interruption of the portal vein was fatal within a few hours of operation in all cases in which the main trunk was ligated; ligation of the central lobar branch of the portal vein resulted in atrophy of the central lobe of the liver, and compensatory hypertrophy of the quadrate lobe.

During the morning session on November 29, under the chairmanship of Prof. W. I. Beveridge, Dr. R. Finlayson (London) gave a short account of the pathology and the incidence of arterial disease as it occurs in wild animals in captivity. Vascular lesions were described in fish, amphibia, reptiles, birds and mammals. Atherosclerosis is seen commonly only in some avian orders and occlusive atherothrombosis is extremely rare in animals. Age is the only factor shown to be fairly directly related to atherosclerosis, but the virtual absence of this condition in some comparatively old animals emphasizes that atheroma is not an inevitable accompaniment of senescence. The role of dietary and other factors which may play a part in the pathogenesis was discussed briefly.

Dr. B. McKinney, of Makerere College, Uganda, East Africa, gave an account of his investigations into arterial lesions discovered in free-living wild animals in East Africa. These were particularly prevalent among ruminants such as buffalo and antelopes, a surprising result in animals which fed only on herbage and the fat intake of which would be largely composed of unsaturated fatty acids. It had been suggested that ruminal digestion resulted in a high intake of acetic and butyric acids which might account for this, but the author discounted the suggestion that this factor could be of significance.

Dr. H. M. Pirie (Glasgow) gave an account of cardiovascular disease in domestic animals as seen in routine studies *post mortem*. He described a wide range of lesions from the aneurysms commonly found in horses associated with vascular invasion by nematode larvæ (*Strongylus vulgaris*) to atheroma of pigs and the atheroma-like lesions often seen in the coronary arteries of dogs.

On the experimental and physiological side, Dr. J. Poole (Oxford) described his work on experimental studies on growth of aortic tissue in baboons. He has used tissue-culture methods from which he believed that aortic endothelium was related to smooth muscle. Dr. A. F. Munro and Dr. R. S. F. Campbell (Glasgow) gave an account of their work on the respiratory metabolism of blood vessels from different species. The authors had evolved the technique of measurement of oxygen consumption by normal and diseased aortæ and had found significant impairment in the latter.

During the afternoon session, under the chairmanship of Prof. K. R. Hill, Dr. M. Crawford (London) described the epidemiology of coronary artery disease. Coronary artery disease cannot be regarded as a disease entity but is made up of two components; (1) mural atheroma; (2) occlusion of the lumen; which are obviously related, but are different from each other. Epidemiological evidence shows that occlusion of the lumen appears to be related, to physical activity and associated with certain diseases such as peptic ulcer, whereas mural atheroma appears to have no relation to these factors. In general, there appears to be an increase in prevalence of coronary occlusive disease among the populace, but not of mural atheroma.

Dr. Jack P. Strong (New Orleans) made some observations on the natural history and geographic pathology of human atherosclerosis. A geographical study of coronary artery disease has shown that white males are more severely involved than other sex or race groups. Aortic fatty streaks are practically universal after the first decade of life, but population differences in the formation of fibrous plaques seem to parallel suspected differences in the clinical manifestations of atherosclerotic heart disease.

Dr. M. I. Wright (London) discussed age changes in peripheral arteries of man. Peripheral arteries were examined from twelve sites at all ages. Two groups of change from the typical infant pattern were found: those which appeared to be associated with growth; namely, muscular elastic cushions, thickening intima, longitudinal elastin fibres, loss of continuity and swelling and beading of the internal elastic lamina, and a layer or layers somewhat resembling the internal elastica. The second group of changes includes small plaques of calcification of the internal elastica, and accumulation of excessive mucopolysaccharide in the media; these are seen best and earliest in the arteries of the leg in adult life.

Prof. S. Gero (Budapest) described his work in relation to mucopolysaccharides in the arterial wall and, in particular, the role of these compounds in the mechanism of lipid deposition. He had found that lipid could be adsorbed to mucopolysaccharide and could thereby be deposited in the arterial wall. He regarded this as one of the main mechanisms which led to the development of the atheromatous plaque.

Mr. W. J. S. Still (London) described electron microscopic studies in experimental atherosclerosis. Electron microscopic studies of dietary-induced aortic atherosclerosis in the rat and the rabbit show that lipid-bearing cells are capable of penetrating the intact endothelium. In contrast, when individual endothelial cells degenerate, lipid-bearing cells from the intima appear to extrude into the lumen. Ultra-microscopy also shows that two main cell types are present in all intimal lesions: first, foam cells, with complex lipid inclusions, and secondly, smaller cells with simple lipid inclusions. These cell types appear to be largely derived from the blood and aortic smooth muscle respectively.

R. N. Fiennes

THE EXPANDING EARTH?

By Prof. L. EGYED

Geophysical Institute, Eötvös University, Budapest

THE change of the Earth's dimensions is an old problem occurring mainly in connexion with mountain building and the moving or origin of continents. Generally, the first problem suggests contraction, while the second expansion of the Earth.

The comments made by J. G. Dennis[1] referring to a communication by C. H. Barnett[2] necessitate the summarizing of the idea of expansion. According to our knowledge Mantovani[3] was the first, at the end of the nineteenth century, to apply the idea of expansion to the explanation of the similarity of the Atlantic coast lines.

B. Lindemann[4] was the next who derived the expansion of the Earth from an excess of heat generated by radioactive elements existing in the Earth's interior. As it has been shown lately[5,6], heat is responsible for a very limited expansion only. The same idea was supported by Bogolepov[7], showing its probability on different geological features.

O. C. Hilgenberg[8] in 1933 was the first to construct a contiguous sialic surface on a sphere of a diameter about half of that of the present Earth and consisting of the present continents connected by shelves. But he had to cut and shift North America in his reconstruction considerably along a fault line. On the other hand, he suggested as the cause of expansion the physically untenable hypothesis according to which an æther-like material from space enters into the interior of the Earth, and hence, the increasing internal mass increases the Earth's volume also.

J. K. E. Halm[9] also suggested the expansion of the Earth to clear up the disruption of and drifting apart of continents. His explanation was based on astronomical considerations.

J. Keindl[10] published a hypothesis according to which the Earth possesses a central core of a very small size located in the centre of an iron core. This central core consists of a very dense material (density of some ten or hundred thousand g/cm³) similar to that of the white dwarfs (that is, corresponding to a Fermi-gas) and disintegrating in the course of time. He applied the expansion idea also to the explanation of 'continental drift'.

Pascual Jordan[11] refers to a private communication by Joel E. Fisher, in which the idea of expansion of the Earth is expressed with the aim of explaining the present distribution of continents and oceans. P. Jordan adopts this result in support of his projective theory of relativity.

The main idea of R. T. and W. J. Walker[12] essentially coincides with that of Keindl with the only difference that, instead of Fermi-gas some mysterious '*Q*-atoms' disintegrate with time and cause expansion. In the first place this idea strives to explain volcanism and mountain building.

It is curious that these authors as well as those mentioned later arrived at the idea of expansion independently, without knowledge of their predecessors. On the other hand, all these authors came upon the idea of expansion in an effort to explain the disruption and drifting apart of continents. At the same time they did not try to treat it in a quantitative way and often defied the laws of physics.

I have already pointed out how the idea of expansion is supported by analysing the interior of the Earth, contrary to the earlier authors, who derived the idea from the requirements of continental wandering. In the course of my investigations I developed a quantitative theory for the dynamism of the Earth, consistent with modern physical theories[13–19] and geological–geophysical observations. While expansion is only a special result of this theory, it also offers an explanation of the development of the Earth's surface[20], also its origin[21] and internal evolution[22]. Moreover, the amount of internal energy is estimated. In the course of my investigations it was shown in different ways and independent geological and geophysical observations that the most probable increase of the Earth's radius is 0·5–1·0 mm per annum.

As the next representative of the expansion theory W. Carey[23] may be considered. He arrived at the idea in connexion with his orocline concept. At first, his work was also influenced by the continental drift theory. The rate of expansion supposed by him, however, seems to be much higher than those values which can be considered as real on the basis of physical, geological and geophysical data.

In connexion with his investigations concerning Mach's principle, R. H. Dicke[24] also expressed the opinion that a decrease in gravity results in the expansion of the Earth. However, I think his estimation of increase in radius is probably too low.

After discovering the oceanic rifts, B. C. Heezen also came upon the idea of expansion as a possible cause of their formation[25,26].

It must also be mentioned that J. Tuzo Wilson, after his recent article[27], seems to be a representative of the expansion conception. However, in 1958 he declared himself as a supporter of contraction and an opponent of expansion. But his recent article[27] expresses no more than the validity of his tectonic concept even in the case of an expanding Earth.

Cox and Doell[28] have determined the Permian radius of the Earth based on an idea of mine[29]. It has been shown that the rate of expansion derived by Carey is too high and that the values suggested by me are between the limits of reality.

INTERTIDAL ZONE CHANNEL DEPOSITS IN MIDDLE JURASSIC GREAT OOLITE SERIES, SOUTHERN ENGLAND

By DR. GEORGE DEVRIES KLEIN

Department of Geology, University of Pittsburgh, Pittsburgh 13

THE Middle Jurassic Great Oolite Series of southern England consists of interbedded, shallow marine, oolitic limestone, shelly limestone, fine-grained limestone and olive silty claystone. Extensive development of oolitic limestone in the Great Oolite Series prompts one to infer depositional conditions similar to parts of the present-day Bahama Banks described by Illing[1], Newell and Rigby[2] and Newell, Purdy and Imbrie[3]. However, the Bahama Banks represent a complex of shallow marine environments which includes not only oolitic shoals[4] but also tidal creeks and mangrove swamps[5], coral reefs[3] and vast accumulations of non-oolitic lime sand and lime mud. Recognition of each of these distinct environments in sequences such as the Great Oolite Series will enable one to determine palæogeography and solve a variety of stratigraphic problems that still exist in these rocks.

A recent investigation of the Great Oolite Series in the Oxfordshire–Cotswolds Basin by me indicates that cross-stratified, shelly, oolitic limestones reported as part of a larger cycle by Arkell and Donovan[6] are characterized by

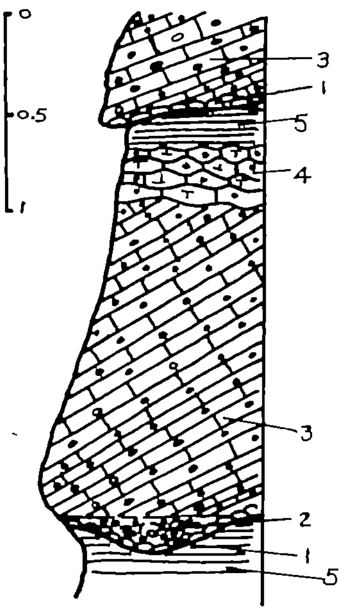

Fig. 1. Vertical sequence of limestone lithologies in channelled limestones, Great Oolite Series. (1) Basal lag concentrate of imbricate brachiopod, clam and oyster shells; (2) shelly, oolitic limestone; (3) cross-stratified, oolitic limestone; (4) wavy bedded, ripple marked, micro-cross-laminated, oolithic fine-grained limestone; (5) olive claystone. Scale in feet

a specific vertical succession of lithologies, textures and primary structures. Such a limestone sequence is also characterized by a downward-thickening, cross-sectional geometry resembling a channel. The downward thickening is at the expense of the underlying beds. Channels in the Chipping Norton Limestone, the Farmington Oolite member of the Stonesfield Slate, the Taynton Stone, the Kemble Beds and the Wychwood Beds show the following vertical sequence of lithologies from the base upward: shelly limestone (0–1 in. thick), shelly-oolitic limestone (0–1 in. thick), cross-stratified, oolitic limestone (1–4 ft. thick), wavy bedded oolitic, fine-grained limestone (2–4 in. thick) and olive claystone (0–6 in. thick) (Fig. 1). The channels average 15 ft. in width. Table 1 records the total number of cycles at the best localities exhibiting these features.

The basal shelly limestone consists of imbricated, convex-upward oriented shells of disarticulated clams, brachiopods and oysters. It lines the channel bottom. The shelly, oolitic limestone which overlies the imbricated shelly limestone is evenly laminated and filled with randomly oriented, disarticulated brachiopod, clam and oyster shells. This upper bed thins out to nothing as the channel margins are approached.

A thick (1–4 ft.) planar cross-stratified, oolitic and partly shelly-oolitic, limestone overlies the beds deposited on the channel floor. The oolites average 1 mm in grain size and are excellently size-sorted. Some cross-strata (about 1 in. thick) show a vertical grading from shelly limestone at the base to medium sand-sized oolitic limestone in the middle to a fine sand-sized oolitic limestone at the top. The cross-stratified limestone is overlain by thin (2–4 in.). fine-grained, poorly sorted, oolitic limestone which in some outcrops is wavy-bedded and in other outcrops is ripple marked and micro-cross-laminated. This wavy bedded, micro-cross-laminated zone is often overlain by an olive claystone, or was excavated by another limestone channel unit.

A somewhat similar cycle occurs in the Hampen Marl (Fig. 2). At the 'Old Quarries' north of Black Heath Clump, Oxfordshire (*SP*256156), the following vertical succession of lithologies was observed: slightly oolitic, quartzose limestone (1–2 ft. thick), brown siltstone (1½–3 ft. thick) and olive grey, platy claystone (6 in.–1 ft. thick). The basal sandy limestone thickens downward and is lined by imbricated, disarticulated clam and brachiopod shells mixed with clay chips. In other outcrops, the basal sandy limestone was observed to thin to nothing.

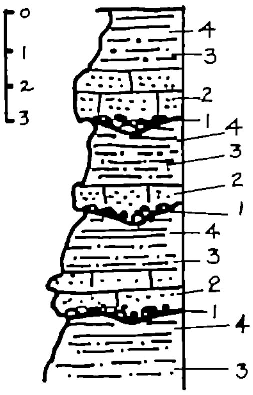

Fig. 2. Vertical sequence of lithologies in Hampen Marl. (1) Basal lag concentrate of imbricate clam and brachiopod shells and clay chips, (2) sandy limestone; (3) siltstone; (4) claystone. Scale in feet

The origin of these vertical successions can be determined by comparison with both Recent and fossil channel deposits in shallow marine environments. Van Straaten[7] has described the lithologies, textures and primary structures associated with laterally migrating creeks in modern tidal flat deposits in the Dutch Wadden Sea. He observed that during low tide, such lateral migration generated a lag concentrate of imbricated, convex-upward oriented, disarticulated clam shells. Such a lag concentrate is buried and preserved by point bar sands during lateral stream migration. The point bars are afterwards buried by inter-channel tidal flat muds. This process was described as "lateral sedimentation"[7]. A similar sequence of sediments occurs in the tidal flats of the Bay of Fundy[8], where, because of a difference in geomorphic setting[8], coarser-grained detritus is mixed in the channel-bottom lag concentrate; cross-stratified, sandy, point bars bury a channel floor lined with cobbles and clam shells. In the Bay of Fundy[9], the cross-stratified point bar deposits are overlain by ripple-marked and micro-cross-laminated, fine-grained sands.

The occurrence of channel bottoms lined with lag concentrates of imbricated, convex-upward oriented invertebrate shells appears to be a distinctive feature of meandering creeks traversing lower tidal flats at low tide. Present-day investigators[7–9], however, have confined their studies to tidal flats consisting of sand, silt and clay. No work has been undertaken on tidal flat disposition in areas of carbonate deposition. Bramkamp and Powers[10], however, have demonstrated that most limestone deposits accumulate by the same mechanical processes as silica clastic deposits. A parallel can therefore be drawn between the vertical succession of lithologies, textures and primary structures in modern tidal flat deposits and the channel deposits of the Great Oolite Series. Shell lag concentrates line channel bottoms in both modern tidal flat creeks and the limestone channels of the Great Oolite. The cross-stratified point bar sands of the Wadden Sea and the Bay of Fundy serve as modern analogues to the cross-stratified, sand-sized, oolitic limestone of the Great Oolite. The ripple-marked higher tidal flat deposits or inter-channel lower tidal flat deposits of the Wadden Sea and Bay of Fundy are analogous to the uppermost ripple-marked, wavy bedded, oolitic fine-grained limestone. I conclude from these data that the channel deposits in the Great Oolite Series were formed by the process of lateral sedimentation generated by intertidal zone creeks in an oolitic limestone-forming area.

Analogous vertical successions of lithologies, primary structures and textures have been observed by others[11–14] from channel deposits of different origin. Visher[11] has observed that modern fluvial deposits and ancient fluvial sandstone in the central and western United States are characterized by a vertical succession containing a basal clay-chip conglomerate, an overlying cross-bedded massive sandstone, an overlying ripple-stratified and thinly laminated sandstone and a capping siltstone and claystone. He infers that such features are diagnostic of meandering stream deposits where the clay-chip conglomerate represents a channel-bottom lag concentrate, the massive, cross-bedded sandstone represents rapid flow and the ripple-bedded zone and claystone represents tranquil flow. Allen[12,13] observed similar features in the Old Red Sandstone of England and drew a parallel to several meandering streams in Nigeria. Oomkens and Terwindt[14] reported such a sequence in modern estuarine sediment deposited by meandering creeks threading through tidal marshes. The only difference between the estuarine succession and the other vertical successions is the presence of a basal lag concentrate consisting of a mixture of shells and clay chips. The Hampen Marl of Oxfordshire shows such a vertical sequence of lithologies (Fig. 2) and was probably deposited by estuarine meandering creeks.

The parallelism in the vertical succession of lithologies between deposits from meandering creeks on lower tidal flats, meandering rivers on land and meandering creeks in estuaries is indicative of a common process. Van Straaten[7] has referred to the lateral shifting and re-working of sediment by meandering tidal creeks as the process of lateral sedimentation. The parallelism of the vertical succession of lithologies in tidal flat, fluvial and estuarine channel deposits suggests that Van Straaten's principle of lateral sedimentation is operative under a variety of sedimentary environments. At present, the only possible way to differentiate the three environments in which lateral sedimentation occurs is by close study of the lag concentrates lining the channel floors, as shell lag concentrates occur in tidal channels, mixed shell and clay-chip lag concentrates occur in estuarine channels and clay-chip conglomerates occur as lag concentrates in the channel floors of meadering rivers.

I thank the American Philosophical Society and the Office of Cultural and Educational Exchange, University of Pittsburgh, for research grants towards this work, W. S. McKerrow for introducing me to the stratigraphic problems in the Great Oolite Series, and E. G. Purdy and G. S. Visher for reading the manuscript.

RADIOACTIVITY OF BIOLOGICAL MATERIALS FROM BRAZILIAN AREAS RICH IN THORIUM COMPOUNDS

By DR. E. PENNA-FRANCA and O. GOMES DE FREITAS
Instituto de Biofísica, Rio de Janeiro, Brazil

THE areas of the world with a high background of radiation due to the presence of radioactive minerals in the soil afford great possibilities for investigations of long-term consequences to biological systems of continuous exposure for very long periods of time to relatively high doses of radiation.

There are two types of high background areas in Brazil where the thorium content of the soil is high. The first is the region of monazite sands, along the coast of the States of Rio de Janeiro and Espirito Santo, where the towns of Guarapary, Meaipe and Cumuruxatiba are situated. The average level of radiation in these towns is respectively 78·1 μr./h, 292 μc./h and 332 μc./h (ref. 1). The human population in this area is estimated at 20,000.

The second type is the region of volcanic intrusives, Morro do Ferro (Iron Hill) in Poços de Caldas, State of Minas Gerais. It is the most representative area of this type with an average level of radiation of 1,330 μr./h (ref. 1). No people are living in this area.

An extensive programme has been established by the Brazilian Atomic Energy Commission to investigate these regions. We have made some radiochemical analyses of samples brought to us by scientists working in this programme, in order to estimate the degree of contamination of their materials.

Among the thorium daughters the most important radionuclides from the physiological point of view are the isotopes of radium: radium-228 (mesothorium I) and radium-224 (thorium *X*). Being an alkaline earth, radium is a bone-seeker with a long biological half-life in animals. Radium-224 has a physical half-life of only 3·64 days and, once separated, it decays very rapidly; its daughters are all short-lived. Radium-228, however, has a physical half-life of 6·7 years and equilibrates very rapidly with actinium-228 (mesothorium II), an emitter of high-energy β- and γ-radiations. This makes radium-228 the greatest contributor, among the thorium daughters, to the internal irradiation of men and animals once they are contaminated by products of thorium decay.

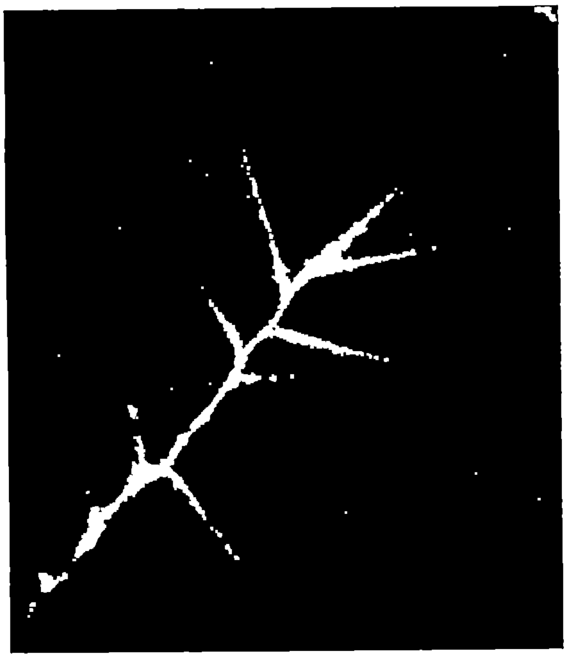

Fig. 1. Autoradiograph of leaves from a tree on Iron Hill, Minas Gerais, Brazil (exposure, 40 days)

Radiochemical separation of the radium isotopes of the thorium series, using barium and lead carriers, leads to the isolation of radium-228 and radium-224. The activity of radium-224 is insignificant after about 22 days, but the activity of radium-228 and actinium-228 in equilibrium is practically constant 22–90 days after separation[2].

The method used for separation of radium, barium and lead from calcium, iron, thorium and other interfering ions were essentially those recommended by the Health and Safety Laboratory, U.S. Atomic Energy Commission, for Sr-90 analysis of strontium-90 (ref. 3).

The separation of barium from lead was conducted by precipitation of the sulphates, followed by solution in alkaline ethylenediamine tetraacetic acid (EDTA). By acidification, only the barium sulphate reprecipitates, leaving the lead complexed in the supernatant[4].

For counting the radium-228 isolated from our samples we used a G.E.C. Geiger–Müller counter of low background (7 c.p.m.). We also counted samples of dried soil or ashed biological materials in a well scintillation counter associated with a spectrometer which was able to detect γ-radiation of 30 keV upwards. Since the isotopic composition and the degree of equilibrium among the different thorium decay products were not the same in the various samples counted, the results are not exactly comparable but give an indication of the total radioactivity present in the samples. Provided that the content in radionuclides from the uranium series is low, the results in counts per minute allow in first approximation an estimation of the number of disintegration occurring per minute, since the spectra of these samples were very similar. Of course radioactive potassium has also a contribution which is particularly important in plant ashes.

Table 1. DETERMINATIONS of RADIUM-228

Type of sample	No. of samples	d.p.m./g ash	μμc./g calcium
(a) Samples from Iron Hill			
Grass (leaves)	10	1,470–3,580	13,200–39,400
Grass (stems)	6	1,770–5,960	11,200–54,800
Bovine stools	4	425–573	13,200–24,500
Bushes (leaves and branches)	4	2,730–5,440	12,000–61,500
Moss	2	1,230–2,250	20,400–38,500
(b) Samples from Guarapary and Meaipe			
Calf bone	2	35	51
Calf teeth	2	12	18
Chick bone	2	8	11
Grass	4	160–270	680–1,340
Lobster shell	2	19	27
Bushes (flowers and leaves)	2	400	1.540
Bee wax	2	50	760
Bees	2	5	100
Bee mound	2	100	640

Table 2. GAMMA-ACTIVITIES

Type of sample	c.p.m./g ash
(a) Samples from Iron Hill	
Soil	784–3,580
Top soil (taken around the roots of grass)	1,060–5,060
Grass	1,260–6,670
Bushes	5,880
Moss	8,300
Fern	960–1,190
Bovine stools	
Mushroom (taken from the gallery of the thorium mine)	10,800
Frog (caught in the gallery of the thorium mine)	21,000
(b) Samples from Guarapary and Meaipe	
Monazite sand	57,500
Calf bone	17
Calf teeth	12
Chick bone	4
Grass (from Meaipe)	44–100
Sea shells	2–8
Lobster shell	8
Honey (*Trigona tataira*)	59–113
Bee wax (*Apis mellifera*)	20
Bees	6
Honeycomb (*Trigona tataira*)	29
Bee mound (*Trigona rufiris*)	88
Algae	616
Bushes (leaves and flowers)	468
(c) Controls.	
Potassium	92
Beach sand (Rio de Janeiro)	1
Top soil (R. J.)	8
Cow bone (bought in R. J.)	2
Honey (bought in R. J.)	15
Grass (R. J.)	57

The efficiency of our γ-radiation detector for radium-228 in equilibrium with actinium-228 was 28 per cent.

For comparison, some samples from a normal area, Rio de Janeiro (soil, sand, vegetation), or marketed in Rio de Janeiro (honey, cow bone) were counted in the same conditions, as well as potassium.

Chemical analysis of top soil from Iron Hill (carried out at the Laboratorio da Producao Mineral, Rio de Janeiro, by Dr. C. Pires Ferreira) gave contents of thorium dioxide ranging from 0·03 to 0·68 per cent in six different samples.

The great differences in the degree of contamination of biological materials from Iron Hill and from the coastal area could be due to differences in the solubility of the monazite sands and the thorium minerals occurring in the first area (thorium fluor carbonates), and also to the very irregular distribution of the monazite sands in the region.

In comparison with the external radiation-levels in the monazite sand zone, these preliminary results indicate that the internal irradiation of plants and animals due to radioactive contaminants should be relatively unimportant.

EXCIMER FORMATION IN POLYCYCLIC HYDROCARBONS AND THEIR DERIVATIVES

By Dr. J. B. BIRKS and L. G. CHRISTOPHOROU

The Physical Laboratories, University of Manchester

EXCIMERS are excited dimers, formed by the association of excited and unexcited molecules: they are dissociated in the ground-state[1]. In solutions of aromatic compounds the presence of fluorescent excimers is characterized by the appearance at high concentrations of a new, structureless emission band at long wave-lengths which is not accompanied by any change in the absorption spectrum. Excimer fluorescence was initially thought to be a property confined to pyrene and its derivatives[2], but recent studies by the authors[3–5] and others[6–9] have shown that it occurs in many polycyclic hydrocarbons and their derivatives. The purpose of this article is to summarize the present data, which indicate that excimer formation is the rule, rather than the exception, in this class of compounds.

The fluorescence spectra of the polycyclic hydrocarbons and derivatives listed in Table 1 have been examined in concentrated solutions at room temperature. The compounds are classified in terms of the number of benzene rings in the parent polycyclic hydrocarbon, and according to whether excimer fluorescence has been observed or not.

Anthanthrene and perylene solutions were earlier reported[9] to show new absorption bands at high concentration, which were attributed to the formation of stable dimers. Subsequent measurements on specimens of higher purity have shown the initial results to be incorrect.

Table 1. SOLUTIONS AT ROOM TEMPERATURE

No. of benzene rings	Excimer fluorescence	Ref.	No excimer fluorescence	Ref.
1	*benzene*	(6)	*p*-xylene	(6)

	5-propyl BA			
	5-amyl BA			
	5-phenyl BA			
	6-isopropyl BA			
5	*perylene*		*picene*	
	1:2-benzpyrene		*1:2,5:6-dibenzanthracene*	
	3:4-benzpyrene		*1:2:7:8-dibenzanthracene*	
	1:2:3:4-dibenzanthracene		*3:4:5:6-dibenzphenanthrene*	
6	*anthanthrene*			
	1:12-benzperylene			
	1:3:4:5-dibenzpyrene			

Anthanthrene has a typical excimer emission peaking at 594-nm wave-length. The excimer fluorescence of perylene in solution at room temperature is very weak, but the crystal fluorescence spectrum, a broad structureless band peaking at 580-nm wave-length, is clearly indicative of excimer formation.

The difference between the fluorescence spectra of a compound in dilute solution and in the crystalline phase is a further source of evidence for excimer formation, provided the crystal lattice structure is favourable for interaction between adjacent excited and unexcited molecules[9,10]. The crystal fluorescence spectra of pyrene, 5-methyl 1:2-benzanthracene, 8-methyl 1:2-benzanthracene, perylene, 3:4-benzpyrene, 1:12-benzperylene and anthanthrene[10,11] are all characteristic of excimer emission, thus confirming the solution data on these compounds (Table 1). The crystal spectra of 20-methyl cholanthrene, coronene and ovalene indicate that these compounds also form excimers.

Several of the compounds listed in Table 1 also show excimer fluorescence in the pure liquid state. These include benzene, toluene, 1-methyl naphthalene, 2-methyl naphthalene, 1,6-dimethyl naphthalene and pyrene. This method of detecting excimer formation is being currently extended to compounds of low solubility.

Studies of the rise and decay times of the monomer and excimer fluorescence of solutions[12] have shown that the excimer formation process is reversible, and that the relatively low quantum yield of excimer fluorescence in solutions of some compounds at room temperature is due to the high rate of non-radiative dissociation of the excimer. This dissociation rate decreases markedly on cooling, with a resultant increase in the excimer fluorescence yield, provided that the solvent remains sufficiently fluid at reduced temperature not to inhibit the diffusion-controlled excimer formation process. A major increase in the excimer fluorescence yield of a 5×10^{-3} M naphthalene solution in toluene has been observed on cooling from 21° to − 62° C (ref. 7). Acenaphthene in toluene solution, which has negligible excimer emission at room temperature, exhibits excimer fluorescence on cooling[13].

There are thus three distinct methods by which the data on excimer formation obtained from observations on solutions at room temperature may be supplemented or extended: from investigations of crystals, liquids and low-temperature solutions. It would therefore be premature to conclude that any compounds which do not exhibit solution excimer fluorescence at room temperature may not do so under more favourable conditions. It is of interest, however, to consider the factors which may inhibit excimer formation.

In anthracene and many of its derivatives, the dimeric interaction is so strong that the compounds form stable photo-dimers. Bonding occurs at the 9 and 10 positions in the two molecules forming the dimer, the central rings losing their aromatic character in the process[14]. It is interesting to note, however, that the formation of stable dimers in 9-methyl and 9-ethyl anthracene does not exclude the observation of excimer fluorescence at solution concentrations above 2×10^{-3} M (ref. 9).

9,10-disubstitution in anthracene prevents the formation of stable dimers, and this has been attributed to the effect of steric hindrance[9]. Similar steric hindrance is probably responsible for the inhibition of excimer formation in *p*-xylene and in the 9,10-disubstituted anthracene and 1:2-benzanthracene compounds. Except in these cases, substitution does not appear to interfere with excimer formation (Table 1).

Förster[8] has proposed certain conditions for excimer formation in solution, namely, the existence of a weak (^1L_b) lowest excited singlet state in the monomer adjacent to a strong (^1L_a) excited singlet state. Most of the compounds in Table 1 which exhibit excimer fluorescence in solution satisfy these conditions. In phenanthrene the $^1L_a - {}^1L_b$ energy separation is relatively large ($\sim$ 5,100 cm^{-1}) and probably exceeds the $^1L_a - {}^1L_a^-$ splitting, so that the $^1L_a^-$ state in the excimer lies above the ^1L_b state of the monomer. This factor has been suggested to account for the absence of excimer fluorescence in phenanthrene solutions[9]. The absorption spectra show that the $^1L_a - {}^1L_b$ energy separation is also large in triphenylene, 3:4-benzphenanthrene, 3:4:5:6-dibenzphenanthrene and picene, thus providing a similar explanation for the absence of solution excimer fluorescence. The f-values and separation of the ^1L_b and ^1L_a states in the two remaining compounds in Table 1, 1:2:5:6-dibenzanthracene and 1:2:7:8-dibenzanthracene, appear marginal for excimer formation.

The Förster conditions are not rigorous, and do not exclude the possibility, under favourable conditions, of excimer formation and fluorescence in compounds which do not satisfy them. A low excited singlet state with a strong transition moment from the ground state is required to provide the necessary interaction strength for excimer formation, but, although a lower weak singlet state is desirable to give a long life-time for the diffusion of the excited monomer molecules, it does not appear to be essential. Thus 2,5-diphenyloxazole, which has a very short monomer life-time of 2·6 nsec in xylene solution, corresponding to a strong lowest excited singlet state, nevertheless exhibits excimer fluorescence in high concentration solutions[15].

To summarize, it appears that excimer formation may be inhibited in the following circumstances: (1) when the interaction is so strong that stable dimers are formed, although excimer fluorescence may still be observed simultaneously in some compounds of this type; (2) when there is steric hindrance at the positions corresponding to the ends of the interacting dipoles; (3) when the transition from the ground state to the lowest excited singlet state of the monomer is weak, and there is no strong transition sufficiently close to provide adequate interaction for excimer formation.

We thank Prof. F. Bergel and Prof. M. S. Newman for the gift of compounds, and the British Empire Cancer Campaign for a grant in support of this work.

PRECURSORS OF CARCINOGENIC HYDROCARBONS IN TOBACCO SMOKE

By Dr. E. GIL-AV and Dr. J. SHABTAI

Daniel Sieff Research Institute, Weizmann Institute of Science, Rehovoth, Israel

A NUMBER of suggestions have been advanced[1] on the mode of formation of polycyclic aromatics in burning tobacco, on the tacit assumption that the thermal reactions involved are essentially unaffected by the simultaneously occurring oxidation process. In particular, tobacco paraffins[1] and cigarette paper[2] have been considered as precursors of the carcinogenic 3,4-benzopyrene (3,4-BP), since they form on pyrolysis small amounts of the latter compound. However, many organic materials have been shown[3] to yield some 3,4-BP at elevated temperature. Comparative experiments under smoking conditions have been reported[2] only in the case of cigarette paper, and it has been concluded[4] that the contribution from this source is not significant.

Terpenes have been mentioned as precursors by Wynder and Wright[1], but without giving any supporting data. In this article we wish to present evidence for the role of terpenic tobacco components in the formation of aromatics.

Earlier work[5] has led us to outline a scheme for the thermal aromatization of hydrocarbons at 550°–750° C, based on the interaction of dienic breakdown products. The reaction mechanism proposed involved mainly the intermediate formation of butadiene, followed by dimerization to 4-vinyl*cyclo*hexene and subsequent evolution of the latter into mono- and polycyclic aromatics. The polycyclic fractions formed in our experiments were not submitted to detailed analysis. Badger *et al.*[6], however, have shown recently that the pyrolysis at 700° C of both butadiene and 4-vinyl*cyclo*hexene results in considerable amounts of polycyclics and, particularly, in significant yields of 3,4-BP (0·34 and 0·48 per cent by weight of the total liquid product, respectively).

A similar pattern is emerging for the thermal reactions of isoprene. Staudinger and co-workers[7] have reported that at 700°–800° C the latter gives an aromatic tar, from which a number of polycyclic compounds were isolated. Recent experiments[8], carried out in this laboratory, showed that at 400° C and 760 mm isoprene forms a dimeric product composed of dipentene, 1-methyl-5-isopropenyl*cyclo*hexene, and a *gem*-type isomer, 1,4-dimethyl-4-vinyl*cyclo*hexene. The evolution of these dimers to aromatics at 450°–700° C is faster than that of 4-vinyl*cyclo*hexene and an almost fully aromatic liquid is produced already at 600° C. The monocyclic fraction (93 per cent by weight of the total liquid) contains benzene 5 per cent, toluene 30 per cent, xylenes 38 per cent, and also, characteristically, considerable amounts of C_9 alkylbenzenes (21 per cent), derived from the dimers by elimination of one carbon atom.

Furthermore, aromatization of *d*-limonene at 450° C was shown by Pines and Ryer[9] to proceed through the intermediate formation of *gem*-dialkyl*cyclo*hexadienes, which give by demethanation important amounts of C_9 alkylbenzenes.

Published data on the composition of tobacco smoke[1] support the view that aromatization based on thermal pyrolysis of isoprene occurs in burning tobacco. Indeed, isoprene and dipentene, as well as C_9 aromatics[1], that is, 1,2,4-trimethylbenzene and 1,3,5-trimethylbenzene, have been identified. 1,4(8)-Menthadiene[1], which could arise by double bond isomerization of dipentene, has also been reported.

Isoprene constitutes 50–80 per cent of the total unsaturated gaseous hydrocarbons present in tobacco smoke (0·87–4·2 mg/cigarette, as compared with 1 mg paraffins, 0·035–0·13 mg acetylene and 0·04–0·12 mg butadiene)[4]. Also, the temperature at which aromatization of isoprene occurs most readily (600°–800° C) corresponds to that found in burning tobacco.

Kennaway[10] has shown that isoprene tar is strongly carcinogenic. We have now established the presence of 3,4-BP in the tar.

100 g of isoprene was pyrolysed at 600° C in an empty stainless-steel tube. At 3-sec contact time 94 per cent of the diene reacted. The liquid product (67 per cent by weight) was distilled at 0·5 mm, up to 150° C, leaving 4·2 g of tar. Part of this material was subjected to elution chromatography on alumina[11] and the combined fractions containing 3,4-BP further chromatographed on acetylated paper. Finally, the amount of 3,4-BP was determined by ultra-violet spectrophotometry (analytical band, λ 385 mμ[11]) and found to be 0·1 per cent of the tar. In another experiment, carried out at 610° C and 4-sec contact time the concentration of 3,4-BP in the tar was 0·15 per cent by weight. The analytical procedure was checked with synthetic blends composed of anthracene, chrysene, fluorene, pyrene and 3,4-BP (0·8–7·0 per cent). It should be noted that the amount of 3,4-BP to be accounted for in the burning of one cigarette is only 0·005–0·025γ[4,12]. 3,4-BP is formed from isoprene already at a relatively mild temperature in accord with the established high tendency of dienes to undergo thermal aromatization[5,6]. In contrast, tobacco paraffins[1] do not yield any trace of this carcinogen at 600° C.

It should be pointed out that 3,4-BP content is only one of the factors determining the carcinogenicity of a tar[13]. Roe[12] has reported recently that the phenolic fraction of tobacco smoke condensate promotes the carcinogenicity of 3,4-BP (for mouse skin). This observation justifies in some respects the attention paid to the presence in tobacco tar of this polycyclic aromatic in spite of its low concentration. On the other hand, additional potent carcinogenic hydrocarbons are no doubt also present in the smoke, and 3,4 : 9,10-dibenzopyrene has actually been identified[1]. It is significant that 0·05 per cent of the latter compound is formed from 4-vinyl*cyclo*hexene at 700° C (ref. 6*b*).

Yields of isoprene ranging from 10–60 per cent have been found in the thermal decomposition of terpenic hydrocarbons[14] and alcohols[15] at 500°–750°. Obviously, terpenes present in tobacco should undergo depolymerization in a similar way. Solanesol[1] occurs in tobacco leaves to the extent of 0·4 per cent. Borneol and linalool have also been identified[1] in the leaves, whereas squalene (0·8γ/cigarette) has been found[1] in smoke condensate. Furthermore, essential oils are sometimes added to tobacco in the course of its processing.

Thus, taking terpenes as the precursors of isoprene, we propose the scheme given in Fig. 1 as an important pathway for the formation of polycyclic aromatics in burning tobacco.

OXIDATIONS AND TRANSHYDROGENATIONS INVOLVING PYRIDINE-DINUCLEOTIDES CATALYSED BY BOVINE MILK XANTHINE OXIDASE

By Dr. D. A. GILBERT

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, Fulham Road, London, S.W.3

THE oxidation of NADH (DPNH) by bovine milk xanthine oxidase was first reported twenty-three years ago[1] while more recently it has been stated that NAD+ (DPN) can act as electron acceptor for the enzyme when xanthine is the substrate[2,3]. These reactions have provoked relatively little interest despite the fact that the changes in the intracellular levels of both the co-enzymes and also xanthine oxidase have been cited as possible contributory factors of abnormal and malignant growth[4–6]. Attention has mainly been confined to ascertaining whether or not a contaminant of the bovine milk enzyme was responsible for the catalytic oxidation of NADH[7–13]. The following is a preliminary report on the results of recent studies on this enzymatic reaction: from these there remains little doubt that xanthine oxidase itself is the catalytic entity involved and that the flavin groups of this enzyme participate in the reactions.

Oxidation of NADH. When following the aerobic oxidation of NADH by the decrease in 340 mμ absorption, I have always observed an induction period[14], the change in optical density during this period being equivalent to the oxidation of about 5 moles of NADH per mole of enzyme (Fig. 1). It is believed that this delay in the attainment of maximum rate is due to a slow approach

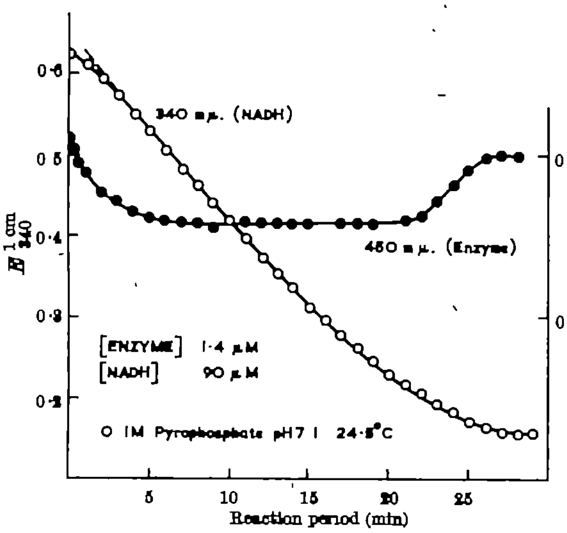

Fig. 1. Variation in extinction of the enzyme and NADH during oxidation of the latter. 5 μl. NADH was added to 2·0 ml. buffer, the reaction started by the addition of 100 μl. enzyme and the 340 mμ absorption followed in a 1 cm cell. In order to observe the changes in extinction of the enzyme at 450 mμ, the experiment was repeated using a 4 cm cell and volumes five times those given here

to the steady state. In agreement with this view is the fact that during this period there is a net partial reduction of the xanthine oxidase as judged from a decrease in the visible absorption of the enzyme (Fig. 1; cf. curve of Gutfreund and Sturtevant for the xanthine reaction[14]). Furthermore, the enzyme is either eventually re-oxidized or further reduced according to whether or not the NADH is in excess of the oxygen acting as electron acceptor.

The decrease in the 450 mμ absorption of the enzyme during the initial period of the reaction (that is, to the steady-state level) was found to obey first-order kinetics over at least 75 per cent of its course under all conditions so far adopted. From the magnitude of the changes that can be produced, it is clear that the flavin groups must be involved. The results also confirm the view that enzyme no longer active toward xanthine is still able to oxidize NADH (refs. 1 and 13). Using one particular enzyme sample, the rate coefficient for this change (k_s) and the steady state concentration of reduced enzyme ($[EH.P]_s$) were found to vary with the NADH concentration at all pH values near neutrality: under otherwise constant conditions, both were maximal at pH 6·7. The rate coefficient k_s was markedly influenced by the nature of the buffer ion, being much smaller in *tris* than in pyrophosphate at the same pH. The changes in the absorption of the enzyme in the region of 600 mμ did not parallel those occurring at 450 mμ; similar observations have been made by Gibson and Gilbert (unpublished) and confirmed by Bray[15] in the case of the xanthine reaction. It is possible that the changes at the higher wave-lengths reflect binding of the oxygen molecule to the enzyme since, in the case of NADH at least, it appears that the changes at 600 mμ occur only when the enzyme is reduced beyond the steady-state level.

In addition to the pre-steady-state investigations, I have also determined the effect of pH on the overall aerobic reaction. From the results obtained with one enzyme sample it was found that the pK$_m$ versus pH graph[16] shows a break at pH 5·9, while V_m and V_s (V_m/K_m—the rate at infinitely low substrate concentration[17]) were maximal at pH 5·7 and pH 6·8 respectively.

Although no qualitative inconsistencies have been observed when using different batches of enzyme and NADH, a wide variation in the magnitude of the Michaelis constant for the latter has been noted[8,19]. A similar variation has previously been found in the value of the Michaelis constant for xanthine (see Bray[19] for a discussion on this point). It seems likely that the factors affecting the magnitude of K_m for one substrate also affects the value of the constant for the other, but not necessarily in the same direction. Bray[19] has presented evidence (with which we are in accord) that some xanthine oxidase samples contain an inhibitor of the xanthine reaction, but he did not determine whether or not the NADH reaction was likewise affected. Previously, however, Bray[18] observed that the specific activity (toward NADH) of one batch of xanthine oxidase decreased as the concentration of the enzyme was increased. This is consistent with the presence of an inhibitor of the NADH reaction in the xanthine oxidase sample.

The addition of NADH to concentrated xanthine oxidase results in a slow decrease in the activity of the latter towards xanthine, the magnitude of this effect correlating with the changes in the visible absorption of the enzyme described here. Thus, the inhibition is spontaneously reversible at low concentrations of NADH (that is, as the latter is eventually oxidized): with higher concentrations of pyridine dinucleotide, gradual spontaneous inactivation of the enzyme becomes significant and somewhat obscures these effects. Since the diaphorase activity of the enzyme is unaffected by a number of processes or reagents which block the xanthine reaction, it is tentatively concluded that the inhibition effect just described, may be attributed to reduction of the flavin groups of the enzyme and not merely to the binding of the NADH molecule. NAD+ can also inhibit the xanthine reaction in a similar fashion although the effect is not so marked as that observed with NADH, except apparently when the enzyme is previously reduced by the substrates xanthine or NADH. Dissociation of the NAD+ by dilution is slow.

Transhydrogenations. Xanthine oxidase has been found to catalyse a number of transhydrogenation reactions utilizing NADH as substrate and various pyridine dinucleotides as acceptors. Thus 3-acetyl-pyridine- and 3-formyl-pyridine-adenine dinucleotides (APAD+ and FPAD+ respectively) and the corresponding hypoxanthine compounds (APHD+ and FPHD+) were all found to be good acceptors for NADH oxidation even under aerobic conditions. At pH 7·1, certain values were obtained with one enzyme sample, the reduction of the analogues being followed at 390 mμ where the contribution of the NADH is relatively small (Table 1).

Table 1

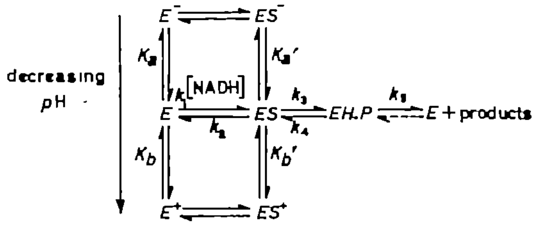
NAD+ analogue	K_m (μM)	V_m $\Delta E^{1\,cm}_{390}$/min	V_m (μmole/l./min) (relative)
APAD+	113	0·08	0·43
APHD+	382	0·08	0·43
FPAD+	222	0·13	1·00
FPHD+	665	0·13	1·00

[NADH] 147 μM. [Enzyme] 1·4 μM; 23·5° C. 0·1 M pyrophosphate pH 7·1 (aerobic system).

It can be seen that the rate of reduction of the NAD+ analogue is dependent on the nature of the pyridine substituent only while the Michaelis constant is also influenced by the purine moiety. The foregoing K_m values may be compared with a dissociation constant of 400 μM calculated for NAD+ when acting as an inhibitor of the xanthine reaction. The effect of pH on K_m, V_m and V_s has been determined in the case of FPAD+ reduction and the results found to be extremely similar to those obtained when following NADH oxidation with oxygen as acceptor. Thus the pK$_m$ versus pH graph shows a break at pH 6·2 while V_m and V_s are maximal at about pH 6·4 and pH 6·7 respectively. The results suggest that the reduced forms of the foregoing analogues are eventually re-oxidized by the enzyme although the reactions involving the isolated reduced compounds have not been studied.

Since NAD+ and NHD+ (nicotinamide hypoxanthine dinucleotide) both decrease the maximum rate of change in 340 mμ absorption when NADH is oxidized aerobically and also increase the induction period, it is concluded that these compounds also act as acceptors even in the presence of oxygen. The apparent inhibition arises because the visible spectra of the reduced forms of these compounds are identical to that of the substrate. Some simple 3-substituted pyridinium compounds did not react. Contamination of the NADH by NAD+ could thus presumably influence the observed kinetics and this factor may contribute toward the quantitative discrepancies referred to here[11,12].

Reaction scheme. The results available have been analysed, bearing in mind the quantitative differences mentioned earlier. All the results seem to be consistent with NADH oxidation proceeding according to the following partial reaction scheme, where $k_3 > k_1$ [NADH] $\gg k_2 \approx (k_4 + k_5)$:



In this scheme, the reactions in the vertical columns represent the ionizations of the enzyme due to the pH (assumed rapid) while those in the horizontal lines represent the rate-determining steps in the overall oxidation process. Thus *ES* is the enzyme–substrate complex, the enzyme still being in the oxidized form: reduction of the enzyme and oxidation of the substrate occurs to give the reduced enzyme–product complex, *EH.P*. The coefficient k_3 must be complex (and may be pH dependent) but was pseudo first-order under the conditions used. From anaerobic studies (when k_5 must be zero) it is concluded that k_4 cannot be zero. The following values have been calculated from the pre-steady-state data already referred to: k_1/k_2 = 500 l./mole; k_3 = 0·2 min^{-1}; $(k_4 + k_5)$ = 0·14 min^{-1} (0·1 M pyrophosphate pH 8·0, 23·5° C). The Michaelis constant for this sample of enzyme was not determined directly but the value calculated from the coefficients just given (800 μM), although rather high, is of the same order of magnitude as some values determined experimentally. It would thus seem that the foregoing reaction scheme may be accepted as a guide for future studies.

In the case of bovine milk xanthine oxidase and possibly other mammalian forms of this enzyme, the rates of oxidation of NADH, or reduction of NAD+, seem to be too low for the reactions to be biologically significant. If, however, these coenzymes can reach the xanthine oxidase *in vivo*, it is possible that their level could control the rate at which purines and/or pteridines are catabolized.

I thank Prof. F. Bergel for his advice.

This investigation has been supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign, the Anna Fuller Fund, and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

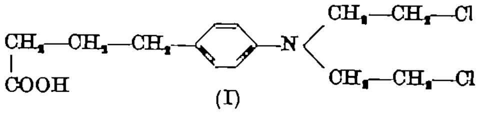
INTERACTION OF CHLORAMBUCIL WITH CELL SURFACES

By J. H. LINFORD, A. FROESE and L. G. ISRAELS

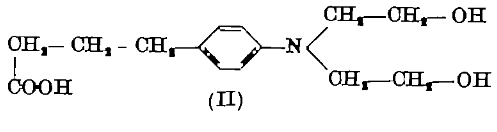
Department of Biochemistry, and Department of Medicine, University of Manitoba, Winnipeg

MANY of the cytotoxic and mutagenic actions of the alkylating agents suggest that the nucleic acids of the cell nuclei are the probable sites for the primary chemical reaction which is responsible for these biological effects[1]. We have found that interaction takes place between chlorambucil and suspensions of human erythrocytes, or of Ehrlich ascites tumour cells. No loss of chlorambucil from solution was evident. The reactions that occurred have been deduced from changes in the solubility of chlorambucil and from the conditions that caused lysis of the red cells, which indicated that only the cell surface was involved.

The compound chlorambucil in the non-ionized form (I) is soluble in benzene and in ethyl acetate. The hydroxyl derivative (II) is insoluble in benzene but is soluble in ethyl acetate. From an aqueous solution of (I) and (II) at pH 3·6 the form (I) present is extractable by benzene and the amount of form (II) is the difference between the amounts extracted by ethyl acetate and by benzene. Both forms (I) and (II) are soluble in water at pH above 7, and in ethanol[2,3].



(I)



(II)

To prepare the reaction mixture, freshly drawn human blood, or ascites fluid from mice bearing Ehrlich ascites tumours, was centrifuged and the cells were washed once in isotonic saline. Approximately 5 ml. of packed red cells or 3 ml. of packed ascites cells was obtained. 4 mg of chlorambucil (I) was dissolved in 4 ml. of 0·5 M sodium bicarbonate and this was diluted to 40 ml. with 0·11 N sodium chloride. The cells were added to 20 ml. of this chlorambucil solution. The remaining 20 ml. was used as a

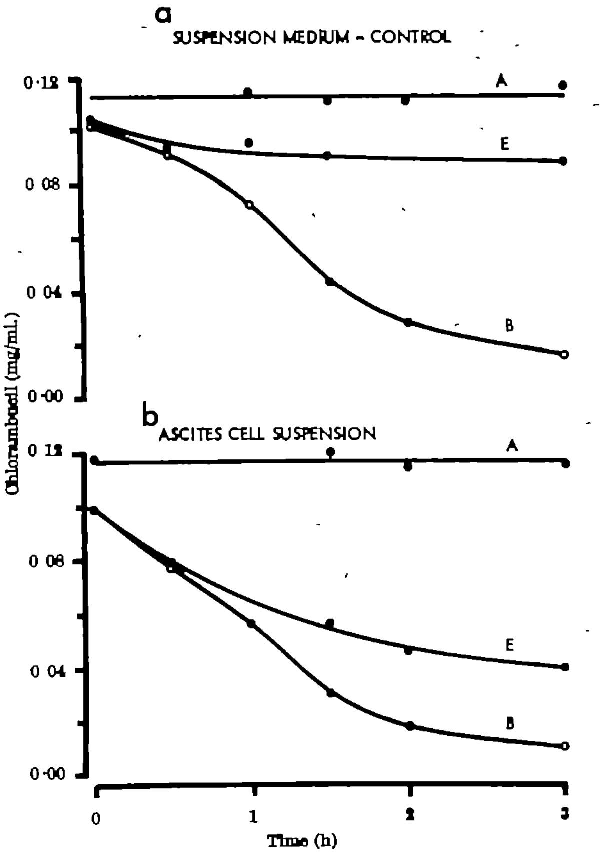


Fig. 1. *a*, Concentrations of derivatives of chlorambucil recovered from a solution of 0·05 M bicarbonate and 0·10 M saline at pH 8·0. *b*, Concentrations of derivatives of chlorambucil recovered from the medium in the presence of a suspension of ascites cells · (*A*) total concentrations by recovery in alcohol; (*E*) combined concentrations of chloro and hydroxyl forms, by recovery with ethyl acetate; (*B*) concentrations of chloro form by recovery with benzene

control. Both mixtures were adjusted to pH 8·0 with a few drops of 0·5 N hydrochloric acid, and were incubated in a 37° C bath with occasional inversion.

To follow the course of the reaction, three 1·0-ml. samples were withdrawn from each mixture at measured intervals of time. 9·0 ml. of ethanol was added to each sample to remove the protein material. The samples were centrifuged, the supernatant alcohol was evaporated from two of the samples from each mixture and the residues were partitioned between 0·1 M phosphate buffer of pH 3·6 and three 5·0-ml. volumes of either benzene or ethyl acetate[2]. The organic solvents were removed under reduced pressure and the residues were dissolved in 10 ml. of ethanol. The absorbance of the three alcohol solutions from each mixture was measured at 258 mμ. The amounts of chlorambucil recovered by the three solvents from a suspension of ascites cells at pH 8·0 and from a control of pH 8·0 in the absence of cells are shown in Fig. 1.

Similar results were obtained when samples in excess of 1·0 ml. were withdrawn from the reaction mixture, and were centrifuged to obtain 1·0 ml. of supernatant solution. Two samples of supernatant fluid from the suspension and two from the control were adjusted to pH 3·6 with about 0·5 ml. of 0·05 N hydrochloric acid, then made up to 5·0 ml. with water. These were extracted as described here. A third 1·0-ml. sample from each source was made up to 10 ml. with ethanol. With this second method, we studied the interaction of chlorambucil with red cells, red cell 'ghosts' and ascites tumour cells, and compared this with control solutions of the same bicarbonate and saline content. We also investigated the effect of a phosphate buffer in the absence of cells. The results are listed in Table 1.

Table 1*. PERCENTAGE OF CHLORAMBUCIL DERIVATIVES PRESENT AFTER 3 H IN CONTACT WITH CELLS IN SUSPENSION AND IONS IN SOLUTION AT pH 8 AT 37° C, RELATIVE TO BICARBONATE–SALINE CONTROL SOLUTION

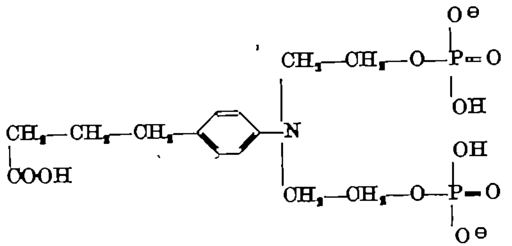
Reaction mixture		Derivatives recovered		
Reactant	Reagent	Chloro (I)	Hydroxyl (II)	Hydrophilic
Bicarbonate 0·05 M	(I)	27	73	0
Red cells 1·5 × 10^6/mm³	(I)	29	38	33
Red cell ghosts ,,	(I)	25	39	36
Red cells ,,	(II)	8	85	7
Ascites cells 3 × 10^4/mm³	(I)	16	6	68
Phosphate pH 7·5 0·05 M	(I)	9	8	83

* The results are expressed as a percentage of the amount initially extracted from the aqueous phase. This was about 0·1 mg/ml. as calculated from the samples in alcohol and about 10 per cent less in the ethyl acetate and benzene extractions[2]. Fig. 1 also refers to this.

When corrected for the (88 per cent) efficiency of extraction by the water-immiscible solvents, the control solutions which contained bicarbonate buffer converted 64 per cent of the chloro form of chlorambucil (I) to the hydroxyl derivative (II), in 3 h. 20 per cent was recovered as the benzene soluble chloro form. The remaining 16 per cent may be accounted for by assuming a reaction with the bicarbonate ion in solution to form an alcohol-soluble or 'hydrophilic' derivative, because 100 per cent of the initial chlorambucil concentration was recovered in alcohol (Fig. 1*a*).

In the presence of cell suspensions, 100 per cent of the initial chlorambucil concentration remained in the alcohol-soluble form but the amount recoverable by ethyl acetate diminished with time relative to the control solution (cf. Fig. 1*a* with *b*). Little effect was evident on the amount recovered by benzene. The decrease in the amount recovered by the ethyl acetate extractions, in the presence of cells, may also be attributed to the formation of a more hydrophilic form of chlorambucil which was soluble in alcohol and water but not in ethyl acetate. This derivative was not attached to the cell and had the same absorbance as chlorambucil because the recovery in alcohol throughout the reaction was equal to the initial concentration of chlorambucil. The decrease with time in the amount recoverable by ethyl acetate, relative to the bicarbonate–saline control, was a measure of the rate of formation of this hydrophilic derivative.

Table 1 indicates that the hydroxyl derivative of the chlorambucil did not interact with the red cell surface; some of the chloro form (I) most probably was present in the hydrolysed solution. An extensive reaction occurred with the phosphate buffer 'control' solution. The reaction with ascites cells was more extensive than with the red cells. Of the solutions and suspensions tested, bicarbonate ion was the least reactive. The nature of the hydrophilic derivatives is indicated by the extensive reaction which occurred in the phosphate buffer 'control' solution, which may have produced a compound of type (III).



(III)

The results suggest that a hydrophilic derivative of chlorambucil was formed at the cell surface by an alkylation reaction involving replacement of the chloro atoms by nucleophilic groups. The hydrophilic product was, moreover, present in solution. Therefore, it is probable that the chlorine atoms in the chlorambucil were replaced by small nucleophilic molecules or anions from the cell surface.

The cell envelope appeared to be weakened by the reaction with chlorambucil. A series of 5·0-ml. volumes

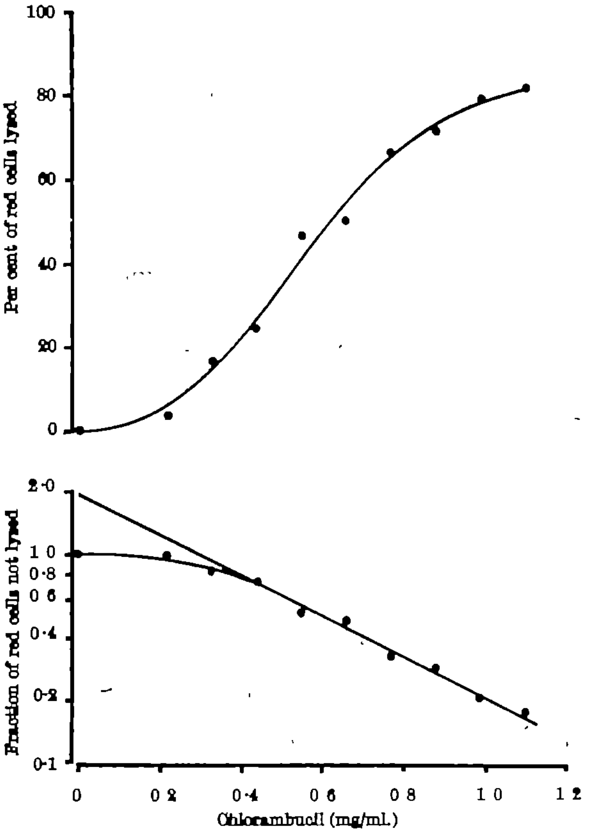


Fig. 2. (Above), Extent of lysis, determined by the absorbance of the supernatant solution after 0·5 h at 37° C, of a suspension of 0·5 ml. of packed red cells in 5·0 ml. of isotonic saline–glucose at pH 8·5 in the presence of increasing concentration of chlorambucil. (Below), The data of above curve plotted as logarithm of the fraction of cells surviving in the presence of increasing concentrations of chlorambucil

of solution were prepared which were 0·09 M sodium chloride, 0·02 M glucose, 0·05 M sodium bicarbonate and contained concentrations of chlorambucil varying from 0·2 to 1·0 mg/ml. 0·5 ml. of washed red cells were added to each volume and the suspensions were incubated at 37° C for 0·5 h with inversion every 5 min. The extent of hæmolysis was determined by measuring changes in absorbance at 550 mμ. Lysis was apparent at chlorambucil concentration greater than 0·3 mg/ml. (0·001 M) and the degree of lysis increased rapidly with increase of concentration, refer to Fig. 2 (above). No lysis was caused by the hydroxyl derivative (II). The derivative of (I) known as phenylalanine mustard reacted as did (I) up to 0·4 mg/ml. The nitrogen mustard cyclophosphamide (Endoxan), which is inert *in vitro*, behaved as (II).

The effect of chlorambucil which caused lysis of the red cells appeared to be additive. Two successive treatments of the same cells (7 × 10^8/ml.) with chlorambucil concentrations of 0·19 mg/ml. for 0·5 h at 37° C lysed only 2·0 per cent of the cells. A third treatment lysed another 14 per cent of these cells. One treatment with chlorambucil at 0·55 mg/ml. lysed 45 per cent of cells from the same stock.

These results, together with the shape of the curve of Fig. 2 (above) and the fact that weak solutions of chlorambucil caused no lysis over periods of 3 h at 37° C, indicated that more than one interaction of the drug with the cell must occur to cause lysis. In Fig. 2 (below) the data of this figure are plotted as the fraction of surviving cells against the chlorambucil dose. By analogy with the action of X-rays on cells[4,5], the existence of the shoulder in Fig. 2 (below) constitutes evidence for a multiple hit mechanism of lysis. Back extrapolation of the first slope of the curve indicated that two hits are required.

The results suggest that a primary action of chlorambucil may be the removal of a simple chemical component from the cell surface.

MEASUREMENT OF MOISTURE BOUNDARY LAYERS AND LEAF TRANSPIRATION WITH A MICROWAVE REFRACTOMETER

By DAVID M. GATES, M. J. VETTER and MOODY C. THOMPSON, Jun.

National Bureau of Standards, Boulder Laboratories, Boulder, Colorado

THE refractive index (n) of air at microwave frequencies is determined chiefly by the air temperature (T), the total pressure (P) and the partial pressure of water vapour (e) present. The dependence of the index on the last quantity is sufficiently large that instruments (refractometers) which measure the index can be used to study variations in water vapour pressure. For practical purposes the index can be expressed as:

$$N \equiv (n - 1) \times 10^6 = a\frac{P}{T} + b\frac{e}{T^2}$$

The sensitivities of N to the factors are given by their partial derivatives, which for typical laboratory conditions have the following approximate values:

$$\frac{\partial N}{\partial T} = -1{\cdot}2\ N/°\mathrm{C}, \quad \frac{\partial N}{\partial P} = 0{\cdot}3\ N/\mathrm{mb}, \quad \frac{\partial N}{\partial e} = 4\ N/\mathrm{mb}$$

Since refractometers have been developed with resolutions of the order of 0·1 N and accuracy of the order of 1 N, measurements of water vapour pressure can be made to corresponding values of 0·025 and 0·25 mb (approximately 0·1 and 1 per cent relative humidity at a temperature of 20° C), if the temperature and pressure of the sample can be properly determined. In many cases total pressure is effectively determined by local gross atmospheric conditions. It is also relatively easy to maintain the temperature nearly constant. Consequently, the refractometer is readily adapted to experiments in which changes of water vapour pressure are to be studied. Several reports are available describing some of these applications.

In the case to be described here, the refractometer is used for examining the moisture profile found near a free water surface or near the surface of organic materials such as leaves, animal skins, etc.

Several types of microwave refractometers have been developed[1–4], and some of these can be purchased commercially at a cost of between 5,000 and 10,000 dollars. All these operate basically by responding to changes which occur in the resonant frequency of a cavity resonator as the index of refraction of its contents change. The

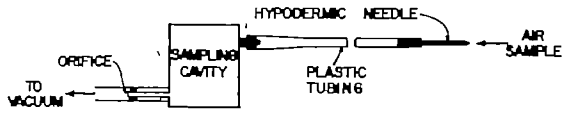

Fig. 1. Diagram of the sampling technique to draw moist air through the hypodermic needle and the plastic connecting tubing into the refractometer sampling cavity

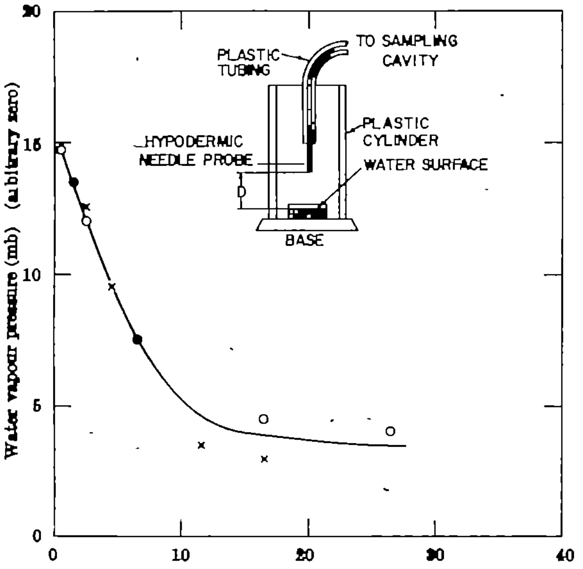

Fig. 2. Method for observing the moisture profile near a free water surface and the observed moisture profile of vapour pressure as a function of the distance above the water surface

experiments described in the following paragraphs were performed using the types described in refs. 1 and 4. These instruments operate at about 9,400 Mc/s. The sampling cavity is a right circular cylinder about 4·5 cm in diameter and 3·0 cm long. Each instrument measures the change of resonant frequency of the sampling cavity by comparing it with a similar reference cavity the contents of which are controlled (usually hermetically sealed and containing dry argon). In the system developed by Birnbaum this comparison is made by sweeping the frequency of a klystron oscillator and noting the relative time between resonance of the two cavities. In the Vetter refractometer the reference cavity is tuned by a servo-operated probe to track the frequency changes in the sampling cavity.

Because of the size and shape of the sensor (sampling cavity) the desired spatial resolution was obtained by connecting the cavity to a vacuum pump (or chamber) and drawing the air sample to be measured into the cavity through a flexible plastic tube fitted with a hypodermic needle on the outer end (Fig. 1). The needle was mounted on a rack and pinion so that its position with respect to the surface could be easily and closely adjusted. By using an appropriate orifice in the gas sampling path a suitable compromise can be made between sampling speed (response time) and the disturbance which the probe creates in the field to be measured. With the arrangement shown in Fig. 1 the time constant of the system was about 30 sec; however, a delay in response of about 5 sec occurs because of the volume of the intake tubing. The time constant is determined by the size of the cavity and the time required to replace the air in the cavity.

Moisture profile above a free water surface. The first measurements were of the moisture profile above a free water surface. The water was contained in a flat dish which was placed inside a closed box in order to avoid local convection effects (Fig. 2). The hypodermic needle probe (observed through a plastic window) was lowered towards the free water surface a few mm at a time and each setting was maintained for approximately 30 sec. The change in water vapour pressure which was observed is shown in Fig. 2. The scatter of the points obtained at the larger distances is believed to be due to the circulation of air within the container.

Transpiration of plant leaves. It is important to be able to measure the transpiration from plant leaves without disturbing the environment of the leaf or the boundary layer near the surface. By placing the hypodermic needle against the lower surface or just off the lower surface, the moisture near the surface can be monitored with relatively little perturbation. For some of the measurements the entire plant was placed within the box, while for others the leaf of the plant was placed inside the box with the stem entering through a small opening in the side. Measurements were first made on the free leaf with the needle against the lower surface. However, some difficulty was encountered with small movements of the leaf during extended periods of measurement which made it advisable to support the leaf with a flat piece of wood against which the leaf was taped along the edges.

An entire bean plant was placed within the chamber and the measurements were made with the needle set against the lower surface of a leaf. A tracing of a recording of the transpiration from the bean leaf is shown in Fig. 3*a*. The plant was initially in complete darkness. The plant was illuminated with approximately 600 ft.-candles of fluorescent light incident on the leaf being investigated.

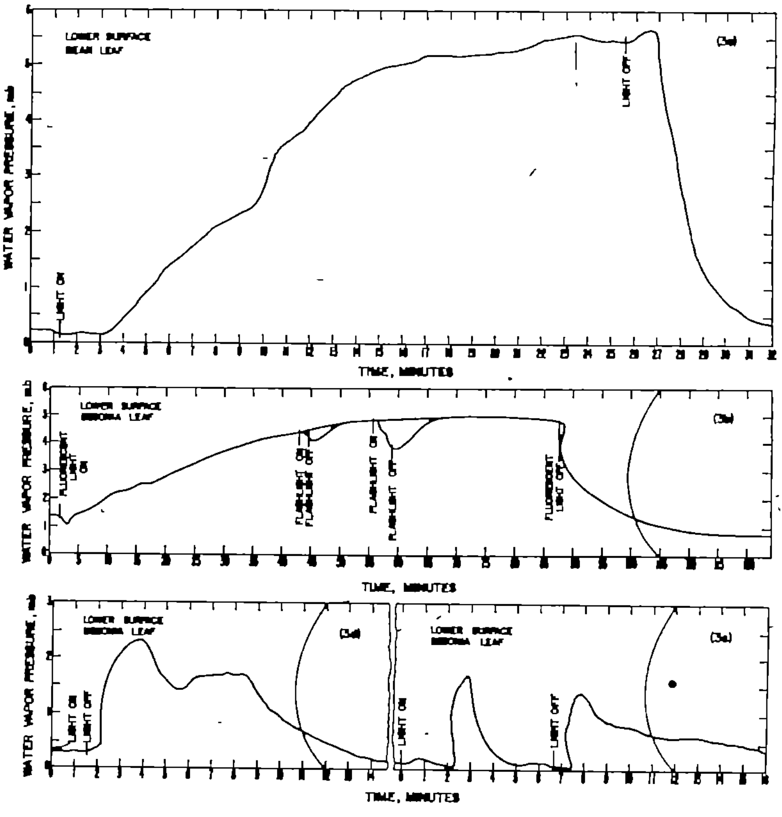

Fig. 3. The water vapour pressure next to the lower surface of a begonia leaf (3*a*) as a function of time after a fluorescent light is turned on and off. Vapour pressure near a bean leaf (3*b*) and some responses of the begonia leaf (3*c*) and (3*d*)

The immediate response was an apparent decrease in transpiration for 30 sec, followed by a slight increase for 1 min and a small decrease for another 30 sec. Then nearly 2 min after the initial stimulus by the fluorescent light an increase in transpiration began which reached a steady state about 20 min later which was about 21 *N* units greater than the initial level. This represented a change of about 21 per cent of relative humidity at 20° C, or an increase in vapour pressure of about 5·5 mb in the boundary layer near the leaf surface. When the light had been turned off the transpiration diminished abruptly for 4–5 min and then levelled off at a level just above the initial starting-level.

Fig. 3*b* shows tracings of direct recordings of the index of refraction of the air drawn into the refractometer cavity from the lower surface of a begonia leaf. The measurements were started with the leaf in total darkness. A fluorescent light was turned on the leaf through the clear acetate window of the box and the leaf illuminated with approximately 640 ft.-candles while the main plant remained in the ambient fluorescent light of the room. The immediate initial response was an apparent decrease in transpiration which lasted for approximately 1 min. Then 2–2·5 min following the initial stimulus by the fluorescent light, which had remained on, the transpiration steadily increased until it reached a steady-state level 52 min later at 13 *N* units above the initial level representing a change of vapour pressure of 3·25 mb or 13 per cent relative humidity at 20° C. Turning the fluorescent light off and placing the leaf in total darkness resulted in an initial slight drop in transpiration for nearly 30 sec, then a precipitous drop followed by diminishing transpiration for the next 30 min or more.

A particularly interesting response of the begonia leaf to light was observed when the leaf was transpiring at its maximum rate under an illumination of 640 ft.-candles of fluorescent light when an additional illumination of about 600 ft.-candles was put on to the leaf with a flashlight. The transpiration rate dropped abruptly rather than increasing as expected. When the flashlight was turned off the transpiration rate returned to its original value or trend. The change in vapour pressure was about 1 mb or 4 per cent relative humidity at 20° C. The precise stomatal action involved here must be explored further, but the response was clearly evident.

Some interesting responses were observed for a begonia plant when the entire plant was placed in the chamber and the air sampled from the lower surface of one of the leaves. The record of this behaviour is shown in Fig. 3*c*. With the fluorescent light turned on the entire plant, an initial small increase in transpiration appeared followed by a slight decrease. 2 min after the light was turned on an abrupt increase in transpiration occurred which amounted to a total change of about 6·5 *N* units (6·5 per cent relative humidity at 20° C). Although the lamp remained on, something shut off the transpiration just as abruptly as it had begun and the moisture concentration in the boundary layer dropped to its original level prior to the stimulus by the light. 1 min after the light was turned off, there was once again a sudden apparent increase in transpiration and the moisture concentration of the boundary layer increased by about 5·4 *N* units (5·4 per cent relative humidity at 20° C) followed by a gradual decrease.

Fig. 3*d* also illustrates an example of illuminating the entire begonia with light from the fluorescent lamp and then after 1·5 min turning off the light. The plant continued with its transpiration action, but after transpiring for about 6 min returned to its dark state in about another 5 min. The air was sampled from the lower surface of a single leaf although the entire plant was within the chamber.

Conclusions. It is shown that a microwave refractometer can be an extremely sensitive and responsive device for detecting the moisture concentration within a boundary layer near a moist surface. The air must be drawn very slowly into the refractometer. A hypodermic needle was used as a probe in the experiments described here. The boundary layer profile was measured over a free water surface. The transpiration from leaves was observed while they were subjected to various stimuli of light and darkness. Changes in moisture concentration amounting to a variation as little as 0·1 per cent relative humidity (at 20° C) can be detected. By reducing the size of the microwave cavity (for example, going to *K*-band rather than *X*-band) it should be possible to reduce the response time by about one order of magnitude and increase the sensitivity.

ROLE OF THE PHOSPHORYLASE ENZYMES IN CARDIAC CONTRACTION: A PROPOSED THEORY FOR THE RHYTHMICAL PRODUCTION OF ENERGY IN THE HEART

By NIELS HAUGAARD

Department of Pharmacology, Schools of Medicine, University of Pennsylvania, Philadelphia 4

RECENTLY, considerable evidence has been obtained that alterations in heart function are associated with biochemical changes in the myocardium. Of the many biochemical events which may be of importance in cardiac contraction, particular attention has been focused on the phosphorylase reaction. In the heart[1], as well as in skeletal muscle[2], the enzyme phosphorylase exists in two forms: phosphorylase *a*, which is active in the presence or absence of adenylic acid (AMP), and phosphorylase *b*, which although inactive by itself, becomes active when AMP is present as a co-factor. From the work of Sutherland, Cori *et al.* it is known that adrenaline in minute amounts activates liver phosphorylase[3] and produces a transformation of phosphorylase *b* to phosphorylase *a* in skeletal[4] and heart muscle[1]. Sutherland and Rall[5] isolated a new coenzyme, 3′,5′ cyclic AMP, demonstrated that this compound was formed in tissues in response to adrenaline and found that it stimulated the formation of phosphorylase *a*.

The work of Krebs, Graves and Fisher[6] showed that one of the actions of cyclic AMP is to increase the activity of phosphorylase *b* kinase, which catalyses the synthesis of phosphorylase *a* from the *b* form of the enzyme. In the heart the positive inotropic action produced by adrenaline and other sympathomimetic amines has been shown to be correlated with an increase in the activity of phosphorylase *a* [7-11]. The increased force of contraction following stimulation of sympathetic nerves to the heart[10] or administration of ganglion stimulating drugs[12] has been found also to be associated with an increase in the activity of phosphorylase *a*. Most recently, Hess, Shanfeld and Haugaard[13] showed that in the open-chest rat preparation vagal stimulation or administration of acetylcholine were followed by a significant decrease in the activity of phosphorylase *a*. It is very likely that the changes in phosphorylase activity seen when the heart is stimulated or depressed reflect variations in the intracellular concentration of cyclic AMP.

We do not at the present time know the exact role that cyclic AMP or the phosphorylase reaction may have in the regulation of cardiac activity. However, the correlation between changes in phosphorylase activity and changes in function demonstrated in the many investigations already quoted, appear to justify the adoption of the working hypothesis that there is indeed a direct relationship between phosphorylase activity and some stage of the contraction cycle of the heart. Such a hypothesis is strengthened by the observations of Ellis and Vincent[14] that adrenaline and acetylcholine produce changes in glycogen content of the perfused heart.

Because of the special properties of the phosphorylase enzymes, there are two ways by which phosphorylase activity may be regulated: (1) by changes in the equilibrium phosphorylase *b* ⇄ phosphorylase *a* produced by cyclic AMP or other factors influencing this reaction, or (2) by changes in the concentration of AMP followed by an increase or decrease in the activity of phosphorylase *b*. As already mentioned, there is considerable experimental evidence that the first of these two mechanisms is involved in the action of the autonomic nervous system on heart function. It is proposed here that the second mechanism operates in the normal contractile cycle of the heart and that AMP may play a unique part in the regulation of heart rhythmicity.

It is proposed that AMP, produced during any stage of the contraction cycle, causes an increase in phosphorylase activity. In turn the stimulation of phosphorylase leads to an increase in glycolysis (or complete oxidation of glucose units), bringing about phosphorylation of ADP and through the intervention of the myokinase reaction, the disappearance of AMP. The essential role of AMP is that it produces an activation of phosphorylase and by this action causes its own destruction. By such a mechanism a discontinuous or rhythmical formation of high-energy phosphate bonds can be envisaged.

Cain and Davies[15] recently demonstrated in convincing experiments that in skeletal muscle, in which creatine phosphoryl transferase was inhibited by dinitrofluorobenzene, the energy for contraction came from ATP. It is therefore likely that in cardiac muscle also the primary source of energy for contraction is ATP. Assuming this to be the case, one may construct a picture of the possible chemical events in the contractile cycle of the heart that includes the proposed role of the phosphorylase reaction (Fig. 1). (1) During systole ATP is split and ADP is produced; (2) the ADP formed is transformed partially to AMP and ATP by the intervention of the myokinase reaction; (3) during diastole the AMP formed from breakdown of ATP stimulates phosphorylase *b*, causing an increased metabolism of glycogen (to lactate or carbon dioxide + water) and an increase in the rate of high-energy phosphate formation with consequent synthesis of ATP from ADP and AMP; (4) the concentration of AMP and the activity of phosphorylase *b* decreases and the concentration of ATP is restored. A new cycle of contraction and relaxation may now start again.

This description of the possible biochemical reactions during the cycle of cardiac activity represents no more than a simplified picture of a very complicated set of events. Ultimate sources of energy other than glycogen as well as the role of ions, for example, have been ignored. Whatever the actual chemical events in cardiac contraction and relaxation may prove to be, what is emphasized here is that AMP may serve as a link between the reactions which cause a splitting of ATP and the reactions involved in the synthesis of ATP. By the intervention of myokinase or possibly by direct dephosphorylation of ADP, AMP is formed when ATP is acted on by ATP-ase. The stimulation by AMP of phosphorylase *b* may be considered a feed-back mechanism whereby ATP is rapidly restored. According to such a concept, the enzyme phosphorylase *b* is involved in a rhythmical formation and transfer of pulses of high-energy phosphate, while phosphorylase *a* produces a steady rate of glycolysis and high-energy phosphate formation. This concept allows a role for both forms of muscle phosphorylase and gives more meaning to the experiments which have demonstrated that alterations in cardiac function produced by a variety of means are associated with changes in the equilibrium phosphorylase *b* ⇄ phosphorylase *a*.

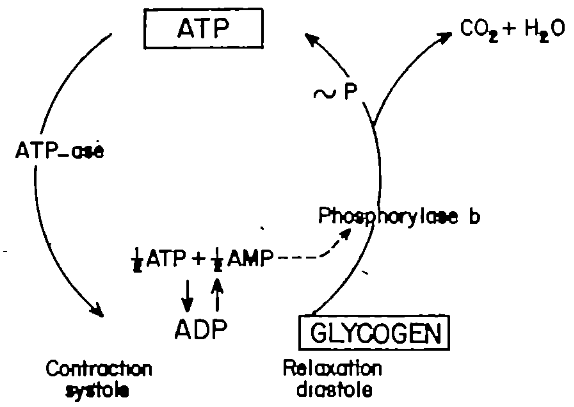

Fig. 1

Although at the present time there is little direct evidence to support the theory proposed here, there is much information about cardiac metabolism which is consistent with it. It has been shown that, except during strong sympathetic stimulation, the major proportion of phosphorylase is present in the *b* rather than the *a* form. In the open-chest rat, for example, control values of cardiac phosphorylase *a* range from 30 to 40 per cent of total phosphorylase[13] and in the isolated perfused heart the activity of phosphorylase *a* is even lower[12]. For AMP to play a part, such as that proposed here, its average concentration in the heart must be near the concentration for half maximal stimulation of phosphorylase *b* (5×10^{-5} M). Accurate values for tissue concentrations of AMP are, unfortunately, extremely difficult to obtain, since the slightest breakdown of ATP or ADP during the analytical procedures will produce erroneously high results. Nevertheless, it has been found by Fleckenstein *et al.*[16] that the concentration of AMP in the heart is extremely low, compared with the values for ADP and ATP. In our own laboratory, using rapid freezing and enzymatic methods, values for AMP in rat heart ranging from 0·1 to 0·2 μM/g (10^{-4} M) were obtained (Haugaard, N., and Corson, S. L., unpublished work). If some AMP exists in a bound form within the cell the average concentration of free AMP may be close to 0·05 μM/g, the amount that produces half maximal stimulation of phosphorylase *b*.

Another indication that the concentration of AMP is low in heart is the observation that AMP is an extremely efficient acceptor of phosphate in this tissue[17]. In heart homogenates, oxidizing glucose or glycogen, rates of phosphorylation of AMP up to 7,000 μM/g/h (wet weight) have been recorded[17]. An additional factor which will tend to maintain a low concentration of AMP in the heart is the presence of a very active 5′-nucleotidase associated with microsomes (Inesi, G., and Haugaard, N., unpublished work). Although the foregoing considerations provide indirect support for the proposed role for AMP and phosphorylase *b* in cardiac contraction, it is obvious that more direct evidence is needed.

Efforts are being made in this laboratory to determine the true concentrations of AMP in the heart under a variety of experimental conditions and to attempt to correlate changes in AMP concentration with alterations in function. In the meantime, it is hoped that the concepts outlined here, even if eventually rejected, will help stimulate work leading to a better understanding of the role of the phosphorylase enzymes in cardiac contraction.

SYNTHETIC CYTOLIPIN *H* AND OTHER LACTOSIDES

By Dr. A. C. SCHRAM, Dr. E. H. BYERS and Dr. R. H. WILSON

Veterans Administration Hospital and Biochemistry Department, University of Texas Southwestern Medical School, Dallas

The hapten cytolipin *H* has been isolated from a cultured human epidermoid carcinoma by Rapport, Graf, Skipski and Alonzo[1]. Chemical degradation of the hapten characterized it as a simple, non-reducing glycolipin composed of sphingosine, a fatty acid, glucose and galactose in equimolar ratios. The carbohydrate moiety was identified as lactose[2], pointing to a ceramide lactoside as a probable structure for cytolipin *H*. This structure could be proved by synthesis. Synthetic analogues of similar structure might exhibit competitive inhibition at some site of the cytolipin *H* metabolism, and thereby be useful in the determination of any metabolic role of cytolipin *H* in cancer cells.

Ceramide was obtained by enzymatic hydrolysis of sphingomyelin[3], which had been extracted from beef heart lecithinsphingomyelin sludge. Purified ceramide and α-acetobromolactose were reacted under the conditions used by Sowden and Spriggs[4] for the synthesis of β-gentiobiose. A lactoside was obtained, which melted with decomposition at 86° C, which had a carbohydrate content of 32 per cent (measured on the acid-hydrolysis products of 100 μg of the compound[5]), and an optical rotation of + 2·1° (0·49 per cent in pyridine). The infra-red spectrum of the compound is practically identical to that of an authentic sample of cytolipin *H* isolated and given to us by Dr. M. M. Rapport (Fig. 1).

The same conditions of synthesis were used for preparing the lactosides of methyl, ethyl, *n*-propyl, *n*-butyl, *n*-pentyl, *n*-hexyl, *n*-heptyl, *n*-octyl, *n*-nonyl, *n*-decyl, *n*-hexadecyl, and isopropyl alcohols, and for the preparation of the lactosides of some fatty acid amides of 2-hydroxyethylamine. The lactosides of phenol, *p*-phenylphenol, *p*-nitrophenol, and *p*-aminophenol were prepared by the method of Babers and Goebel[6].

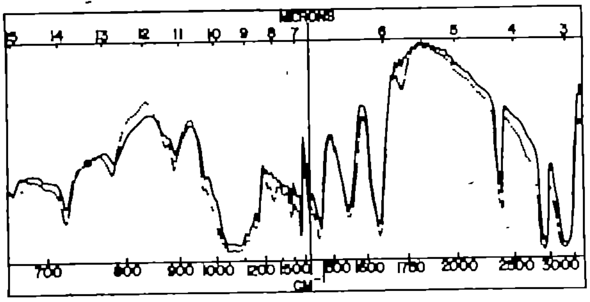

Fig. 1. Infra-red spectra of cytolipin *H* (solid line) and ceramide lactoside (broken line), pressed in potassium bromide

For immunological investigations, the *p*-aminophenollactoside was diazotized and coupled to bovine serum albumin and to egg albumin according to the method of Goebel and Avery[7]. Rabbits were immunized with a single intramuscular injection of 10 mg diazophenollactoside bovine serum albumin, homogenized in Freund's adjuvant and hyaluronidase[8], and boosted 6 weeks later with an intravenous injection of 65 μg of the same preparation of diazophenollactoside bovine serum albumin.

Rapport *et al.*[1] showed in inhibition investigations that the carbohydrate residue of cytolipin *H* had the configuration of lactose[2]. Cytolipin *H* is non-reducing, and therefore the lactose moiety must be linked through an acetal bond to the ceramide moiety. Of the two hydroxyl groups on the sphingosine molecule, the terminal (primary) hydroxyl group is most likely the one involved in the bond. This is the kind of structure assigned to cerebrosides, and the infra-red spectrum of cytolipin *H* (Fig. 1) is very similar to that of cerebrosides[9].

The synthesis of galactosphingolipids reported by Shapiro and Flowers[10] would yield a dihydrosphingosine analogue of cytolipin *H*. A preliminary investigation of the infra-red spectrum of cytolipin *H* revealed an absorption maximum at 969 cm⁻¹, which is characteristic of the *trans* configuration of a HC=CH double bond. Therefore, it appeared that natural cytolipin *H* must contain sphingosine, and another method was chosen. The fatty acid residue of cytolipin *H* has not been entirely characterized; but it is unlikely that a specific fatty acid is required for haptenic activity[11]. As the fatty acid is apparently linked to the sphingosine moiety through an amide bond, ceramide was the obvious starting material, even though ceramide prepared from natural extracts will contain a mixture of fatty acid residues.

Since the synthetic ceramide lactoside contains about 32 per cent carbohydrate, this compound has only one lactose entity per molecule. A lactoside linked to the secondary hydroxyl group of ceramide is rather unlikely, since the hydrogen of a secondary hydroxyl group is less readily replaced than that of a primary hydroxyl group, especially in this case where the secondary hydroxyl group is a sterically hindered allylic hydroxyl group. This argument is substantiated by the fact that the lactoside of *N*-(2-hydroxyethyl)-docosanoamide (which is the lactoside of a primary hydroxyl group) has an infra-red spectrum very similar to that of cytolipin *H* and of ceramide lactoside.

The main differences between the spectra of cytolipin *H* and of ceramide lactoside are found in three places

(Fig. 1): around 1,725 cm^{-1}; between 1,200 and 1,400 cm^{-1}; and between 850 and 950 cm^{-1}. The absorption at 1,725 cm^{-1} is due to a trace of ester, attributed to some acetate residue on the carbohydrate moiety. As ester carbonyl absorption is very strong, the intensity of the peak shows that only a trace of acetate is present. The differences in the 1,200–1,400 cm^{-1} region are probably due to differences in the fatty acid residues of the two compounds. It has been our experience that lactosides of different fatty acid amides of 2-hydroxyethylamine differ in that part of the spectrum. As an example, Fig. 2 shows the relative differences in the spectrum of the lactosides of *N*-(2-hydroxyethyl)-docosanoamide (line *D*) and of *N*-(2-hydroxyethyl)-oleamide (line *C*) in comparison with the corresponding part of the spectrum of ceramide lactoside (line *B*) and of cytolipin *H* (line *A*). The single peak present at 1,252 cm^{-1} in lines *B* and *D* strongly suggests a saturated straight-chain fatty-acid residue for ceramide lactoside. Indeed, ceramide obtained by the same enzymatic hydrolysis and from the same source has been shown to contain mostly lignoceric acid[3]. The peak at 969 cm^{-1} for both cytolipin *H* and ceramide lactoside shows that both compounds do have some degree of unsaturation (sphingosine), barring interference from the carbohydrate absorption, which is so heavy in that part of the spectrum.

The absorption maxima at 874 and 892 cm^{-1} in the spectrum of ceramide lactoside are due respectively to the D-galactosidic and β-glucosidic links[12]. The spectrum of lactose itself (Fig. 3, line *E*) shows those two peaks at 876 and 897 cm^{-1}. They are present in all the lactosides which have been synthesized, though the intensity of the β-glucosidic bond absorption is increased in the lactosides, presumably by stabilization of the acetal bond after replacement of the hydrogen by another radical (methyl, etc.).

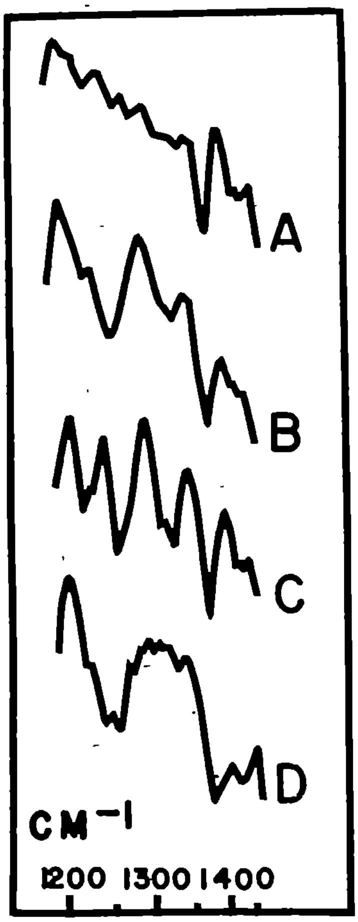

Fig. 2. Infra-red spectra in the region of 1,200–1,400 cm^{-1}, of cytolipin *H* (line *A*); of ceramide lactoside (line *B*); of the lactoside of *N*-(2-hydroxyethyl)-oleamide (line *C*); and of the lactoside of *N* (2-hydroxyethyl)-behenamide (line *D*); pressed in potassium bromide

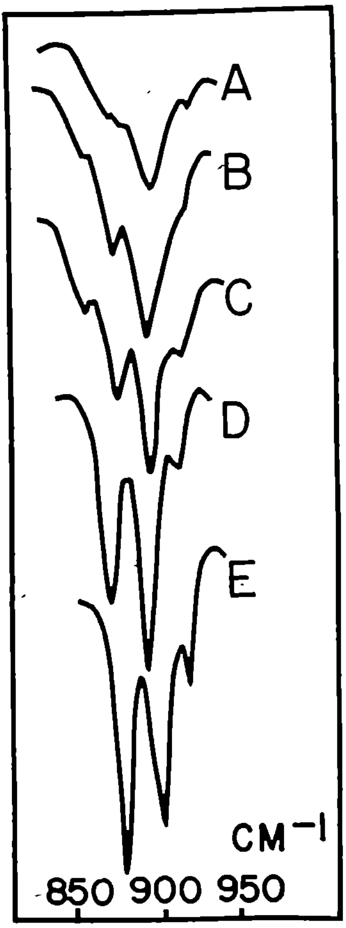

Fig. 3. Infra-red spectra in the region of 850–950 cm^{-1}, of cytolipin *H* (line *A*); of ceramide lactoside (line *B*); of the lactoside of *N*-(2-hydroxyethyl)-palmitamide (line *C*); of *n*-hexadecyl lactoside (line *D*); and of β-lactose (line *E*); pressed in potassium bromide

The methyl lactoside had an optical rotation of +6·4°. β-Methyl lactoside has been reported to have an optical rotation of +6·3° (ref. 13), showing that the β-lactoside had been obtained exclusively. The other lactosides all exhibited relatively negative optical rotations, varying from −12·7° (*n*-propyl lactoside) to +6·4° (methyl lactoside). Since all showed the characteristic maximum absorption in their infra-red spectrum between 889 and 892 cm^{-1}, the optical rotations support the labelling of the compounds as β-lactosides.

The complement-fixation tests which were so useful in the isolation and characterization of cytolipin *H* cannot prove the identity of cytolipin *H* and ceramide lactoside. Since it was found that lactose is the determinant site of this hapten any lactolipid would elicit a positive response[3].

Skin tests of ceramide lactoside and other lactosides were positive only in rabbits immunized against the diazophenollactoside bovine serum albumin, as one would expect from animals immunized against a lactoside hapten. This showed the presence of a lactoside group in the compounds which elicited a positive skin reaction Ring precipitin tests proved that the lactose structure had not been affected during the handling in the synthetic procedures: lactose and all lactosides tested exhibited inhibition of the precipitin reaction between antiserum and diazophenollactoside 'egg albumin, while other sugars were inactive.

Absolute proof of identity of cytolipin *H* and ceramide lactoside has not been established. But the accumulation of data from synthesis, infra-red spectrum analysis, and immunology shows that the synthetic compound is a ceramide-β-lactoside, and is very similar, if not identical, to cytolipin *H*.

We thank Mr. A. P. Boer and Mr. V. Jurevics for their assistance. We also thank the Lederle Laboratories (Pearl River, New York) for gifts of lecithinase *D*, from *Clostridium perfringens* type *A* toxin; Mr. S. Rosenberg (Sylvana Chemical Co., Orange, New Jersey) for gifts of lecithinsphingomyelin sludge; and the Wyeth Pharmaceutical Co. for gifts of hyaluronidase ('Wydase').

This work was supported in part by National Institutes of Health grant *E*–3852 and American Cancer Society grant *T*–246.

STRUCTURAL REQUIREMENTS FOR PUROMYCIN INHIBITION OF PROTEIN SYNTHESIS

By Dr. DANIEL NATHANS* and Dr. AMOS NEIDLE

The Rockefeller Institute, New York, and Columbia University, New York

THE antibiotic puromycin[1] has been found to inhibit protein synthesis in a wide variety of organisms and tissues[2–5]. Its structure (Fig. 1) has a striking resemblance to that of aminoacyl-*s*RNA, as first recognized by Yarmolinsky and de la Haba[6], who showed that the antibiotic inhibits amino-acid transfer from *s*RNA into proteins. Along with inhibition of protein synthesis puromycin induces the formation of small peptides from the amino-acids originally attached to *s*RNA[7,8]. Although growth of the peptide chain on the ribosome appears to be interrupted by puromycin[9–11], its action is not yet entirely understood in biochemical terms. In the course of studies on protein synthesis from aminoacyl-*s*RNA in the *E. coli* ribosomal system[12], we have examined the effect of analogues and isomers of puromycin in this system in the hope that a definition of the structural requirements for inhibition would help in understanding its mode of action.

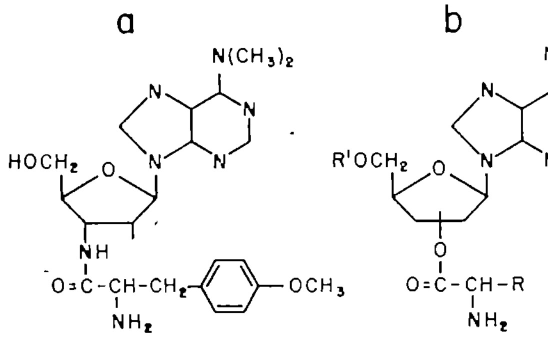

Fig. 1. Structure of puromycin (*a*) and the adenosine end of aminoacyl-*s*RNA (*b*)

Most of the compounds tested were the gift of Dr. Leon Goldman of the Lederle Laboratories, American Cyanamid Corporation, Pearl River, New York. The remainder (synthetic puromycin and the L-phenylalanyl, L-prolyl and L-phenylalanyl-*p*-methoxy-L-phenylalanyl analogues) were synthesized from the aminonucleoside of puromycin (or in the case of the peptidyl analogue, from puromycin) and the corresponding carbobenzoxy amino-acid by the method of Baker *et al.*[13]. The 2′-isomer of puromycin was obtained by coupling the corresponding 2′-aminonucleoside (9-(2′-deoxy-2′-amino-β-D-ribofuranosyl)-6-dimethylaminopurine, obtained from Dr. Goldman) with carbobenzoxy-*p*-methoxy-L-phenylalanine. The product, which was not crystallized owing to the small amount of starting material available, had the same R_F as puromycin in three chromatographic systems and the same electrophoretic mobility at *p*H 4·7. These properties differed markedly from the starting 2′-aminonucleoside, the mobility of which was identical to that of the 3′-aminonucleoside. Also, the absorption spectrum of the 2′-isomer of puromycin, purified by paper chromatography in butanol–acetic acid–water, was the same as that of puromycin.

Results of the inhibition studies are given in Table 1. Each compound was tested both in the regular system with *s*RNA esterified with all amino-acids, including ^{14}C-leucine[12], and in the polyuridylate system of Nirenberg and Matthaei[14] with ^{14}C-phenylalanyl-*s*RNA. Though the latter system seems somewhat less sensitive to puromycin, the results in the two cases are practically identical. In addition, many of the compounds were tested with rat liver preparations[15] and similar results obtained. As indicated in Table 1, the effect of each compound on the enzymatic formation of peptides and free amino-acids ('alcohol-soluble products') from aminoacyl-*s*RNA (ref. 8) has also been determined.

With the reservation that in some instances only a single compound of a given type has been tested, the major conclusions with regard to the structural specificity of puromycin may be summarized as follows: (1) Both the aminonucleoside and amino-acid are required. (Yarmolinsky and de la Haba previously observed that removal of the purine base resulted in loss of activity[6].) (2) The aminonucleoside must be substituted at the 3′-position. (3) The amino-acid must be of L-configuration. (4) Aromatic amino-acid derivatives are by far the most potent, whereas derivatives with certain amino-acids are inactive. (5) Compounds with a dipeptide side-chain are inactive.

The great differences in activity of compounds with different amino-acids were unexpected. One might have anticipated that any analogue with a natural amino-acid would be equally effective since each of these compounds would resemble an aminoacyl-*s*RNA. As noted, however, substitution with some amino-acids (glycine, proline) leads to analogues with no activity; substitution with others (L-leucine) gives slight activity; and the presence of phenylalanine (with or without a *p*-alkoxy group) or tyrosine results in marked activity. The basis for this specificity is unknown, but could reflect a tighter binding of the aromatic aminoacyl derivative to the inhibited site.

The fact that the phenylalanyl analogue is a more potent inhibitor of both phenylalanine and leucine incorporation than is the leucyl analogue suggests that the amino-acid substituent does not confer specificity for the inhibition of incorporation of that particular amino-acid.

---

* Present address: Department of Microbiology, the Johns Hopkins University School of Medicine, Baltimore, Maryland.

Table 1

Compound	Conc. (M)	Phenylalanine incorporation % inhibition	Phenylalanine incorporation % in alcohol-soluble products	Leucine incorporation % inhibition	Leucine incorporation % in alcohol-soluble products
Puromycin	10^{-4}	72	20	83	28
	10^{-3}	96	21	93	33
Puromycin (synthetic)	10^{-4}	66	20	84	39
	10^{-3}	95	27	91	37
Altered aminonucleoside					
2′-puromycin isomer	10^{-4}	0	0	3	1
	10^{-3}	0	0	2	0
5′-puromycin isomer	10^{-4}	0	0	0	0
	10^{-3}	0	0	0	0
N-diethyl analogue	10^{-4}	23	7	63	30
	10^{-3}	60	14	81	36
3′-aminonucleoside of puromycin	10^{-3}	—	—	0	0
Altered side-chain					
L-phenylalanyl analogue	10^{-5}	—	—	49	—
	10^{-4}	55	13	79	—
	10^{-3}	94	20	90	40
O-butoxy-L-phenylalanyl-analogue	10^{-4}	22	7	60	18
	10^{-3}	63	16	78	27
D-phenylalanyl analogue	10^{-4}	0	0	17	3
	10^{-3}	19	0	35	18
L-tyrosyl analogue	10^{-4}	14	3	65	19
	10^{-3}	67	12	81	—
L-tryptophanyl analogue	10^{-4}	0	0	0	0
	10^{-3}	6	0	12	7
L-leucyl analogue	10^{-4}	0	0	10	6
	10^{-3}	0	0	35	17
L-prolyl analogue	10^{-4}	—	—	10	0
	10^{-3}	—	—	9	2
Glycyl analogue	10^{-4}	1	0	7	2
	10^{-3}	0	0	4	4
Peptidyl side-chain					
Glycyl-*p*-methoxy-L-phenylalanyl analogue	10^{-4}	11	0	—	—
L-phenylalanyl-*p*-methoxy-L-phenylalanyl analogue	10^{-4}	6	2	—	—

Incubation conditions were similar to those given previously[12]. In a volume of 0·10 ml. the following components were present: 0·4 mg of ribosomes (phenylalanine) or 1·0 mg (leucine); 10 μg of transfer factor; 0·0005 M GTP; 0·01 M phosphoenolpyruvate; 3 μg pyruvate kinase; 0·01 M glutathione; 0·012 M $MgCl_2$; 0·08 M KCl, 0·05 M *tris* HCl pH 7·4. In the phenylalanine experiments 0·2 μg of polyuridylate and 25 μg of sRNA charged only with ^{14}C-phenylalanine (2,890 c.p.m.; 1·2 × 10^6 c.p.m./μmole) were also present; and in the leucine experiments, 12 μg of aminoacyl-sRNA containing 5,360 c.p.m. ^{14}C-leucine (1·6 × 10^6 c.p.m./μmole). After 10 min at 30°, 2 volumes of cold ethanol containing 1/20 volume of 20 per cent potassium acetate was added and an aliquot of the supernatant counted. The precipitate was then extracted with 5% TCA at 90° for 15 min, washed, and counted as described previously[12]. In the absence of inhibitor, 1,250 c.p.m. were incorporated into the TCA precipitate and 580 c.p.m. were found in the alcohol supernatant with phenylalanyl-sRNA; and 2,070 c.p.m. in the precipitate and 1740 c.p.m. in the alcohol supernatant, with leucyl-sRNA. Per cent inhibition refers to the incorporation of isotopic amino-acid into acid-precipitable form; per cent in alcohol-soluble products refers to the per cent of added ^{14}C-amino-acid found in this fraction minus that due to chemical deacylation.

Table 2

Compound	Conc. (M)	Per cent inhibition leucine	Per cent inhibition proline
Puromycin	10^{-4}	80	85
Leucyl analogue	10^{-3}	57	67
Prolyl analogue	10^{-3}	13	0

Incubation conditions were similar to those given in the legend of Table 1.

Also consistent with this is the observation (Table 1) that the tyrosine analogue inhibits phenylalanine incorporation in the polyuridylate system. This lack of specificity is again seen in the experiment reported in Table 2; the leucyl analogue is equally effective in reducing leucine and proline incorporation, whereas the proline analogue has little or no effect in either instance.

The striking difference in activity between the 2′ and 3′ substituted nucleosides deserves comment, since it might be related to the specific position of the amino-acid on the adenosine of sRNA[16]. Such an interpretation, however, must await the determination of the exact position of the amino-acid in esterified sRNA.

As shown in Table 1, the amount of alcohol-soluble compounds formed in the presence of various analogues correlates well with the degree of inhibition of protein synthesis by a given compound, thus substantiating the conclusion that the enzymatic formation of small peptides from aminoacyl-sRNA is intimately related to the mechanism by which puromycin inhibits protein synthesis.

Finally, the specific structural requirements for inhibition suggest that puromycin acts by binding to the active centre of an enzyme or to a ribonucleoprotein involved in the last steps of protein synthesis. In considering the reactions which occur[7], the possibility that puromycin interacts with the peptide bond-forming enzyme is an attractive hypothesis.

We thank Dr. Fritz Lipmann and Dr. Heinrich Waelsch, in whose laboratories this work was carried out, for their interest and advice.

EFFECT OF RNA FROM NORMAL HUMAN BONE MARROW ON LEUKÆMIC MARROW *IN VIVO*

By Dr. S. DeCARVALHO

Laboratory of Hæmatology, Doctors Hospital and Laboratory of Cancer Virology and Immunology,
Rand Development Corporation, Cleveland, Ohio

It is now generally accepted that RNA, conveying DNA's information, directs specific proteinopoiesis. This notion, derived mainly from cytochemical and biochemical evidence, is being utilized to demonstrate specific proteinopoietic activities of native ribonucleic acids extracted from different cellular systems. It has been shown that RNA from yeast cells adapted to copper specifically protects unadapted strains against lethal doses of copper[1], and that a new type of RNA appears in yeast cells when catalase synthesis is induced by exposure to oxygen[2].

True redifferentiation of mouse ascites tumour cells by RNA from normal calf liver may have been obtained by Niu[3–5]. On the other hand, normal mouse kidney cells treated by RNA from the ascites tumour cells were able to induce local tumours in mice[5]. We have shown that RNA from human leukæmic and tumour cells can be cytopathogenic for cultures of primary lines of human cells[6,7] and oncogenic and leukæmogenic for animals[8]. The interplay of normal and malignant RNA with malignant and normal cells obtained with the Novikoff tumour model points towards the possibility of redifferentiating human malignant cells with human normal RNA[9-12]. RNA information transfer between sickle hæmoglobin-producing and normal human erythroblasts was apparently obtained by Weisberger[13]. Significant reduction in tumour takes were obtained by Harel *et al.*[14] by the effect of normal mouse liver RNA on *FLS* ascites carcinoma cells of the Swiss mouse. Proof of penetration of labelled RNA into normal and tumour cells was obtained by Schwarz *et al.*[21].

The foregoing evidence led to the hypothesis that RNA from malignant cells is biologically different from RNA from non-malignant cells and that the degree of differentiation or undifferentiation of the malignant cells might reflect the relative amounts of normal and abnormal RNA. Abnormal RNA would be unable to direct specific protein synthesis; enzyme deletions and antigenic simplification, both found in malignant cells, could be the indirect result of the unfitness of the abnormal RNA[15]. Of the two classes of RNA now described by Sibatani[16] the high metabolically active, low in guanidine content and the less metabolically active, high in guanidine content, the last was reported a few years ago to be predominant in malignant cells[17].

A pattern for alterations of normal RNA under carcinogenic influences (viral, physical, chemical) may have been set by the experiments of Tsugita and Fraenkel-Conrat[18] and Siegel[19], and the findings of Alderson[20]. The transformation of cytosine into uracil in the RNA of the tobacco mosaic virus by nitrous acid resulted in a mutant producing a protein differing from the natural TMV protein in the replacement of proline by leucine in a certain location. It is recalled that a similar difference in one single aminoacid is all that distinguishes hæmoglobin *A* from sickle hæmoglobin and other hæmoglobins. Similar mutagenic alterations on the TMV RNA were brought about by 4-nitroquinoline-N-oxide[22], a substance which is leukæmogenic for the mouse by mechanisms suggesting endovirogenesis[23].

Departing from the hypothesis that malignant cells remain undifferentiated because of a deficiency of normal proteinopoietic RNA, an attempt was made to supply these cells *in situ*, with RNA extracted from normal cells. Leukæmic marrow and RNA from normal bone marrow seemed an ideal system for such experiment.

It must be emphasized that the aim of the work recorded here is to examine some biological properties of the RNA from normal marrow, specifically to determine if the hæmatopoietic information it contains can be transferred by a sort of sub-cellular homografting of a template to other cells. This work by no means contains a therapeutic or pharmacological implication, and it is presented for the possible biological consequences rather than for its content of clinical repercussions.

RNA from human normal bone marrow. Non-leukæmic bone marrow was obtained from a 48-year-old white male presenting a history of epigastric distress which on X-ray was shown to be due to herniation of gastric mucosa through the pylorus. The following were his hæmatological parameters: Hæmatocrit value 52; hæmoglobin 15·30 g per cent; red blood cells 5,200,000 per mm³; white blood cells 8,000 per mm³; differential count in the peripheral blood: neutrophils 57 per cent, lymphocytes 42 per cent, and monocytes 1 per cent.

25 ml. of marrow were drawn from a sternal puncture in 2·5 ml. of 3·8 per cent sodium citrate. This marrow contained a total of 1·75 × 10⁶ cells per ml. and the myelogram was within normal limits.

RNA from this marrow was extracted by phenol. The alcohol-precipitate was redisolved in isotonic phosphate-buffered saline at *p*H 7·1. The final concentration of RNA was adjusted to 90 μg/ml. This preparation was filtered through 03 Selas porcelain filters and kept at −20° C for 24 h when it was thawed to 2° C for use.

Leukæmic patients' histories. H. M., 57-year-old white male. Admitted for the first time on October 28, 1959, because of petechiæ and small ecchymoses over chest and limbs. Three weeks before admission started noting easy fatigue and tiredness, pallor of skin and mucosæ, petechiæ and small ecchymoses and papullar infiltrations over the skin of chest and legs. His blood data were: hæmoglobin 8·65 g per cent; red blood cells 2,560,000/mm³; white blood cells 11,400/mm³; 52 per cent stem cells, 30 per cent lymphocytes, 11 per cent neutrophils, 1 per cent plasmocytes; 40,000/mm³ platelets, *O* reticulocytes. The sternal bone marrow was hypoplastic and paucicellular with partial megaloblastic transformation of the erythropoiesis. The leukæmic cells, representing about 15 per cent of all elements, were of myeloblastoid resemblance.

The treatment from October 30, 1959, to March 14, 1960, had consisted of transfusions, methyl-prednisolone and 6-mercaptopurine.

During the period of treatment the hæmoglobin oscillated between 8 and 12 g per cent, the leucocyte count from 14 to 40,000/mm³ and the platelets from 40 to 80,000/mm³ with 25–90 per cent of leukæmic cells. No remissions were ever achieved, although the general condition was satisfactory, the patient was asymptomatic, ambulatory and even resumed part-time work. Two weeks before this experiment, all treatment was discontinued. Tables 1 and 2 contain marrow data a few minutes before the experiment started.

Table 1. MYELOGRAMS OF PATIENT H. M. (% OF 500 CELLS COUNTED)

Place of instillation	Before normal RNA		2 days after 1st installation of normal RNA	10 days after normal RNA
Sternum	Leukæmic cells	84	63	91·5
	Erythroblasts	9	21	6
	Myelocytes	7	14 5	2·0
	Megakaryocytes	0	1·5	0·5
Place of instillation	Before buffered saline		2 days after buffered saline	10 days after buffered saline
Iliac bone	Leukæmic cells	92·5	92	92
	Erythroblasts	5	6·5	5·5
	Myelocytes	2·5	1·5	2·5
	Megakaryocytes	0	0	0

Table 2. MYELOGRAMS OF PATIENT M. H. (% OF 500 CELLS COUNTED)

Place of instillation	Before normal RNA		2 days after normal RNA	10 days after normal RNA
Sternum	Leukæmic cells	99	55	99
	Erythroblasts	1	30	0 5
	Myelocytes	0	13·5	0·5
	Megakaryocytes	0	1·5	0
Place of installation	Before buffered saline		After buffered saline	10 days after buffered saline
Iliac bone	Leukæmic cells	99·5	99	100
	Erythroblasts	0·5	0·5	0
	Myelocytes	0	0·5	0
	Megakaryocytes	0	0	0

M. H., 71-year-old white male. Admitted on April 1, 1960, because of weakness, dizziness and faintness. The laboratory findings on admission were: hæmoglobin 7·5 g per cent; red blood cells 2,160,000/mm³; white blood cells 4,100/mm³; of the last, 50 per cent were myeloblastoid anaplastic stem cells and 5 per cent basophils. The bone marrow was cellular and monomorphic, 95 per cent of its cells being leukæmic cells. Treatment consisted, until 2 weeks before this experiment, of transfusions and antibiotics.

Intra-osseous instillation of normal marrow RNA. A puncture was made in the middle of the second sternal piece. Marrow was aspirated for morphological study. Through the same needle 1 ml. of the normal RNA preparation was injected. At the same time a puncture was made in the right iliac crest at a point 1 cm behind the anterior superior spine at an angle pointing to this spine. Marrow was obtained for morphological study followed by injection of 1 ml. of phosphate-buffered saline as control. Later aspirations of marrow were made in the same marked places.

Differential counts represent percentages of cells in Wright stained smears. Each value is the average of three different counts. Absolute total counts were made from a suspension of 2 ml. of marrow diluted to 10 ml. with citrate-buffered saline. Counts were made in Levy–

Hausser counting chambers. Each value represents an average of three counts in 64 large squares. Absolute figures for leukæmic cells, myelocytes and megakaryocytes were calculated from the percentages in smears and total counts. Absolute counts of erythroblasts were obtained directly in cell suspensions with the violet light microscope method described by Wilkins and us[11,12] making use of the specific hæm absorption in the Soret band. This method permitted to check the accuracy of the indirect absolute estimations which we found to represent an approximation of ± 7 per cent.

Tables 1 and 2 summarize the cellular composition of the marrows obtained before and after instillation of normal marrow RNA and control-buffered saline.

Because of the slight, though clear, change in the hæmopoietic direction and the quick reverse to the previous full leukæmic stage after this first RNA instillation, an amount of normal marrow RNA 10 times larger was reinstilled in patient H. M. 900 μg of the same RNA in 10 ml. of buffered saline was instilled in the sternal manubrium 30 days after the first RNA instillation in the second sternal piece. Samples of marrow were taken before and 2, 6, 10 and 14 days after this reinstillation. Table 3 gives the results.

Table 3. RELATIVE AND ABSOLUTE DIFFERENTIAL CELL COUNTS OF MARROW CELLS OF PATIENT H. M. AFTER SECOND REINSTILLATION OF 900 μG OF NORMAL HUMAN MARROW RNA IN THE STERNAL MANUBRIUM

	Time after RNA instillation									
	0 days		2 days		6 days		10 days		14 days	
Cells	Rel.	Abs.	Rel.	Abs.	Rel.	Abs.	Rel.	Abs.	Rel.	Abs.
Leukæmic cells	91	3 7	2	0·1	20	0·6	40	1·2	90	3 6
Erythroblasts	6·5	0·25	65	2	56	1·6	36	1	6	0·2
Myelocytes	1·5	0 1	31	0·9	22	0·6	13	0·4	4	0 2
Megakaryocytes	0	0	2	0·6	2	0·1	0·3	0 001	0	0
Total absolute cell numbers	4 05		3·6		2·9		2·6		4·0	

Relative counts: Percentages in 1,000 cells in smears
Absolute counts. Millions in 2 ml. of marrow

Fourteen days after the second instillation of RNA, when the local marrow had reverted back again to a full leukæmic stage, intravenous injections of 1,800 μg of RNA were made three times at two-day intervals. No change was detected in the peripheral blood counts or in an iliac marrow sample taken 8 days after the last intravenous injection.

Morphological studies and differential cell counts of the marrows of the two leukæmic patients clearly indicated a local hæmopoietic response following instillation of the RNA from normal marrow. For reasons not well understood, this hæmopoietic response either fades away or it is completely obscured by the leukæmic proliferation. There seems to be a relationship between the amount of RNA instilled and the degree of hæmopoietic response as well as the period of time for reversion to the previous leukæmic stage. When 90 μg of RNA were instilled, only a slight hæmopoietic response was noted with reversion to the *statu quo ante* within 10 days. When 10 times that amount was re-instilled, a full hæmopoietic response was obtained in 2 days with progressive decline within 14 days.

Failure of intravenous administration of RNA to induce marrow changes may probably be accounted for by quick inactivation in the circulation by ribonuclease or inhibition by strong combination of the RNA with plasma proteins. Data on this problem are apparently conflicting. Gierer and Schramm[23] have indicated that highly purified RNA from tobacco mosaic virus is largely inactivated by proteins in serum. However, injections of tumoral and leukæmic RNA have been successful in inducing disease in mice[8,24-26], thus indicating persistence of activity after injection. It may be that these preparations are not so highly purified as those of Schramm and that residual protein affords some degree of protection. Ellem[27] and we found[7] that in testing the cytopathogenicity of RNA preparations, it is very important to wash off the medium of the tissue culture and to operate in conditions of osmolality, *p*H, temperature and time for absorption which proved the most favourable to the nucleic acid, while extracellular. The foregoing conditions were to a certain extent reproduced in the method of intra-osseous instillation and this fact probably accounts for the success of local application and the failure of the intravenous administration of the RNA.

While it is possible to obtain these conditions *in vitro*, it will probably be necessary to learn how to reproduce them *in vivo* before we will be able to bioassay specific proteinopoietic activities of the ribonucleic acids from different sources.

A third patient provided the opportunity for further probing into the possibilities of protecting RNA intravenously injected.

W. B., a 40-year-old male, was diagnosed of acute stem-cell leukæmia about three months after the first symptoms of weakness and fatigue. The patient had not received any form of treatment, not even transfusions. By the time of the experiment the hæmatological findings were: sternal bone marrow: 95 per cent leukæmic cells; hæmoglobin 7·00 g per cent; red blood cell 2·8 × 10^6/mm³; white blood cell 4 × 10^4/mm³ of which 80 per cent were leukæmic cells, reticulocytes 0 per cent, platelets 2 × 10^4/mm³.

An intravenous infusion of 1 g of calcium disodium versenate in 150 ml. of 5 per cent glucose in water was dripped for 1 h. Urine collected before, during this time, and in the following 2 h was assayed for calcium content, and showed an elimination of 1/5 of the total previous blood calcium. Blood calcium-levels, however, did not show appreciable differences due to bone calcium mobilization in accordance with reported findings[18]. Magnesium in the blood dropped from 3 to 0·7 mg per cent.

The last was particularly the one intended to be decreased since it is the activating oligoelement of ribonuclease.

Immediately following the last drops of the chelating agent 1,480 μg of RNA in buffered versenate saline obtained from pooled normal human bone marrow were injected intravenously.

The same procedure was repeated for 3 days. 1–2 h after the EDTA–RNA administration, chills and temporary elevation of temperature were noted. Table 4 summarizes the hæmatological findings in the first 2 weeks of observation. The hæmatopoietic response by the systemic RNA, as shown by the moderate reticulocyte elevation and hæmoglobin build up, was maintained for about the same time as that observed in the local stimulation by regional instillation of RNA.

Table 4. EFFECT OF INTRAVENOUS EDTA FOLLOWED BY NORMAL MARROW RNA ON LEUKÆMIC BLOOD

Day	Hb (g %)	RBC (10^6 mm³)	WBC (10^3 mm³)	Leukæmic cells (% of WBC)	Platelets (10^4/mm³)	Reticulocytes (%)
0	7·0	2·8	50	80	2	0
0·5	7·0	2 8	57	85	2	0
1	7·0	3·0	28	40	4	0·1
2 2·5	7·8	3·2	18	30	5	1·0
3 3·5	8·10	3·4	13	10	6	1·4
4	8·80	3·5	12	10	6	2·7
5	9·1	3·7	12	10	6	3 1
6	10·1	3·8	10	6	6	4
7	10	3·9	10	6	6	4 2
15	8	3·2	26	15	4	3·1

The question of whether the phenomena described represent specific hæmopoietic redifferentiation of the leukæmic cells by a hæmopoietic RNA template or if they represent non-specific hæmopoietic stimulation of reticulum cells by the preparation cannot be solved until RNA from organs other than bone marrow is used in the same way. Local changes of megaloblastic into normoblastic marrow were induced by Horrigan[28] following local instillation of vitamin B_{12}. In 1927 Larsell *et al.*[29] injected nucleic acid preparations from erythrocytes of the fowl intravenously into rabbits and into 11 anæmic patients. Marked hæmopoietic stimulus was noted as judged by peripheral blood cell counts. With the method of preparing the nucleic acids used by these authors, degradation of the nucleic acids and heavy protein contamination was to be expected and thus transfer of intact templates may probably be excluded. Non-specific stimulation of the hæmopoiesis by thymidine residues and analogues was probably the mechanism of action in this case. This and similar works established the basis for the therapeutic use, now discontinued, of nucleotides in aplastic anæmia to stimulate hæmopoiesis. However, one problem is to stimulate hæmopoiesis and another is to redifferentiate anaplastic leukæmic stem cells. Further evidence for true redifferentiation of the leukæmic cells may have to be gained by the use of normal RNA on cultures of leukæmic cells in the absence of potentially hæmopoietic normal reticulum cells.

CHANGE OF HUMAN CHROMOSOME COUNT DISTRIBUTIONS WITH AGE: EVIDENCE FOR A SEX DIFFERENCE

By PATRICIA A. JACOBS, MURIEL BRUNTON and W. M. COURT BROWN

Medical Research Council, Clinical Effects of Radiation Research Unit, Western General Hospital, Edinburgh

AND

RICHARD DOLL and HARVEY GOLDSTEIN*

Medical Research Council, Statistical Research Unit, University College Hospital Medical School, London, W.C.1

In previous communications we reported that the proportion of aneuploid cells in cultures of human leucocytes increased with the age of the subject[1], and that, at any given age among adults, the proportions did not differ appreciably between persons with and without cancer[2]. We now have much more data, and also have evidence that there is a difference between the sexes both in the manner in which the proportions of aneuploid cells change with age, and also in regard to the chromosomes affected.

Altogether data are available for 8,380 cells from 247 subjects with normal karyotypes inclusive of those reported previously. These cells have been obtained from blood cultures prepared by the technique of Moorhead *et al.*[3]. For each aneuploid cell an attempt has been made to describe the missing or additional chromosomes. The distribution of chromosome counts is recorded in Table 1 for each age-group, and divided according to chromosomal sex. The proportion of aneuploid cells (expressed as a percentage of the diploid cells) increases with age in both sexes; but the rate of increase in the proportion of hypodiploid cells differs between the sexes. Comparison of the regression coefficients in the linear regression formulæ (Table 1) shows the coefficients for men and women to differ significantly ($P < 0·01$). Furthermore the male data are satisfactorily explained by a linear regression, whereas inspection suggests that the female data would be better fitted by a cubic curve in which the rate of increase is low under the age of 45 years, high between the ages of 45 and 64 years, and low again at ages over 65 years. Under 45 years of age, the trend in the female data is similar to that for males, and can be fitted by the linear equation $y = 0·056x + 2·03$.

Table 1. DISTRIBUTION OF CHROMOSOME COUNTS BY AGE AND CHROMOSOMAL SEX

	Age group (yr.)	No. of subjects	Mean age*	No. of cells	No. of cells with counts of <46	46	>46	Expressed as % of diploid cells <46	>46
XY Chromosomal sex	0–4	10	1·10	300	11	287	2	3·83	0·70
	5–14	13	9·98	370	13	354	3	3·67	0·85
	15–24	22	20·84	989	36	948	5	3·80	0·53
	25–34	25	29·61	990	40	941	9	4·25	0·96
	35–44	8	37·72	256	13	239	4	5·44	1·67
	45–54	14	49·77	597	34	556	7	6·12	1·26
	55–64	10	58·50	300	19	275	6	6·91	2·18
	65–74	10	70·47	320	23	292	5	7·88	1·71
	75+	11	80·67	349	30	307	12	9·77	3·91
	All ages	123	36·15	4,471	219	4,199	53	5·22	1·26
XX Chromosomal sex	0–14	9	7·22	270	6	262	2	2·29	0·76
	15–24	33	20·08	968	33	930	5	3·55	0·54
	25–34	28	29·74	900	29	860	11	3·37	1·28
	35–44	13	39·08	452	19	427	6	4·45	1·41
	45–64	16	57·07	571	33	533	5	6·19	0·94
	65–74	11	68·09	330	37	291	2	12·71	0·69
	75+	14	81·72	418	46	356	16	12·92	4·49
	All ages	124	39·66	3,909	203	3,659	47	5·55	1·28

Regression on age of the percentage of: (i) hypodiploid cells (*XY*) $y = 0·082x + 2·26$; (ii) hypodiploid cells (*XX*): $y = 0·161x - 0·84$; (iii) hyperdiploid cells (*XY*): $y = 0·360x - 0·04$; (iv) hyperdiploid cells (*XX*): $y = 0·031x + 0·05$. Each of the regression coefficients differs significantly from zero. For (i)–(iii), $P < 0·01$; for (iv) $P = 0·04$.

* Weighted for the number of cells counted.

In examining the types of chromosomes involved in the formation of the aneuploid cells, an attempt has been made to assign the missing or additional chromosomes to one or other of the following six groups, based on the Denver classification. Where this has been possible a cell is said to have been fully analysed. In a number of cells a full analysis was not possible, but a partial analysis could be made. Such cells in males were included with those fully analysed even though the chromosome could only be ascribed to the M/L group, and in females where the chromosome could only be ascribed to the S group (S_1–S_4).

---

* Research Assistant, Department of Statistics, University College, London.

Chromosomes	Group
21, 22 and Y	S_1
16, 19 and 20	S_2
17 and 18	S_3
13, 14 and 15	S_4
6–12 and X	M
1–5	L

In group L, autosomes Nos. 1, 2 and 3 can of course be recognized as individual entities, but so few cells contained an abnormal number of L autosomes that this refinement was omitted. In the subsequent analyses of the aneuploid cells, those cells have been omitted which were of too poor a quality for full analysis, together with all cells carrying structural chromosomal abnormalities. Furthermore, cells with a chromosome count of 43 or less have also been discarded as many or all are likely to be artefacts due to rupture of the cell. The distributions of the counts in the remaining cells are given in Table 2; the results show that the proportion of hypodiploid cells still increased with age, and that the regression coefficients still differed significantly ($P < 0{\cdot}01$). In this and the subsequent analyses the numbers of hyperdiploid cells were found to be too small for any valid conclusions to be drawn.

Table 2. DISTRIBUTION OF CHROMOSOME COUNTS BY SEX AND AGE AFTER EXCLUSION OF CERTAIN GROUPS OF ANEUPLOID CELLS*

Chromosomal sex	Age group (yr.)	No. of cells with chromosome counts <46	>46	Percentage of diploid cells: Cells with hypodiploid counts	Cells with hyperdiploid counts
	0–14	17	3	2·65	0·25
	15–24	28	5	2·95	0·52
	25–44	45	3	3·81	0·57
XY	45–54	24	2	4·22	0·47
	55–74	21	1	3·70	0·34
	75+	20	10	6·52	2·81
	All ages	155	24	3·60	0·64
	0–24	26	4	2·18	0·62
	25–34	20	2	2·09	0·21
XX	35–54	18	10	3·30	0·85
	55–64	21	5	4·90	0·90
	65–74	20	5	6·87	0·88
	75+	32	7	8·99	2·28
	All ages	137	33	3·65	0·79

Regression on age of the percentage of:
selected hypodiploid cells, sex XY : $y = 0{\cdot}036x + 2{\cdot}39$
" " " " XX : $y = 0{\cdot}104x - 0{\cdot}40$
Both regression coefficients are significantly different from zero ($P < 0{\cdot}01$)

* See text for definition. The number of subjects, their mean ages and the numbers of diploid cells counted in each group are given in Table 1.

Inspection of the data suggested that in males an undue proportion of the hypodiploid cells was missing an S_1 chromosome, whereas in females an undue proportion was lacking an M chromosome. In fact the proportion of these cells not only increases with age (Table 3), but also these cells account for nearly all the regression on age previously observed. If these cells are excluded then the regression of the remaining hypodiploid cells on age becomes extremely small, and the coefficients do not differ significantly from zero in either sex (males, $y = 0{\cdot}006x + 2{\cdot}15$; females, $y = 0{\cdot}005x + 1{\cdot}41$).

The results reported here are open to criticism on the grounds that the observations were not made on a representative sample of the general population. The subjects were comprised of healthy volunteers, hospital in-patients, parents of children with chromosome abnormalities, etc. To offset this difficulty a study is in progress of a group of subjects, selected at random from the lists of general practitioners. This investigation will eventually include men and women of all ages from 15 years and upwards, but so far data only referable to those of 65 years and more are available. These, however, confirm the findings already noted for this group, and in this study every cell has been fully analysed. Examination of 1,050 cells from 35 males (mean age 71·69 years) shows 9·26 per cent to be aneuploid and that the proportions increase progressively for the age-groups 65–69, 70–74 and 75 years and over, being respectively 7·14, 10·09 and 12·15 per cent. 48 cells with 45 chromosomes were available for analysis, 27 of which were missing an S_1 chromosome (expected number on the basis of random loss, 5·22). In 12 of these cells the missing chromosome could confidently be said to be a Y chromosome, whereas only 1·04 such cells would be expected if all chromosomes had an equal chance of being lost. The findings from the analysis of 1,290 cells from 43 females (mean age 73·49 years) again confirmed the earlier findings. The proportion of aneuploid cells was 11·50 per cent and this proportion did not change progressively for the age-groups 65–69, 70–74, 75–79 and 80 years and over, the relevant proportions being 11·37, 12·68, 11·94 and 10·20 per cent. 95 cells with a count of 45 chromosomes were available for analysis, of which 81 were missing an M chromosome (expected number on the basis of random loss, 33·04). The substantial agreement between the earlier and later findings for ages of 65 years and more does indicate that it is unlikely that any serious bias has been introduced into the earlier findings due to the composition of the study population.

Table 3. DISTRIBUTION OF HYPODIPLOID CELLS LACKING S_1 AND M CHROMOSOMES BY AGE AND CHROMOSOMAL SEX

Chr. sex	Age group (yr.)	Cells lacking only S_1 chromosomes: Number	% of Diploid cells
	0–14	4	0·62
	15–24	4	0·42
	25–44	6	0·51
XY	45–54	8	1·44
	55–74	8	1·41
	75+	10	3·26
	All ages	40	0·95
		Cells lacking only M chromosomes	
	0–24	9	0·76
	25–34	5	0·52
XX	35–54	10	1·88
	55–64	10	2·33
	65–74	15	5·16
	75+	27	7·58
	All ages	76	2·02

Regressions on age of the percentage of
(i) XY cells : $y = 0{\cdot}030x - 0\ 120$
(ii) XX cells : $y = 0{\cdot}096x - 1{\cdot}823$
Both regression coefficients differ significantly from zero ($P < 0{\cdot}01$)

It seems reasonable to postulate that the observed increases in the proportion of aneuploid cells with age, which in males is mainly due to the loss of an S_1 chromosome and in females to the loss of an M chromosome, is in fact largely due to divisional errors involving the Y chromosome in men and the X chromosome in women. Direct evidence is available for the Y chromosome as in good preparations it is identifiable, and therefore its absence is recognizable. Direct evidence for the involvement of the X chromosome is not yet available, but it may become so from techniques using tritiated thymidine labelling. It may well also be relevant that the major change involving an M chromosome in women occurs at the time of a sharp decline in sexual activity. Both in males and females the findings could be explained: (1) if there was a special liability for cells to lose a sex chromosome, or (2) if all chromosomes were liable to be involved, but that the cells with an abnormal number of autosomes were at a disadvantage and failed to survive, or (3) if both possibilities occurred together.

We thank Dr. J. Williamson and his staff of the Edinburgh Geriatric Hospital Service for access and assistance with patients. We also thank Dr. R. Scott and his staff of the Edinburgh University General Practice Teaching Unit, and the following general medical practitioners: Drs. W. G. Butters, T. E. Dickson, A. Irons, J. S. Milne, A. I. Richardson and I. S. Stokoe.

CHEMICAL COMPOSITION AND TERMINOLOGY OF SPECIALIZED ORGANELLES (MELANOSOMES AND MELANIN GRANULES) IN MAMMALIAN MELANOCYTES

By Dr. M. SEIJI*, Prof. T. B. FITZPATRICK and R. T. SIMPSON
Department of Dermatology, Harvard Medical School
AND
M. S. C. BIRBECK
Chester Beatty Institute for Cancer Research, London

Development of Melanin Granules

In the past few years, investigations of the fine structure of the melanocyte have altered the concept of the nature of this cell. Birbeck, Mercer and Barnicot[1] were the first to point out that melanocytes contain a system of membranes similar to those seen in secretory cells. They have also observed that the melanin granules present in the cytoplasm of the melanocyte are not of uniform structure, but appear at any given moment to be in varying stages of development. "The granules appear to start as hollow vacuoles in which a tenuous material appears in the form of a folded lamella. . . . This material is rapidly thickened and defined by the deposition of more dense material. . . ."[2]. Later investigations of the fine structure of melanin granules have confirmed and extended these findings[3-9].

At the fifth International Pigment Cell Conference in New York, an investigation was described[10] in which particles isolated from pigmented tissues by ultracentrifugal, density-gradient methods had been studied by both biochemical techniques and electronmicroscopy[3,4]. The results of this work have made it possible to outline the successive steps in the development of melanin granules. Because melanin granules were found to be specialized organelles which differ from mitochondria not only in structure and development but also in chemical and enzymatic composition, a set of new terms was proposed for the various stages of their development. Introduction of these new terms is justified by inadequacy of the single, inclusive term, 'melanin granule', to describe with precision the structural and chemical metamorphoses which take place in the granule during melanization. In Fig. 1 are outlined the essential features of pre-melanosomes, melanosomes and melanin granules—the three specialized organelles found in melanocytes.

It is believed that three stages can be recognized in the formation of the *melanin granule*—the final product of the melanocyte (Fig. 1).

(I) A first stage in which polypeptides are synthesized and condensed into the secondary and tertiary structures of the enzymatic protein molecules.

(II) An intermediate stage in which the enzyme molecules are arranged in structural form—the *pre-melanosome*. The enzyme molecules are aligned in an ordered pattern.

(III) A third stage in which melanin biosynthesis begins and melanin accumulates inside the pre-melanosome. During this stage, the granule contains tyrosinase activity and is a *melanosome*.

The final product, in which melanization is complete, and in which no tyrosinase may be detected, is a *melanin granule*.

During stage II, the arrangement, shape and size of the pre-melanosomes are thought to be both species- and site-dependent. Melanin is not yet synthesized at this stage. During the early parts of stage III, the lamellar pattern of the pre-melanosome can still be seen in electronmicrographs, but as the process of melanization continues, the lamellar pattern gradually becomes obliterated by deposited melanin and an amorphous *melanin granule* eventually results. As melanin gradually forms within the melanosome, the tyrosinase activity of the melanosome correspondingly decreases : in other words, melanin formation and tyrosinase activity are inversely related[11].

Melanin appears to be synthesized *in vivo* predominantly during stage III : nevertheless, active tyrosinase may be recovered *in vitro* from the small-granule fraction. It is possible that extraction of the enzymatic protein results in its activation. There is reported to exist in insects an inactive enzyme called pro-tyrosinase which may be activated both *in vivo* and *in vitro*[12-15]. Melanin cannot be seen in electronmicrographs of rough or smooth membranes, yet small amounts may be present, but not detectable, because melanin and the other cytoplasmic structures have a similar density.

This series of developmental steps must hereafter be considered in any study of the regulatory mechanisms of melanin formation, whether they are hormones, ultraviolet light or disease states.

Chemical Composition of Melanosomes, Melanin Granules and Mitochondria

Stein[16] has examined the chemical composition of melanin granules isolated from the choroid of the eye of the ox and has compared his data with those obtained from the mitochondria of rat and mouse liver. It has seemed worth while to compare the chemical composition of the 'melanosomal' and 'mitochondrial' fractions isolated by differential and density-gradient techniques as a means of clarifying the biochemical characteristics of these two distinctive components of the melanin-forming cell. In evaluating results, however, one must remember that the so-called 'melanosomal' fraction may contain both melanin granules (as defined here) and melanosomes.

The *B*-16 mouse melanoma and the Harding–Passey mouse melanoma used in the experiments reported here were serially transplanted in *C*-57 and Swiss strain mice respectively. The entire, actively growing tumours were excised when their diameter reached 1·0–1·5 cm and promptly homogenized in 0·25 M sucrose at about 0° C. All subsequent processing occurred in a cold environment (about 3° C). The homogenate was centrifuged at 700*g* for 10 min. The resulting 'low-speed' supernatant, when centrifuged at 11,000*g* for 10 min, yielded a sediment which was resuspended in 0·25 M sucrose and recentrifuged at 15,000*g* for 10 min. This sediment was again suspended in 0·25 M sucrose to make the 'large-granule' preparation used as starting material for density-gradient centrifugation. Density-gradient sucrose columns were prepared in the tubes of the Spinco swinging-bucket rotor (*SW*-39-*L*) by layering 0·5 ml. of eight different concentrations of sucrose solution in serial order with the most concentrated

---

Fig. 1. STAGES IN THE DEVELOPMENT OF MELANIN GRANULES

Name and size	Morphology	Biochemical composition		
Ribosome (100–150 Å)	•	RNA + protein	Site of polypeptide biosynthesis	Stage I Biosynthesis of protein
Golgi vesicle (0·05μ)	•	Phospholipid + protein	Condensation (?)	
Intermediate vesicle (0·5μ)		Phospholipid + protein	Tyrosinase arranged in structural form	Stage II Development of organelle
Premelanosome (0·7 × 0·3μ*)		Phospholipid + protein tyrosinase	End of tyrosinase arrangement Final product of albino melanocyte	
Melanosome (0·7 × 0·3μ*)		Tyrosinase + melanin	Specific site of melanin formation	Stage III Biosynthesis of melanin
Melanin granule (0·7 × 0·3μ*)		Melanin + no measurable tyrosinase activity	Final product of melanocyte	

* Typical size of human brown melanin granules.
Adapted from *Subcellular Localization of Melanin Biosynthesis*, by Seiji, M., Shimao, K., Birbeck, M. S. C., and Fitzpatrick, T. B. Chapter in *The Pigment Cell: Molecular, Biological and Clinical Aspects*, edit. by Riley, V., and Fortner, J. G., 100, 497 (New York Acad. Sci., 1963).

layer at the bottom of the tube. They were then allowed to stand overnight (about 18 h) so that the gradient might become smooth. The sucrose concentrations used for the separation of melanosomes were 2·6 M, 2·4 M, 2·2 M, 2·0 M, 1·8 M, 1·6 M, 1·55 M, and 1·5 M; for the separation of mitochondria, the concentrations were 2·0 M, 1·8 M, 1·6 M, 1·55 M, 1·5 M, 1·4 M, 1·2 M, and 1·0 M. Immediately before centrifugation, 1 ml. of freshly prepared large-granule suspension from mouse melanoma was layered carefully over the top of each tube. After centrifugation at 103,000*g* for 60 min, the melanosomal fraction and the mitochondrial fraction were isolated from their respective centrifuge tubes by a centrifuge-tube cutter. The fractions thus obtained were then subjected to chemical analysis and their tyrosinase, succinoxidase and glutamate oxidase activity were measured.

The analytical technique of Schmidt and Thannhauser[17], modified by substituting perchloric acid for trichloroacetic acid, was used for the extraction of lipid and ribonucleic acid. Phospholipid content was estimated from the phosphorus content of the lipid fraction. Phosphorus content was determined by Fiske–Subbarow's method[18]. Ribonucleic acid content was calculated from the phosphorus content of the RNA fraction. To determine the protein–nitrogen content, the protein was precipitated by adding an equal amount of 10 per cent trichloroacetic acid to each sample. The precipitate was spun down, washed once with 5 per cent trichloroacetic acid, and dissolved in 1 *N* sodium hydroxide solution. The nitrogen content of this alkaline solution was determined by the method described by Johnson in 1941[19]. The zinc content was estimated by Vallee's method[20,21]. Tyrosinase activity was estimated manometrically by measuring the oxygen consumption, using a 10:1 mixture of L-tyrosine and L-*dopa* as substrate (1·77 μmoles) in M/10 phosphate buffer (*p*H 6·8)[22]. Succinoxidase activity was estimated respirometrically by measuring oxygen consumption in the presence of cytochrome *c*, as described by Umbreit[23]. Glutamate oxidase activity was estimated respirometrically by measuring oxygen consumption in the presence of ATP, DPN, nicotinamide, magnesium chloride and cytochrome *c* (ref. 24).

Table 1 contains analytical data obtained from melanosomal and mitochondrial preparations isolated from *B*-16 and Harding–Passey mouse melanoma by methods described here[25]. As can be seen, the composition of the melanosomal fraction contrasts sharply with that of the mitochondrial fraction as regards content of each component studied. The melanosomal fraction contains much more zinc than the mitochondrial fraction. Although the role of zinc has not yet been clarified, the fact that it does play a part in the formation of melanin is increasingly evident[26]. The high zinc content of the melanosomal fraction seems to be specific for that fraction. The RNA content of the mitochondrial fractions examined agrees well with the figures reported by Schneider and Hogeboom[27]. Especially significant is the great contrast between the low content of RNA and phospholipid in the melanosomal fraction and the high content of these substances in the mitochondrial fraction. RNA has been shown to be essential for biosynthesis of protein within the

Table 1. ANALYTICAL DATA SHOWING THE MARKED DIFFERENCES BETWEEN MITOCHONDRIAL AND MELANOSOMAL FRACTIONS OBTAINED BY CENTRIFUGAL TECHNIQUES

Component	Type of melanoma	Melanosome (μg/mg protein N)	Mitochondria (μg/mg protein N)
RNA–P	Harding–Passey	2·2 ± 0·32*	32·5 ± 0·87*
	B-16	4·7 ± 1·2	20·2 ± 1·38
Phospholipid-P	Harding–Passey	13·1 ± 0·9	158·2 ± 2·9
	B-16	19·1 ± 1·2	115·0 ± 1·2
Zinc	Harding–Passey	26·5 ± 0·5	<1
	B-16	39·0 ± 2·6	1·62
Enzymes		Specific activity (μl. O_2/h/mg protein N)	
Tyrosinase	Harding–Passey	1,028 ± 7·1	0
	B-16	243 ± 4·8	0
Succinoxidase	Harding–Passey	0	2,017 ± 11·0

	B-16	0	640

* Average value ± *S.E.*

cell[28]. The low RNA content of the melanosomal fraction is evidence that, so far as protein biosynthesis is concerned, melanosomes are probably very inert components of the melanin-forming cell.

A recent examination of the *in vivo* incorporation of leucine labelled with carbon-14 provides more direct evidence that the role of melanosomes in protein biosynthesis is very small as compared with that of mitochondria. In these experiments, animals were treated and fractionation carried out by methods already described[25]. The specific radioactivity of melanosomal and mitochondrial fractions obtained from melanoma excised 1 h after injection of leucine-^{14}C was 37·8 and 308 c.p.m./mg protein respectively. In other words, much less leucine-^{14}C was incorporated by melanosomes isolated from *B*-16 mouse melanoma than by mitochondria from the same tissue.

Tyrosinase, the oxidative enzyme responsible for melanin formation in mammals, is localized for the most part in melanosomes. Measureable amounts of tyrosinase activity were not found in the mitochondrial fraction isolated from mouse melanoma.

The amount of succinoxidase activity found in the mitochondrial fraction from the same source (Table 1) is comparable with that reported in hepatoma by Schneider[29]. In comparing the figures shown in Table 1 with the figures obtained from other normal and neoplastic tissues, it is necessary to be aware that Harding–Passey and *B*-16 mouse melanoma are composed of both melanoma cells and phagocytes, and that cell particles isolated from these tumours may be derived from both types of cells. The tissue may contain 40–60 per cent phagocytes. In a few of the experiments reported here, succinoxidase and glutamate oxidase activity were detected in melanosomal fractions isolated by centrifugation, but in almost negligible quantities. When melanosomal fractions containing this very small amount of succinoxidase and glutamate oxidase activity were purified again by density-gradient centrifugation (sucrose concentrations 1·5–2·6 M), a very faint white band could be observed at the position in the tube of fraction 2 (ref. 24). After centrifugation in the high-density gradient (1·5–2·6 M sucrose), fraction 2 was found to contain mitochondria. No succinoxidase or glutamate oxidase activity was observed in the purified melanosomal fraction. Therefore, the traces of succinoxidase and glutamate oxidase activity detected in the melanosomal fraction may be interpreted as evidence of contamination with mitochondria.

The results reported here support the concept that melanosomes are distinctive sub-cellular particles which differ from mitochondria; are unique in their localization within the cytoplasm of melanin-forming cells; contain a specialized metabolic pathway in which tyrosine is converted to melanin; and appear to be quite inert sub-cellular particles without biological function except in the formation of melanin.

We thank Prof. K. Ogata of Niigata University School of Medicine, Niigata, Japan, for useful suggestions concerning the work with leucine-^{14}C and for his help with the experiments on *in vivo* incorporation of this radioactive material.

ENCEPHALOPATHY IN MICE FOLLOWING INOCULATION OF SCRAPIE SHEEP BRAIN

By DR. J. ANTHONY MORRIS* and DR. D. CARLETON GAJDUSEK†

National Institutes of Health, Bethesda, Maryland

A CHRONIC, progressive, degenerative disease of the central nervous system has been induced in mice inoculated with brain material obtained from a sheep with naturally acquired scrapie. There was a remarkable parallel between the bizarre clinical manifestations and course of the experimentally induced disease in mice and the clinical pattern of scrapie in sheep. Furthermore, the neurological signs and histopathological lesions seen in our affected mice were similar to those observed by Chandler in mice inoculated with passage material from goats with induced scrapie[1,2]. In addition, Chandler's observations of a scrapie-like degenerative disease of the central nervous system in mice inoculated with scrapie goat brain material was, in the course of this work, confirmed.

A Cheviot ram which belonged to a flock in Illinois first showed signs of scrapie at 4 years of age and died with advanced disease on October 1, 1961, after 5 months of illness. Post-mortem examination was performed promptly and materials obtained for virus isolation and histopathological study. Microscopic examination of the brain revealed demyelinization, neuronal degeneration, satellitosis, neuronophagia, gliosis and vascular thickening. Occasional neurones showed vacuole formation. These findings were considered consistent with the histologic lesions of scrapie and confirmed the clinical diagnosis in this instance. The brain of this Cheviot ram, which had been stored at − 70° C for 40 days, served as the inoculum for viral studies. A finely ground 10 per cent suspension of the brain in physiological saline was clarified by low-speed centrifugation and the supernatant used immediately after preparation. Mice of 5 different breeds weighing 8–10 g, and, in addition, suckling Syrian hamsters, were injected intracerebrally with 0·03 ml., or intraperitoneally with 0·1 ml., of the test material. After 9 months, when none of the hamsters had developed disease, they were inadvertently discarded. Table 1 summarizes the results obtained in mice inoculated with the sheep material.

Table 1. INCIDENCE AND INCUBATION PERIODS OF SCRAPIE-LIKE DISEASE IN MICE OF FIVE BREEDS INOCULATED WITH SCRAPIE SHEEP BRAIN FROM NATURALLY OCCURRING DISEASE

Breed of mice	No. of mice inoculated	Incubation period Earliest	Incubation period Latest	Mortality after 1 year from scrapie-like disease	Survivors
Swiss, *GP*	9	3½	8	8/9*	1 Sick
Swiss, *NIH*	9	2½	8	8/9†	1 Sick
CFW	15	2½	8	15/15	0
*CDF*₁	14	7	8	10/14‡	4 Sick
*C*57/Black	10	6	10	6/10§	0

* 2 of these affected mice were killed for passage and histological examination.

† 1 of these 8 affected mice was killed for passage and histological examination.

‡ 3 of these 10 affected mice were killed for passage and histological examination.

§ 2 of the 6 affected mice were killed for passage and histological examination; 4 other clinically well mice killed at 10 months are not included among the 6 dead from scrapie-like disease.

Disease appeared as early as 2½ months after inoculation in some mice, and as late as 10 months after inoculation in others. In the CDF_1 and *C*57/Black mice the shortest incubation period was twice as long as in the Swiss and *CFW* mice. A few of the animals were killed for pathological and auto-immune hypersensitivity investigations before the disease developed, and others were killed for passage and pathological examination in advanced stages of illness. All other mice receiving this sheep brain inoculum developed a scrapie-like syndrome.

The first signs in affected mice were a hyper-excitability evidenced by rapid jerky movements and increased speed of the normal activities, particularly those of grooming. The animals tended to run and jump and to execute circular movements, changing irregularly from clockwise to counter-clockwise direction. This was more evident when the animals were disturbed by handling or by exposure to bright light or to noise. Vibration or touch stimulation resulted in excessive response in the affected mice as compared with unaffected animals. However, this circling also occurred spontaneously without provocation. In addition to these manifestations an increase in scratching, scraping and licking activities suggested a parallel to the reactions seen in sheep with scrapie and attributable to itching[3]. These activities of the mice led to excoriation of the ears, lumbosacral region and snout, with frequent loss of hair, bloody scabbing and ulceration. Hyperextension of the neck was common, and the gait became waddling, with lowered hindquarters. This latter was associated with spastic hind limbs which were held in strong adduction when the mouse was suspended by the tail, while the fore-limbs retained normal muscle tone. The tail was stiff and when bent into abnormal shapes maintained these for a minute or so. With the onset of neurological signs, a progressive deterioration of nutrition developed. The mice became emaciated and hyper-excitability decreased. Soiling of the abdominal coat, suggesting urinary and fæcal incontinence and persistent priapism were often present.

The brains of several of the mice have been examined histologically and, after being stained with Cajal's gold chloride, revealed a marked astrogliosis and moderately severe loss of neurones, with some vacuolated neurones and others pyknotic and shrunken in cerebrum, cerebellum and medulla oblongata. Inflammatory lesions, such as are usually associated with acute encephalitis, were not present. Dr. Philip Paterson of the New York University, in a personal communication, stated that he found no detectable anti-brain complement-fixing antibodies to normal mouse brain antigen in the sera of inoculated mice in varying stages of the disease. Moreover, he saw no evidence of histological change suggesting allergic encephalomyelitis in the animals (see Table 1 for list of mice killed).

Inocula prepared from brain tissue of 6 other American sheep, diagnosed as having scrapie, have thus far failed to produce scrapie-like disease in our mice. In addition, mice inoculated with non-scrapie sheep brain, as well as non-inoculated shelf mates, have remained free of neurological disease for more than a year, and have served as controls. None of these animals has exhibited neurologic signs of illness; nevertheless, they are still under observation, some for 13 months since inoculation.

Brain material from an experimentally infected scrapie goat, received from Mr. I. H. Pattison of the Agricultural Experiment Station, Compton, Berkshire, was inoculated into mice of the Swiss *NIH* and Swiss *GP* breeds. This represented ninth passage of the scrapie agent in goat brain from an animal affected with 'drowsy' type of disease (in contradistinction to the scratching type); this passage was one beyond that from which Chandler had induced disease in mice. This Compton material in our hands induced a degenerative disorder of the central nervous system associated with clinical signs like those described by Chandler[1-4]. The disease followed either intraperitoneal or intracerebral inoculation with incubation periods ranging from 6 to 17 months at dilutions up to 10^{-4} of the original goat brain. Carefully removed supernatant from 16,000 r.p.m. centrifugation for 30 min produced similar disease at 10^{-3} but not at greater dilution. Seitz filtrate of this high-speed supernatant produced disease at only 10^{-1} dilution.

Remission and exacerbation of the disease has been evident in two mice inoculated with goat brain material. These developed the syndrome of clumsy gait with spastic hind extremities and the slow movements and 'drowsy' behaviour of the scrapie-like disease, and then, after a period of 64 and 46 days, respectively, of this progressive disease appeared to recover completely. The first of these animals remained well for 74 days and then again developed the same syndrome. This recrudescence lasted for only 7 days, when the animal died of the disease. The other animal appears well 157 days after the initial recovery.

Second passage in mice of mouse brain material from both the sheep brain and goat brain-induced diseases has yielded no disease as yet; however, the longest observations have thus far been for only 4 months since inoculation. There is, as yet, no serological or immunological test for scrapie, hence it has not been possible to relate our experimental encephalopathy in mice to the natural disease in sheep. However, Chandler has recently demonstrated that material from mice suffering from his scrapie goat brain induced encephalopathy produces typical scrapie when inoculated back into goats[4].

Breeding experiments to determine whether the disease in mice can be genetically or congenitally transmitted are in progress. We are also performing experiments to determine whether neutralizing antibody develops in affected sheep or mice and to investigate whether immune tolerance may exist to the scrapie agent inoculated *in utero* or early in neonatal life, as is the case in lymphocytic choriomeningitis in mice with subsequent persistent infection[5].

The apparent genetic or congenital transmission of scrapie in nature in sheep, the marked differences in breed susceptibility, the remarkable stability of the scrapie agent, especially its resistance to boiling, and slowly progressive character of the essentially non-inflammatory disease in the central nervous system, and some clinical, epidemiological and neuropathological similarity between scrapie in sheep[3] and kuru disease in man in New Guinea[6,7] account for the intense interest of scrapie in medicine, virology, genetics and veterinary medicine. This chronic, progressive, degenerative disease of the central nervous system in mice inoculated with scrapie sheep brain (or scrapie goat brain), which resembles naturally occurring scrapie closely in both clinical aspects and neurohistopathology, offers a challenging experimental model for the study of the etiological agent and for the pathogenesis of slow infections of the central nervous system.

We thank Drs. J. M. Hejl, J. L. Hourigan, E. M. Jones, T. P. Koudelka, P. H. Kramer, H. A. Waters and their associates of the U.S. Department of Agriculture, for their co-operation in supplying us with the scrapie sheep brain material.

ROLE OF PHOSPHATIDES IN NON-ENZYMATIC BROWNING

By H. S. BURTON and D. J. McWEENY

Food Science and Plant Health Division, Ministry of Agriculture, Fisheries and Food, London, S.W.1

In investigations into the browning reactions taking place in dried foodstuffs, it has become clear that more than one type of reaction is involved. At moisture-levels above 5 per cent sugar/amino reactions probably predominate in most cases, and the pathways involved have been dealt with elsewhere[1-5].

When the products are very dry it appears that oxidative effects due to splitting of unsaturated fatty chains may occur, probably by free radical reactions.

Vegetables contain various quantities of phosphatides, but little seems to have been reported on them or their effects on browning reactions[6].

Channon and Chibnall[7] found that cabbage contained about 0·14 per cent 'phosphatidic acid' (converted to a dry-weight basis), but they used an extraction process whereby phosphatides in physical association with carbohydrates or proteins were not extracted. Rewald[8] stated that potatoes contained up to 0·17 per cent phosphatides, calculated on the dry matter. Hanahan and Chaikoff[9], in their examination of dehydrated carrot, found that on dehydration the unsaturated fatty acid figure was reduced, but in their extraction of phosphatides from cabbage, they found a phosphatide content of about 1·5 per cent, corrected to a dry-matter basis, and, moreover, that the phosphatidic acid isolated earlier by Channon and Chibnall was an artefact produced from the phosphatides. Phosphatides can occur closely bound to both sugars and proteinaceous compounds, and should the fatty chains split on oxidative attack at a double bond, the resultant carbonyl compounds will react with any amino-groups present in the system, and join in a polymer-forming reaction of the type already described elsewhere[3,4,10,11]. Much of the browning occurring in phosphatide systems is probably, therefore, of the carbonyl/amino type (cf. Lea on unsaturated fatty compound browning[12]), which is perhaps the reason why sulphur dioxide and sulphites were found, by us, to be good retarding agents for the browning of phosphatide systems. The unsaturated fatty acids will undergo browning reactions when incubated with aqueous glycine; for example, linoleic and linolenic acids gave chromophores on incubation at 40° C which were more soluble in the fatty acid than in the aqueous phase, whereas the saturated caprylic acid underwent no colour change whatsoever. The presence of potassium metabisulphite retarded colour development in the unsaturated fatty acid systems.

In our experimental work on phosphatide browning the reactions were carried out in aqueous dispersion. Lecithin was used as the phosphatide after isolation in crystalline form, from egg-yolk, as described by Saunders[13]. After recrystallization from methyl ethyl ketone the lecithin was measured volumetrically in solution in this solvent, the solvent being blown off rapidly by a stream of air passed over a known volume of the solution in the reaction bottle.

The browning system consisted of lecithin, either alone or together with glycine, aliquots of each being treated separately in separate vessels with one of a range of additives respectively. These additives had previously been found to be, or were suspected by us as being accelerators or inhibitors of chromophore development in browning systems. They were added to the lecithin dispersions to give a concentration of 80 mg lecithin per 5 ml. of water and 800 mg glycine was added to the appropriate mixtures where the effect of glycine was to be examined. Potassium metabisulphite was added in 10-mg and 50-mg quantities, as were ascorbic acid, potassium pyrophosphate and ferrous sulphate. Calcium chloride (100 mg), aneurine (5 mg), ascorbic acid (100 mg) and sodium acetate (5, 20, and 50 mg) were also tested. In further experiments glycine was replaced by its ethyl ester, and by phenyl glycine, which was largely insoluble in the solutions. The reaction vessels were tightly stoppered and incubated at 40° C.

The rate of colour development was estimated visually, mainly because of the non-homogeneity of the system, and since both we and Hodge[14] support the view that the eye can be a more sensitive evaluator of the browning than the colorimeter in such systems, where the hues obtained are often different and the degree of dispersion may vary.

Using the same additives, there were marked differences in chromophore development to that occurring in the corresponding glucose/glycine system, some of which appear to be indicative of mechanisms operating in browning reactions. In the presence of added phosphate, the rate of colour development in sugar/amino systems increased, whereas a slight reverse effect was observed in the phosphatide/amino system. The accelerating effect noted in the sugar system[10,15] paralleled the higher polarographic readings obtained in the presence of phosphate by Cantor[16] and also the subsequent faster development of conjugated unsaturation[17], and thus seems to be a reflexion of the initial sugar stability in the solution.

In this respect it is noted that Pomeranz *et al.* have found[18], by an empirical method, the same order of browning for various sugars as we had already found and predicted[10] on theoretical grounds. The presence of calcium chloride had little or no effect on the phosphatide/amino system whereas it had a retarding effect on sugar/amino browning[10]. This again indicates that the main effect of calcium chloride is connected with its reaction with the sugar component. Simon[19] has shown that calcium chloride retards the browning of certain dehydrated vegetables, but no indication has so far been given as to how the calcium compound achieved this result. Calcium chloride may form complexes (believed to be in certain ring forms[20]; or presumably conformations) with the sugars, but it may also combine with diketones, amino compounds, pyrrole derivatives and phosphates.

These differences between the effect of phosphates and calcium chloride on the two systems in aqueous solution appear, therefore, to be important, since they suggest that the main effects of calcium and of phosphate are more closely connected with the changes—probably rate-determining—occurring in the sugar in the early stages prior to chromophore development[16], than with the potentialities in reactions occurring later in the browning sequence. If calcium is present in the early stages as a sugar complex, it will most certainly affect the later rate of dehydration of the sugar residue. Further evidence for believing that the effect of calcium chloride is mainly connected with sugar structure is derived from our investigations on its effect on straight carbonyl/amino systems, which parallels the results described herein on the phosphatide/amino reaction, but which is dissimilar to the effects exerted on aldose/amino systems.

The addition of sulphites or sulphur dioxide retarded the phosphatide/amino reaction, the degree of retardation being greater the larger the quantity of sulphite used. This was expected, since it probably acts in the manner discussed by Burton, McWeeny and Biltcliffe[2-4] in the carbonyl/amino system formed, the sulphite protecting the carbonyl group and reacting with centres of unsaturation.

Experiments in which lecithin was incubated at 40° C in glucose and in glycine separately showed quite clearly that the colour development was much more rapid in the presence of glycine. Lecithin and glucose, without additive, gave no colour after 3 months at 40° C, but in the presence of glycine the initial chromophores appeared within five days and even in presence of 10 mg of sodium metabisulphite the initial chromophore developed in 20 days, and had become a deep orange shade in 30 days. The importance of the nitrogen function for the rapid development of browning in carbonyl systems has been emphasized previously[2,4,10,11]. In the glucose/glycine 2·0 M w.r.t. glucose and 0·5 M w.r.t. glycine the degree of browning was greater with rising lecithin content over the concentrations studied, that is, 10–100 mg lecithin/7·5 ml. glucose/glycine.

The addition of ascorbic acid caused more browning to develop; in the absence of glycine, however, the effect of the ascorbic acid was much less than in its presence, demonstrating quite clearly that ascorbic acid browns quite rapidly with glycine, and fitting in with our previous findings that the browning of ascorbic systems is rapid in the presence of a nitrogen function. Ferrous sulphate caused an even more rapid browning reaction in the lecithin/glycine system, an insoluble brown pigment forming within a few days. Esterification of glycine led to a reduced rate of browning, while phenylglycine reacted in heterogeneous mixture with lecithin to give a dark solid which eventually became a black tar; metabisulphite retarded this reaction for a very long time, which may be explained as a normal reaction of sulphite at carbonyl and unsaturated centres, coupled with the lower availability of the amino compound for reaction in the solid state. Attempts to retard browning by pretreatment of lecithin with sulphur dioxide led to unknown products which slightly decreased the time before colour developed.

We are now aware that sulphite can very easily become attached at sites of unsaturation; Dodge[21] thought that the hydrolysability of the sulphonates depended on the location of the double bond, and we have been able to show that sulphite, added to a system containing unsaturated compounds, readily reacts at the unsaturated centre, and may become organically bound in a stable manner[11,22,23]. This appears to be the explanation for the otherwise unaccountable loss of sulphite after addition to foodstuffs when assayed by the Monier-Williams procedure, since it is not converted to sulphate[2,10,11].

It is of interest to mention that an unaccountable loss of sulphur dioxide (about 30 per cent) occurred during sulphitation and drying of cabbage at the Low Temperature Research Station, Cambridge. We have checked this experiment using sulphur-35 as a tracer, and have found that there was no loss of volatile sulphur-35 compounds, despite the low Monier-Williams recovery figures. In view of Hanahan and Chaikoff's results, it might well be that the added sulphite had combined with unsaturated lipids, known from their work to be present in cabbage, to a much greater extent than in other vegetables dehydrated at the time. There seems little doubt that the fatty acids and chains become substituted at unsaturated centres, and more sulphite is needed to prevent cabbage from browning than is needed, for example, for potatoes.

In experiments not reported here we found that sulphur-35 metabisulphite, added to other vegetables during scalding (blanching), appeared in part in the lipid fraction very soon after scalding, and in model systems not only become attached to the unsaturated compounds, but also retarded their browning with glycine.

It would seem that the browning reactions of phosphatides and presumably of unsaturated fatty acids are largely due to the production of chromophores following a carbonyl/amino reaction, and that its inhibition by sulphite is due to interference by the sulphite in this reaction to prevent chromophore development[2,4,11].

We wish to thank Mr. J. F. Hearne for his encouragement. This work is financed under U.S. Public Law 480.

EFFECT OF 2:4-DINITROPHENOL ON CARBON DIOXIDE FIXATION BY A *THIOBACILLUS*

By D. P. KELLY and P. J. SYRETT

Department of Botany, University College, London

THIOBACILLUS rapidly oxidizes thiosulphate and other sulphur compounds to sulphate, the oxidation being coupled to carbon dioxide fixation[1]. Carbon dioxide fixation is mainly by reactions similar to those of the Calvin cycle in photosynthetic cells[2-4], and presumably requires a supply of reducing power, such as reduced pyridine nucleotide, and adenosine triphosphate[5]. It has been suggested that thiosulphate is first oxidized to tetrathionate and that other polythionates are formed as intermediates in the oxidation to sulphate[6–8]; adenosine triphosphate might then be formed by coupled oxidative phosphorylation. Peck[9], however, has recently proposed that the first step in thiosulphate oxidation is the reductive cleavage of thiosulphate to sulphide and sulphite. Sulphite combines with adenosine monophosphate and is finally oxidized to sulphate, the oxidation being accompanied by a substrate phosphorylation, which is insensitive to 2:4-dinitrophenol. If these reactions occur in intact cells, the sulphide formed from thiosulphate must also be oxidized to sulphate by an unknown pathway. Since the substrate phosphorylation studied by Peck is insensitive to dinitrophenol, while any oxidative phosphorylation might be expected to be sensitive to this inhibitor, it was of interest to investigate the effect of 2:4-dinitrophenol on carbon dioxide fixation by a *Thiobacillus*.

The organism used was isolated from canal water and most closely resembles *Thiobacillus thioparus*[1]. Cultures were grown in a liquid medium containing 1 per cent thiosulphate and aerated for 12 h after thiosulphate exhaustion. The cells were collected and suspended in 0·1 M phosphate buffer, pH 7·0 or 7·2, to give either a thin suspension (about 0·2 mg dry wt./ml.) or a thick suspension (about 2·5 mg dry wt./ml.). Experiments were carried out in Warburg flasks at 30° C in the presence of ^{14}C-bicarbonate and were started by tipping known quantities of thiosulphate or sulphide. Experiments were terminated when oxidation ceased and an aliquot of cell suspension from each flask was pipetted into an equal volume of ethanol containing 5 per cent (v/v) acetic acid. Carbon-14 fixation was measured by drying portions of this mixture to give infinitesimally thin samples for counting. At the end of some experiments aliquots of cell suspension were taken for sulphate determination[10].

No carbon dioxide is fixed unless thiosulphate is added and fixation ceases when the thiosulphate has been completely oxidized (Fig. 1). Carbon dioxide fixation is inhibited by low concentrations of 2:4-dinitrophenol which either do not affect or stimulate rate of oxygen uptake (Fig. 2).

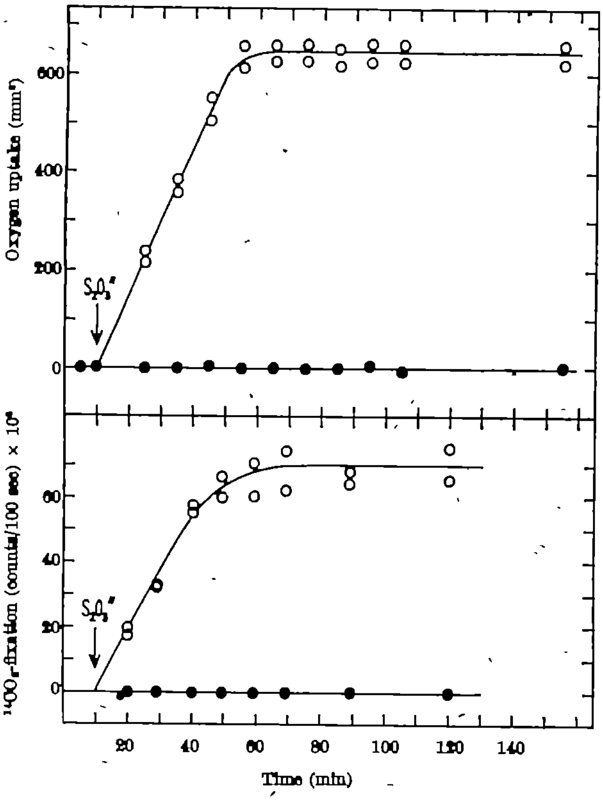

Fig. 1. Coupling of $^{14}CO_2$-fixation to thiosulphate oxidation by a thin cell suspension. Upper graph: oxygen uptake: lower graph: $^{14}CO_2$-fixation. Controls (black circles) received no thiosulphate. Theoretical oxygen uptake for complete oxidation = 672 mm³

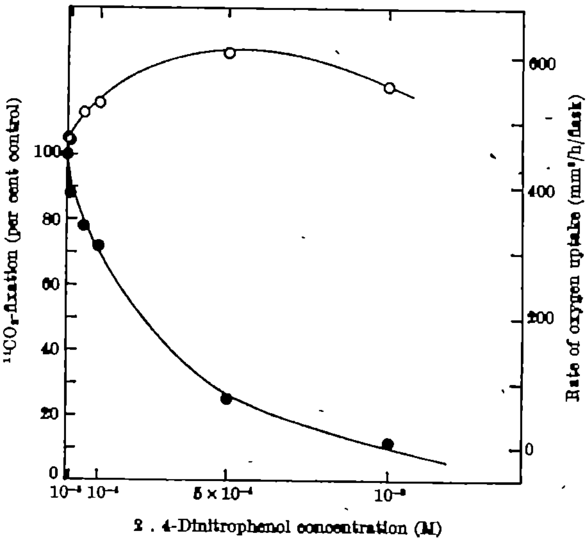

Fig. 2. The effect of 2:4-dinitrophenol on the rate of oxygen uptake and $^{14}CO_2$-fixation by thin cell suspensions oxidizing thiosulphate. Open circles, oxygen uptake; black circles, $^{14}CO_2$-fixation

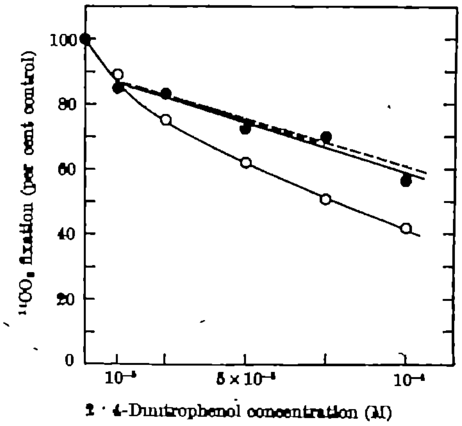

Fig. 3. The effect of 2:4-dinitrophenol on $^{14}CO_2$-fixation coupled to sulphide (open circles) or thiosulphate (black circles) oxidation by thick cell suspensions. 4·0 μmoles of each substrate were oxidized. The broken line shows the calculated $^{14}CO_2$-fixation coupled to thiosulphate oxidation

Sulphide is also rapidly oxidized provided that not too much is added and that thick cell suspensions are used. This oxidation can also be coupled to carbon dioxide fixation but the fixation differs in two respects from that coupled to thiosulphate oxidation.

First, less carbon dioxide is fixed per molecule of substrate oxidized when sulphide is the substrate instead of thiosulphate. In experiments in which care was taken to add equimolar quantities of sulphide and thiosulphate and complete oxidation was checked by sulphate analyses at the end of the experiment, carbon dioxide fixation with sulphide as energy source was 62·5 ± 4·9 per cent of that with thiosulphate as substrate. Yet both a molecule of sulphide and one of thiosulphate require two molecules of oxygen for complete oxidation to sulphate. Secondly, carbon dioxide fixation linked to sulphide oxidation is more sensitive to inhibition by 2:4-dinitrophenol (Fig. 3 and Table 1). For example, 10⁻⁴ M dinitrophenol gives 60 per cent inhibition of carbon dioxide fixation with sulphide as substrate, but only 40 per cent inhibition with

Table 1. EFFECT OF 2:4-DINITROPHENOL ON $^{14}CO_2$-FIXATION COUPLED TO THE COMPLETE OXIDATION OF SULPHIDE OR THIOSULPHATE BY THICK CELL SUSPENSIONS OF THIOBACILLUS

The percentage inhibition, compared with controls without dinitrophenol, is given. 4·0 μmoles of each substrate were oxidized.

	Exp. 1		Exp. 2		Exp. 3	
Substrate / DNP Concentration	S″	S_2O_3''	S″	S_2O_3''	S″	S_2O_3''
0	0	0	0	0	0	0
5 × 10^{-5} M	38	—	—	—	—	—
2·5 × 10^{-4} M	95	71	72	61	82	69
5 × 10^{-4} M	—	—	90	80	94	88

Sulphate analysis at the end of experiment 2 gave 113 per cent recovery of sulphur from both sulphide and thiosulphate. At the end of experiment 3, recovery was 107 per cent.

thiosulphate. The difference is consistent and extends over a range of dinitrophenol concentrations.

The inhibition of carbon dioxide fixation by low concentrations of dinitrophenol, which do not inhibit the oxidation of sulphur compounds, suggests that oxidative phosphorylation is involved in the coupling between carbon dioxide fixation and substrate oxidation. If, as appears not unreasonable, carbon dioxide fixation can be used as an index of high-energy phosphate production, oxidative phosphorylations, inhibited by dinitrophenol, may be relatively more important in the oxidation of sulphide than of thiosulphate.

If Peck's scheme for thiosulphate oxidation is correct[9], our finding that carbon dioxide fixation during sulphide oxidation is 63 per cent of that with an equimolar amount of thiosulphate as substrate, suggests that two-thirds of the phosphorylation coupled to thiosulphate oxidation occurs during the oxidation of sulphide to sulphate and one-third during the oxidation of sulphite. Moreover, if we assume that all the phosphorylations coupled to sulphide oxidation are sensitive to dinitrophenol, and that therefore only two-thirds of those coupled to thiosulphate oxidation are similarly sensitive, we can calculate the carbon dioxide fixation expected by cells oxidizing thiosulphate in the presence of dinitrophenol; the calculated values are not dissimilar from those observed (Fig. 3, broken line).

Thus our results suggest that both oxidative and substrate-phosphorylations are coupled to the oxidation of thiosulphate by *Thiobacillus*.

A THERMOSTABLE HÆMOLYTIC FACTOR IN SOYBEANS

By YEHUDITH BIRK, A. BONDI, B. GESTETNER and I. ISHAAYA

Faculty of Agriculture, Hebrew University, Rehovot, Israel

IT is a well-known fact that raw soybean oil meal is not utilized efficiently by the living organism. The nutritional value of the meal can be raised by adequate heat processing, as soybeans contain growth-depressing materials which are destroyed by heat. Among these alleged anti-nutritional factors are the saponins, which are generally characterized by their bitter taste and foam-forming and hæmolytic activities[1]. The aim of this work was to examine the effect of heat processing, under conditions found as most favourable for elevating the nutritional value of the meal for chicks and rats, on the hæmolytic activity of soybean saponin extract. Since soybean saponin extract partly inhibits the proteolytic activity *in vitro* of *Tribolium castaneum* larval midgut enzyme solution and also trypsin and α-chymotrypsin[2], it was of interest to examine the effect of autoclaving on these inhibitory activities as well.

Soybean saponin extract was prepared from ether-extracted soybean flour, Lincoln variety, by a combination of two methods[3,4] as follows: 200 g soybean flour were suspended in 2 l. ethanol 80 per cent, stirred for 12 h at 50–60° C and the residue was re-extracted after filtration with another 2 l. ethanol 80 per cent. The ethanol was removed from the combined filtrates by distillation in vacuum to 400 ml. Accompanying materials and pigments were removed by extracting the solution with 200 ml. portions of ethyl ether until the latter was colourless. To the remaining aqueous solution 20 g sodium chloride and hydrochloric acid to pH 4·0–5·0 were added and the solution was then shaken with 300 ml. and 150 ml. butanol, successively. The combined butanol extracts were washed twice with 50 ml. sodium chloride 5 per cent. The washed butanol phase was concentrated to dryness yielding 4 g crude material. 1 g of the dried preparation was suspended in 100 ml. water and treated with 1 g calcium monoxide. The precipitate formed was separated by filtration, suspended in 50 ml. hot methanol 80 per cent and neutralized with hydrochloric acid. The resulting turbid solution was filtered and the filtrate concentrated to 0·75 of its volume. 50 ml. water were then added and the soybean saponin that precipitated was collected by filtration, washed with acetone and dried. The same procedure was applied for preparation of soybean saponin extract from autoclaved soybean meal. Heat processing of soybean meal and of soybean saponin extract was performed by autoclaving at 15 lb. pressure for 20 min. The following designations were used for the various soybean saponin extracts: $SBSE_1$, extract from raw soybean meal; $SBSE_2$, extract prepared from autoclaved soybean meal; $SBSE_3$, autoclaved $SBSE_1$. The nitrogen content of each preparation was about 0·18 per cent. All three preparations could form foam easily when shaken in an aqueous solution.

The hæmolytic activity of soybean saponin extract was determined by Kofler's method[5] as modified by O'Dell *et al.*[6]. 1 ml. solution of soybean saponin extract in 0·3 M phosphate buffer pH 7·4 was mixed in a test tube with 1 ml. suspension of previously washed ram red blood cells. The mixed suspension was allowed to stand at room temperature for 20 h. Full hæmolysis was defined, according to Büchi *et al.*[7], as absence of precipitate at the bottom of the test tube, and the hæmolytic index, as weight of reaction mixture divided by weight of soybean saponin extract assayed.

The inhibitory effect of soybean saponin extract on the proteolytic activity of *Tribolium castaneum* larval midgut enzyme solution and on α-chymotrypsin (crystallized 3 times, salt-free, Worthington Biochemical Corp.) has been examined by the casein digestion method at 280 mμ[8]. Larval midgut enzyme solution was prepared according to Birk and Applebaum[9].

Paper-chromatographic separation of soybean saponin extract was performed on Whatman No. 3 *MM* filter paper. The paper was washed, prior to chromatography, with solvent—butanol/ethanol/water (6 : 2 : 3) and dried in the hood. Soybean saponin extract solutions in 80 per cent ethanol were then applied and chromatographed (ascending direction) in the same solvent. The chromatograms were dried in the hood at room temperature and then at 100° C for 30 min. The spots were detected by dipping the paper in the Carr–Price reagent (saturated solution of antimony trichloride in chloroform) and heating for 5 min at 100° C. Corresponding spots were cut out from the duplicate chromatograms, which had not been dipped in the reagent, and eluted with warm 75 per cent ethanol. The ethanol was removed by distillation and the residues were examined on hæmolytic activity and on inhibition of larval midgut enzyme solution and α-chymotrypsin.

The comparative detrimental activities of $SBSE_1$, $SBSE_2$ and $SBSE_3$ are shown in Fig. 1. It appears from this figure that $SBSE_2$ (prepared from autoclaved soybean meal) exhibits even higher hæmolytic activity than $SBSE_1$. However, autoclaving of $SBSE_1$ resulted in a considerable decrease in hæmolytic activity as can be seen from the value of $SBSE_3$. It seems that the hæmolytic activity of soybean meal is protected, when *in situ*, against the possible diminution caused by heat processing. No considerable difference has been found between the three soybean saponin extracts concerning their inhibitory effect on the proteolytic activity of *Tribolium castaneum* larval midgut enzyme solution and α-chymotrypsin.

The paper chromatographic behaviour of $SBSE_1$, as compared with that of $SBSE_2$ and $SBSE_3$, is shown in Fig. 2.

Spots *B*, *C*, *D* of each soybean saponin extract preparation possess foam-forming activity. It may be concluded from Fig. 2 that heat processing does not affect the chromatographic behaviour of soybean saponin extract. All three preparations can be separated, each, into four well-defined spots with similar R_F values. Spots *A* from the various origins have no hæmolytic activity. All the other three spots of each preparation are hæmolytic. The hæmolytic index of the spots designated *D* is about 2,000 and of those designated *C* about 400. Component *B*, however, seems to be affected by heat processing, as the hæmolytic index of *B* from $SBSE_1$ is more than 10,000, the hæmolytic index of *B* from $SBSE_2$ is even higher, and that of *B* from $SBSE_3$ is about 5,000. These results indicate that the sensitivity of component *B*, when $SBSE_1$ is autoclaved, accounts for the lower hæmolytic activity of $SBSE_3$ (Fig. 1). Spots *B*, *C* and *D* of all three soybean saponin extract preparations exhibit considerable inhibition of the proteolytic activity of *Tribolium* larval enzymes and chymotrypsin.

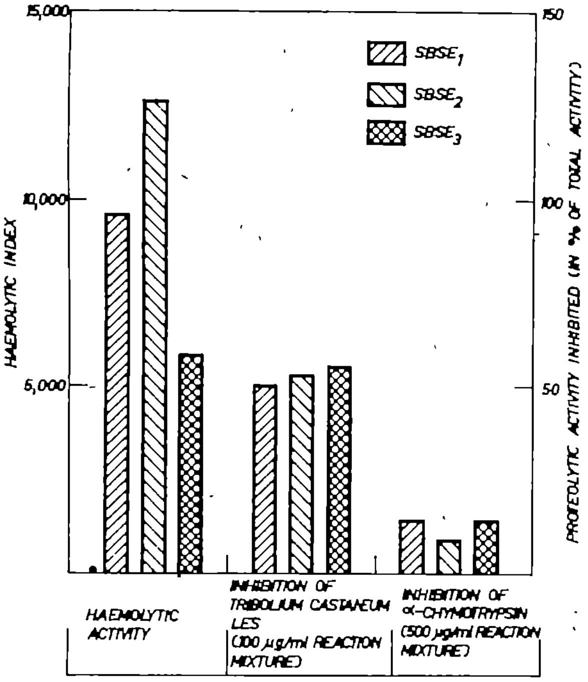

Fig. 1. Comparative hæmolytic and proteolysis-inhibiting activities of raw and autoclaved soybean saponin extracts

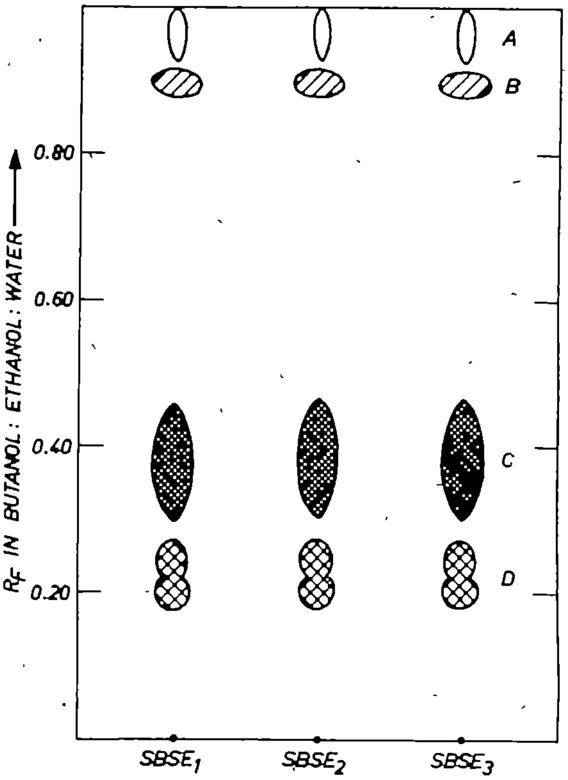

Fig. 2. Comparative chromatographic behaviour of $SBSE_1$, $SBSE_2$ and $SBSE_3$. The colours of the spots are as follows. *A*, brown; *B*, brown; *C*, purple; *D*, purple. The distribution of chromatographed soybean saponin extract per spot is: White, ~5 per cent, single hatching, ~10 per cent; double hatching, ~30 per cent; deep hatching, ~55 per cent

Summarizing its hæmolytic activity, it appears safe to claim that soybean saponin extract is highly hæmolytic (hæmolytic index ~ 10,000) as compared with saponins from other sources[10]. This activity is not affected at all when soybean meal is autoclaved under optimal conditions and may still be classified as very high in $SBSE_2$.

This work is financed by grant No. *FG–IS*–112 from the U.S. Department of Agriculture.

LETTERS TO THE EDITOR

ASTROPHYSICS

Deficiency of Metals in Population II Stars

I PROPOSE the following as an explanation for the deficiency of heavy elements in Population II stars.

Consider the ionization potentials of the elements. A brief list is given in Table 1 for representative elements. If we assume that there is a certain amount of ionization of interstellar matter, it is clear that the heavy elements, with rare exceptions, will have a considerably higher probability of being ionized than will the light elements. It is commonly believed that the galaxy possesses a magnetic field of 10^{-5}–10^{-6} gauss[1]. Therefore, elements which are ionized are effectively contained in the galactic disk, where the field exists, while neutral particles have relatively little difficulty in escaping from the surface of the galactic disk towards the halo regions. This escape is particularly easy for hydrogen and helium atoms in the high velocity tail of the Maxwell velocity distribution; gravitational attraction somewhat aids the magnetic field in preferentially retaining heavier elements. Moreover, the elements which are retained need not be ionized for all time—should they become ionized at any instant of time, the magnetic field will halt any outward motion they might have. Consequently, it is reasonable that interstellar matter should be increasingly depleted in the metals as the distance from the disk increases, and stars formed in the halo region must be deficient in the metals. This, in fact, is what is observed since the metal-poor Population II stars[2] show a deficiency in the metals which increases with galactic latitude[3]. There is a similar dependence on the space velocity of stars[3].

This interpretation removes a major difficulty which attends explanations depending on nucleogenetic developments, for those explanations require a steady growth with time in the proportion of helium and heavy elements in the galaxy[3,4–7]. In fact, old Population I stars, such as those of *M* 67 (refs. 8–10), and very young stars, have essentially identical metal contents[11–13]. In addition, there is some evidence that Population II stars have a normal abundance of helium[13] which is incompatible with the nucleogenesis theory of stellar chemistry. I argue that the paucity of metals in Population II stars is not evidence that the galactic abundances have changed with time.

The present model suggests that neutral gas escaped from the galactic disk, but this admittedly presents a serious problem of how that (low-density) gas could condense into stars. A more reasonable picture is that of Eggen *et al.*[3], who discuss formation of the Population II stars in terms of matter left behind as the nascent galaxy collapsed. I suggest that the collapsing gas contained a magnetic field which helped drag ionized matter, that is, the metals, into what is now the disk. In this case, the metals were left behind whenever they became neutral, so that some metals were present in the matter which formed the Population II stars. Ionization became increasingly important as stars formed because of the hot radiation from them. Thus all elements with small ionization potentials have remained trapped in the galactic disk since the earliest days of star formation, and the distribution of the metals with height above the galactic plane is readily understood.

I thank Prof. G. P. Kuiper and Miss B. M. Middlehurst for stimulating discussions of this topic.

PHYSICS

Mean Life and Mass of Elementary Particles

THE weak interaction constant G may determine the mean life of some elementary particles. If the muon mean life of $2{\cdot}212 \times 10^{-6}$ sec is equated to $(1/2\ \pi a)\ (\lambda_e^2\hbar/G)$ then G equals $1{\cdot}48 \times 10^{-49}$ erg cm^3 (a is the fine structure constant and λ_e is the Compton wave-length of the electron). The charged pion mean life equals $1/4\ (\lambda_e^2\hbar/G)$ or k while the Σ^- hyperon mean life equals $a\,k$. Three types of particles may exist corresponding to the presence of a with exponents of -1, 0, or $+1$ in a function giving the mean life of the particle.

The weak interaction constants may be similar to the Rydberg constants ($R_\infty = a^2/2\ \lambda_e$) in that they depend on a centre of mass factor. However, for present purposes this can be neglected.

Table 1 lists the observed mean life of some elementary particles together with the mean life calculated from the multiple of k listed.

Table 1. PARTICLE MEAN LIFE (SEC)

Particle	Observed*	Calculated	Interaction factor
π^+	$2{\cdot}55 \times 10^{-8}$	$2{\cdot}54 \times 10^{-8}$	k
K_2^0	$6{\cdot}1 \times 10^{-8}$	$5{\cdot}1 \times 10^{-8}$	$2\,k$
K_1^0	1×10^{-10}	$0{\cdot}9 \times 10^{-10}$	$a\,k/2$
Σ^-	$1{\cdot}6 \times 10^{-10}$	$1{\cdot}85 \times 10^{-10}$	$a\,k$

* *Handbook of Chemistry and Physics* (1962).

Particle mean life and particle structure should be related. If dimensional units are defined so that the mass of the electron equals 2π then the components of particles can be represented by rest masses of $\pi/2a$, $1/2\ a$ and 2π (refs. 1 and 2). The neutral kaon with two different lifetimes may consist of two different arrangements of these units. For example:

$$K_1^0 = 4(6\pi/2a + 1/2a) + 4\pi/2a + 1/2a = 4 \text{ muons} + 4\pi/2a + 1/2a$$

$$K_2^0 = 4(8\pi/2a) - [4(\pi/2a - 2\pi) - 1/2a] = 974 \text{ electron masses}$$

Table 1. FIRST IONIZATION POTENTIALS (I.P.) (eV) FOR VARIOUS ELEMENTS

Element	H	He	N	O	F	Ne	Si	Cr	Mn	Ga	Sr	I	Ba	Eu	Hg
I.P.	13·6	24·6	14·5	13·6	17·4	21·6	8·1	6·8	7·4	6·0	5·7	10·5	5·2	5·7	10·4

The pions and the charged kaon may be similar to K_2° in structure (ref. 2).

The hyperons may have structures similar to the K_1° particle because of the similarity in mean life. For example:

$$\text{neutron} + \text{muon} + 4\pi/2a = \Lambda = 2{,}182{\cdot}5 \text{ electron masses}$$

$$\text{neutron} + \text{muon} + 2(4\pi/2a) + 1/2a = \Sigma^{\circ} = 2{,}330{\cdot}4 \text{ electron masses}$$

$$\text{neutron} + \text{muon} + 2(4\pi/2a + 1/2a) = \Sigma^{-} = 2{,}341{\cdot}3 \text{ electron masses}$$

$$\text{proton} + \text{muon} + 2(4\pi/2a) + 1/2a = \Sigma^{+} = 2{,}327{\cdot}9 \text{ electron masses}$$

The resonances can also be represented as combinations. For example:

$$\text{proton} + 3(4\pi/2a + 1/2a) + 4\pi/2a = 1{,}235 \text{ MeV} = N^{*}$$

$$\text{proton} + 4(4\pi/2a + 1/2a) + 2(4\pi/2a) = 1{,}383 \text{ MeV} = Y^{*}$$

$$2\pi^{\circ} + 4(4\pi/2a) = 550 \text{ MeV} = \eta^{\circ}$$

$$2\pi^{\circ} + \pi^{+} + \pi^{-} + \text{mu}^{+} + \text{mu}^{-} = 760 \text{ MeV} = \rho^{\circ}$$

The pion resonance does not involve charge formation. Eliminating a charge gives:

$$3(4\pi/2a - 1/2a) = 193 \text{ MeV}$$

The proton may consist of two resonant states represented by an average mass of:

$$4[2((4\pi/2a) - 1/2a) + \text{muon}] = 938{\cdot}2 \text{ MeV} = \text{proton}$$

Apparently a charge with rest mass of 2π can acquire a rest mass of $4\pi/2a$ or $1/2a$. Combinations of these units form the resonances and the elementary particles.

Seasonal Variations of Cæsium-137 in Air at Ground-level during 1960 and 1961

MEASUREMENTS on radioactive fall-out in air and rainwater in different parts of the world from 1954 onwards showed that during late winter and spring an increase in specific activity was observed. This increase was attributed by Stewart[1] and Machta[2] to seasonal effects while it was attributed by Martell[3] mainly to the testing schedule of polar explosions. The presence of 'spring peak' was observed in India and other countries from the measurements made in the spring of 1960 as there were no tests between November 4, 1958, and February 13, 1960.

The spring increase in the concentration of cæsium-137 in the air at ground-level recorded at Bombay during 1957–60 has already been published[4]. The peaks in cæsium-137 activity were observed at Bombay during the period February–May in the years 1957–60. In ref. 4 the peaks in cæsium-137 activity observed at Srinagar, Delhi, Nagpur, Calcutta, Bangalore and Ootacamund during 1960 were also reported. As two French tests were conducted in February and April 1960, respectively, the spring increase observed in 1960 had to be confirmed by similar measurements in 1961.

Since the level of activity in the air during 1961 was very small, samples from 4 northern stations (Srinagar, Delhi, Gangtok and Calcutta) and 4 southern stations (Nagpur, Bombay, Bangalore and Ootacamund) were pooled to determine whether the seasonal effects could be observed during 1961. Fig. 1 gives the levels of cæsium-137 in the ground-level air for the northern stations, the southern stations and the average levels for all the stations. It can be seen from Fig. 1 that in the month of September 1960 the levels of cæsium-137 in the air had reduced to less than 10^{-15} c./m³ air. After September 1960 an increase is observed. In the northern stations the peak is observed in the month of April 1961 and in the southern stations two peaks are observed in January and May 1961 respectively. It is significant that the peak-levels of activity during 1960 and 1961 are nearly the same in the southern stations and the 1961 peak-levels in the northern stations are even higher than the 1960-levels.

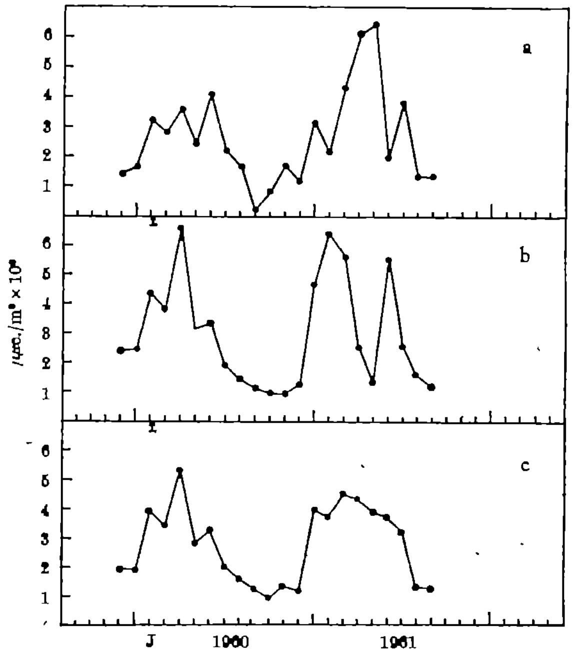

Fig. 1. Cæsium-137 concentrations in the air at ground-level. *a*, Northern stations average, *b*, southern stations average; *c*, average for all stations

The mechanism of spring increase is not fully understood and different explanations have been offered. Lindblom[5] has observed spring peaks at Stockholm and Edsvalla in Sweden during 1961 and the peak levels at these two stations during 1961 were as high as the levels during 1960. Kuroda[6] has also observed an increase in strontium-90 concentration in spring rains during 1961, the magnitude of which is comparable with that in 1960. He has attributed this to the descent of radioactive fall-out from upper stratosphere to the lower stratosphere.

Production of Liquid Drops

DURING an investigation into methods of producing small, uniform-sized drops the following observations were made on the mechanism of drop formation when influenced by the application of high voltage.

Drops of water were produced from a vertical stainless-steel, hypodermic needle, 0·27 mm bore and 0·48 mm outside diameter. The tip of the needle was ground flat and thoroughly cleaned before use. Water pressure was provided by a constant liquid head.

In the case where gravitational forces alone applied drops grew to a diameter of about 4 mm before becoming detached from the tip, this occurring once every 3–4 sec. On the application of smoothed, positive, high voltage (about 4 kV) there was a marked change in the mechanism of drop production. In ordinary light water appeared to leave the tip of the needle in a continuous, narrow jet.

This effect was reported by Vonnegut and Neubauer[1] in a qualitative paper which did not attempt to describe the formation of the individual drops.

When such a jet is viewed in stroboscopic light it is apparent that it is composed of a series of small drops (about 300μ diameter) produced at a definite frequency. The frequency is sometimes caused to vary by factors such as change in the liquid properties and the condition of the atmosphere into which the drops are sprayed. However, the frequency can be maintained constant by making fine adjustments to the applied voltage.

Observation of the tip of the needle under a low-power microscope, with stroboscopic back lighting, indicates that the process is highly repetitive. This is evident from the sharpness and steadiness of the image when the stroboscope is synchronized with the object motion. Photographs 1–13 (Fig. 1) record the peculiar manner in which the drops are produced. These photographs are not all of one particular cycle but are a collection of stills taken at random over a period of 5 min and put into order after printing. They represent a sequence of events which recur at a rate of 300/sec.

The water behaves in a manner which would be expected of a liquid of very low surface tension, there being only a very short retention time at the tip before the drop is ejected. The shape of the liquid at the tip also shows a great departure from sphericity.

The process can be explained qualitatively by considering the opposing effect to surface tension of electrostatic charge at the surface.

In the early stages (1–2) the shape of the advancing liquid front is almost spherical but continual flow of the water and gravitational force on the accumulated liquid soon produce an elongation, creating a small radius of curvature at this front (3–5). Here a higher charge density at the high curvature reduces surface tension more than elsewhere on the surface. Consequently water flows through this weak area at an increasing rate (6–7), creating a sharp-nosed filament (8–9). As this lengthens the more usual process of jet break-up commences and 'necking' occurs (9–10). When the filament breaks away, the curvature of the liquid remaining on the needle is suddenly decreased (11) and the liquid withdraws for a brief period (12) until flow of liquid through the needle causes the process to start again (13–1).

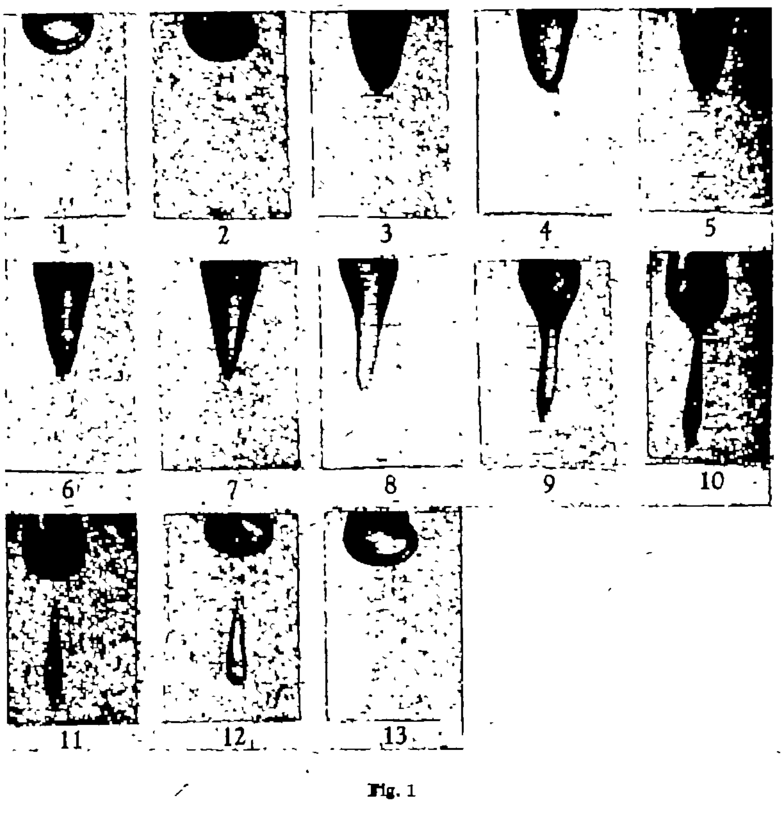

Fig. 1

Secondary drops which may be produced from the thin tail of the parent drop are repelled, by electrostatic forces, at an angle to the primary drop stream depending on the relative drop sizes. This angle is large enough to allow the secondary drops to be removed without affecting the primary stream. Thus, the system produces a continuous stream of uniform-sized drops of controllable frequency. The drop size may be varied by altering the flow rate.

Occurrence of Maximum and Minimum in the Principal Magnetic Susceptibility versus Temperature Curves

IN an examination of the temperature variation of principal magnetic susceptibilities of paramagnetic salts of the iron group of elements from room temperature down to about 80° K, it has been found in certain cases that the square of the effective magnetic moment (p^2) value comes down so rapidly with the decrease of temperature that the corresponding susceptibility actually shows a maximum in the susceptibility versus temperature curve[1]. The condition for the occurrence of such a maximum can be easily investigated.

By definition, $p^2 = \frac{3k}{N\beta^2}\chi T$, where χ is the gram molecular susceptibility. Now $\frac{dp^2}{dT} = \frac{3k}{N\beta^2}(\chi + T\frac{d\chi}{dT})$. At the temperature corresponding to the maximum susceptibility $d\chi/dT$ should be zero. Thus when the slope of the p^2–T curve exceeds the value p^2/T, the thermal coefficient of susceptibility, namely, $d\chi/dT$, should be positive, whereas ordinarily it is negative. This criterion can be expressed geometrically in the following manner. Consider any point Q on the p^2–T curve. Then the temperature variation of susceptibility at Q will be positive if the slope of the curve exceeds the line joining Q and the origin ($T = 0$, $p^2 = 0$). This condition is satisfied for the lowest of the three principal magnetic moments in the hexahydrated cobalt selenate crystal, and the corresponding susceptibility shows a maximum at about 130° K, below which the susceptibility decreases with the lowering of temperature. Another crystal, namely, copper acetate monohydrate, also shows similar maximum in all three principal susceptibilities owing to the fact that the effective moments for the three directions come down rapidly with the fall of temperature. The p^2–T curves for all the three principal directions of this crystal have slopes higher than that given by the foregoing equation.

Besides having a maximum susceptibility in the susceptibility versus temperature curve described here, the curve can also exhibit a minimum under suitable conditions. Such a minimum has been observed, for example, in samarium salts at about 400° K. The ground-state of Sm^{+++} is $^6H_{5/2}$. The multiplet interval between the lowest components for samarium is not large, so that it is not only the level for which J is $5/2$ but the immediately higher level ($J = 7/2$) will also be occupied. Now the higher level corresponds to a considerably larger magnetic moment than the lower level. Starting from low temperatures, as the temperature is raised continually there will come a stage when the population in the upper level will increase rapidly. The average moment per ion will thus increase sufficiently quickly with the rise of temperature to overbalance the direct influence of temperature. If p_1^2 be the value characteristic of the lower level and p_2^2 of the higher level, then as the temperature is raised the values of p^2 will rise from p_1^2 to $\frac{1}{2}(p_1^2+p_2^2)$. Suppose that in the p^2–T curve at the point Q of inflexion the slope of the curve is greater than the critical value deduced here, then evidently there will be two points A and B where the slope will have the critical value. If T_A and T_B be the corresponding temperatures, then $d\chi/dT$ will be normal, that is, negative for temperature $T < T_A$ or $> T_B$, whereas for temperatures in the interval $T_A < T < T_B$ $d\chi/dT$ will be positive. The temperatures T_A and T_B will thus be the positions of the minimum and maximum of the curve. If p_1^2 is zero, that is, if the lower level is non-magnetic, the susceptibility will fall continually as we lower the temperature from T_A without exhibiting a minimum.

GEOPHYSICS

Examination of Irregular Sub-surface Structures by Seismic Refraction Methods

THE great volume of modern refraction data has revealed the inadequacy of what was, until recently, the usual method of interpretation, that is, the process of fitting a series of straight lines to the travel-time observations, and of interpreting the resulting diagram in terms of a plane-stratified crustal model. Sometimes the artificiality of such models is revealed within the area of a single survey. On other occasions, discrepancies have appeared when structures postulated to explain data from neighbouring areas have failed to agree at the survey boundary.

One approach towards greater generality is that which has been discussed by Willmore, Scheidegger and Bancroft[1,2] from which the postulate of plane stratification is eliminated. Instead of this, it is assumed that there is a surface in the ground below which the travel-time is a function of distance only, and that one can identify the packet of energy which passes downwards from the source to this 'marker-layer', is refracted into it, and is then refracted again to the receiver. If the marker-layer is not assumed to be plane, one has to solve sets of equations of the form:

$$t_{ij} = a_i + a_j + f(\Delta_{ij}) \tag{1}$$

where the subscripts i and j refer to the source and received respectively, t_{ij} is the travel time, and Δ_{ij} is the distance between the feet of the perpendiculars drawn from the source and receiver to the marker-layer. It is shown that the constants a_i, a_j are simply related to the lengths of the corresponding perpendiculars, and that they are almost independent of azimuth. In a preliminary solution, we use the great circle distance between the ith source and the jth receiver as a first approximation to Δ_{ij}, and the solution yields a first approximation to the velocity in the marker-layer and to the contours of the interface. In successive approximations, corrections can be introduced to allow for the effects of quite steep dips in the marker-layer, and for curvature of the refracted rays. The equations can be solved for extended networks of sources and detectors, without requiring that the elements of the net should conform to any particular pattern.

In another approach, which has been discussed by Hagedoorn[3], Hawkins[4] and others, the sources and receivers are laid out in the form of a linear profile shot from both ends. The quantities a_i, a_j are derived, in this special case, by a very simple arithmetical procedure, and the configuration has the advantage that all the ray paths lie close to a single vertical plane. By subtracting a_i and a_j from the travel-time to each detector in turn one can follow the progress of the refracted wave front along a particular line in the surface of the refractor. It is assumed here that there is no significant average increase of velocity with depth, which would cause the wave to plunge deeply below the boundary. When this is done, any irregularity in the apparent progress of the wave front can be accounted for by postulating local variations in the velocity below the marker-layer. However, the completeness of this solution is obtained at the cost of losing control over the experimental uncertainties, because the number of constants fitted to the system has become equal to the number of observations available.

It now appears possible to combine the advantages of both systems by having a two-dimensional net, with a sufficient number of sources and receivers to give good statistical control over the constant terms, and deriving an average marker velocity in a first approximate solution. For any pair of detectors which are approximately in line with a given shot, one can derive an estimate of the local crustal velocity by forming the quantity:

$$\frac{\delta(t_{ij} - a_j)}{\delta(\Delta_{ij})} \tag{2}$$

Similarly, one can derive the local velocity below pairs of shot points as being equal to:

$$\frac{\delta(t_{ij} - a_i)}{\delta(\Delta_{ij})} \tag{3}$$

If these local estimates fit into a regional pattern, successive approximations to the structure can be built up.

All these methods depend on the possibility of recognizing onsets from a particular crustal stratum and this will not necessarily be easy in the general case. It is therefore very desirable to include small groups of fixed elements in the system, and so to plan the operation that observations from these groups of elements are obtained for waves which have travelled a number of significantly different distances. Special studies of the data from these small groups will determine the apparent velocity of any given phase, and whether this apparent velocity depends on distance. If this scheme is to be successful, adequate attention must be paid to the resolving power of the fixed-element array in terms of apparent velocity. This requires that conservative estimates of error in determining arrival times should be combined with information theory to yield the necessary array-length, sampling point interval and sampling density to avoid ambiguity. In this way, we may strengthen the method of distinguishing non-linear terms in $f(\Delta_{ij})$ from the effects of regional variations in velocity.

It is unnecessary to elaborate further at this stage, our object being mainly to emphasize the fact that the numerous special techniques which are now being developed all embody the same general principles. In particular, the theory indicates that all methods which yield a complete solution must satisfy the following conditions:

(*a*) Each recording site should be occupied for the observation of waves from at least two sources in different azimuths, the distances being such as to permit the observation of corresponding phases for all sources. Conversely, each source should be observed by a number of detectors.

(*b*) To eliminate an arbitrary constant which appears in the equations, one or more source points should be used as recording sites for waves from other sources.

The literature contains numerous descriptions of investigations in which structural conclusions are advanced, but in which the foregoing conditions have not been satisfied. In all such cases, assumptions such as plane layering, or zero average dip of the marker, have been introduced, even if they have not been recognized explicitly. We should further emphasize that, if the conditions cannot be satisfied in a single field operation, the possibility of combining data from past or projected operations should be borne in mind.

It would appear that something analogous to this approach can be applied to any set of data in which an observed quantity can be represented as the sum of a continuous function of another observed quantity and a number of constant terms. In particular, we might observe the surface waves spreading from a number of sources. At any one frequency, the phase should vary linearly with distance, and discrete phase-shifts may exist at each source and receiver. Each 'phase term' should be capable of further analysis into a part characteristic of the source mechanism or the detecting equipment, and a part characteristic of the crustal structure. The phase velocity extracted from the analysis should have the same significance as that derived in conventional phase-velocity studies, but should gain in accuracy from the localization of effects at the sources and receivers. The amplitude of a given phase should also be susceptible to study in the same way.

The three types of study which have been suggested are all applicable to the calibration of the permanent seismograph arrays which are now being used for the detailed investigation of seismic wave trains. On a larger scale, appropriate investigations should yield time, phase and amplitude corrections applicable to the conventional seismograph stations of the world network.

GEOLOGY

A Potassium/Argon Age Determination from a Lewisian Inlier

THE potassium/argon age of pyroxene from an eclogite occurring within the Glenelg Lewisian inlier has been determined.

The eclogite from which the pyroxenes were extracted occurs on the north-east shore of Loch Duich, Ross-shire (Grid ref. —*NG*903236). Here the rock forms a rounded knob projecting from the beach above high-water mark. The relationships between the eclogite and the surrounding rocks are obscured by vegetation and beach material at this particular locality, but at other occurrences in the neighbourhood the eclogites form the cores of large-scale augen structures in garnet–biotite–gneiss.

The specimen of eclogite collected is a very striking bimineralic rock consisting of emerald green clinopyroxene (omphacite) and bright red garnets. The texture is equigranular with individual crystals about half a centimetre in diameter. This particular specimen was selected for dating because neither of the minerals shows any signs of alteration, unlike most specimens of eclogitic rocks collected in the same area which show retrograde metamorphic effects[1]. The rock was crushed and the pyroxenes extracted by the use of a Franz electro-magnetic separator. No heavy liquids were used in the separation.

Argon extraction and estimation were made by the standard technique of isotope dilution. Potassium oxide content was determined using a flame photometer. Six separate analyses were made, the figure 0·060 per cent K_2O given in Table 1 being the average of all six.

Table 1. RESULTS OF AGE DETERMINATION

Material	Ref.	K_2O (per cent)	Per cent atmospheric contamination	Vol. of radiogenic argon (mm³ N.T.P.)/g	Age and experimental error
Pure clinopyroxene	2032/30 *KA*/416	0·060	7·1	0·004616	1,515 ± 104 M. yr.

$\lambda_\beta = 4{\cdot}72 \times 10^{-10}$ yr.$^{-1}$. $\lambda_e = 0{\cdot}584 \times 10^{-10}$ yr.$^{-1}$

Apart from errors arising from uncertainties in potassium oxide and argon content, it has been recently shown[2] that pyroxenes can sometimes contain excess radiogenic argon-40. It is thought that this argon is incorporated in lattice defects at the time of crystallization, though not all pyroxenes exhibit this effect.

If this sample of clinopyroxene does contain a significant amount of excess radiogenic argon its true age would be less than the 1,515 ± 104 million years yielded by the measurement. It could be supposed that the mineral was last recrystallized in the Caledonian (420 ± 15 million years) folding, during which it incorporated excess argon-40 from the surrounding rock. Work on micas from Morar, Knoydart and southern Ross has shown that certain parts of the area were affected little by the last (420 ± 15 million years) folding (Brown and Miller, in preparation). It is considered, therefore, that this particular clinopyroxene has not been contaminated with excess radiogenic argon and has yielded an age which corresponds to a specific geological event.

This new age determination is of interest for the light it throws on the history of the Lewisian rocks of the Glenelg inlier and its relationship to the history of the Lewisian rocks of the Caledonian foreland.

In the Glenelg inlier the Lewisian and Moinian rocks outcrop as alternating belts running in a north–south direction (Geol. Surv. Sheet 71, Scotland). The locality from which the eclogite used in the age determination was obtained lies within the eastern outcrop of Lewisian rocks where eclogitic rocks are associated with paragneisses.

With the evidence now available[3–6] it is possible to construct an outline of the sequence of metamorphic and structural events which affected the Lewisian rocks of the eastern part of the Glenelg inlier:

(1) Early metamorphism—granulite facies (eclogites)—1,515 ± 104 million years (this communication).

(2) Retrograde metamorphism—amphibolite facies (eclogites amphibolitized[1]).

(3) First folding (F_1)—responsible for the interbanding of the Lewisian and Moinian rocks *circa* 740 million years[4]. Certainly older than 560 million years (Brown and Miller, in preparation).

(4) Later folding (F_2 and F_3)—about 420 million years[5,6].

The episodes of folding (3) and (4) here affect both the Moinian and the Lewisian rocks so that they can be considered to form part of the Caledonian orogeny. The retrograde metamorphism (2) has also been considered a result of the Caledonian orogeny by Clough and Alderman but direct evidence is lacking. The early metamorphism (1) has been previously considered to be of Scourian age[3], on the supposition that the high-grade metamorphic rocks, including the eclogites, found at Glenelg could be correlated with the pyroxene granulites of Scourie in the Lewisian of the foreland.

The new date from a Glenelg eclogite falls well within the range of dates given by Giletti *et al.*[6] for the Laxfordian of the Loch Laxford area. This evidence therefore introduces the possibility that the early high-grade metamorphism of the Glenelg area should be correlated with the Laxfordian rather than the Scourian.

We are aware that a single date from an area with a complex structural and metamorphic history does not constitute proof of age and the date given in this communication can only be considered a minimum age. But it is emphasized that the minerals of the specimen of eclogite used in this age determination show no signs of retrograde alterations, unlike most of the eclogitic rocks in the same neighbourhood.

The possibility of a Laxfordian age for the Lewisian rocks in the eastern part of the Glenelg inlier invites comparison with the Lewisian rocks of South Harris recently described by Dearnley[7]. The marked similarities in lithology and metamorphism between the Lewisian rocks of South Harris and those of Glenelg have long been appreciated. The recent work of Dearnley and the new data from Glenelg make possible a closer comparison (Table 2).

Table 2

	South Harris[7]	East Glenelg
Scourian	Sedimentation First granulite facies metamorphism Intrusion of igneous complex	Sedimentation* Not definitely identified Intrusion of basic and ultra-basic rocks
Early Laxfordian	Second granulite facies metamorphism	Granulite facies metamorphism
Late Laxfordian	Retrograde metamorphism	Retrograde metamorphism
Caledonian		Folding (F_1, F_2, and F_3) with associated metamorphic effects

* The evidence from Glenelg does not preclude a post-Scourian age for the deposition of the Glenelg sediments.

Geographical Variations of Oxygen-18/Oxygen-16 Ratio in Surface Snow and Ice from Queen Maud Land, Antarctica

THE work recorded here is a continuation of that reported in *Nature*[1,2] on the isotopic composition of Antarctic snows.

The ratio of oxygen-18 to oxygen-16 has been measured in some hundred samples of surface snow and ice in the region of the King Baudouin Station (70° 26′ S., 24° 19′ E.), and taken from an area extending from the coast to the southern slopes of the Sor-Rondane Mountains, situated 300 km to the south. Information concerning the geodesy and morphology of this region has been published[3,4].

These samples were collected during the Belgian Antarctic Expeditions of 1959 (Commandant F. Bastin) and 1960 (Commandant G. Derom).

Detailed results will be published elsewhere. We report here only those results relative to samples of which the thickness represents one or more years of accumulation, in order to minimize the seasonal variations.

The ratio of oxygen-18 to oxygen-16 is expressed, as in previous publications, by δ, in parts per thousand of relative variation with respect to the standard mean ocean water (SMOW).

Fig. 1 shows the locations at which samples were taken and the values of δ. Each value corresponds, in general, to the average of several neighbouring samples of similar isotopic composition.

Fig. 2 shows the variations of δ as a function of the altitude at which the samples were taken. We have added two points taken from other publications: the point from the South Pole according to Epstein and Sharp[5], and a group of points corresponding to Victoria Land, and measured by Roth, Nief and Botter. The latter points have been estimated from the average content of deuterium reported by Lorius[6], and the altitudes reported by Stuart and Heine[7]; the deuterium concentrations have been translated into δ according to the relation found at the King Baudouin Station in 1958[8].

Despite the poor statistical value of samples of which most represent only one year, the values of δ follow well the general scheme of variations of isotope composition of precipitations[8,9]. It is known that the value of δ depends principally on the temperature of precipitation. In the Antarctic, the average annual temperature is essentially a function of the altitude.

Table 1 indicates that the four classical geographical zones of the Antarctic are characterized by clearly different values of the δ of precipitations.

TABLE 1 AVERAGE OXYGEN-18/OXYGEN-16 RATIO OF SURFACE SNOW FROM THE FOUR GEOGRAPHIC ZONES—PRINCESS RAGNHILD COAST

Zone	δ (SMOW) averages
Sea ice* and ice-shelf (68°–70° S.)	−22
Continental slope (70°–71° 30′)	−22 to −26
Mountains (71°–72°)	−26 to −37
Polar plateau (72°–90°)	−37 to −50

* Snow precipitated on the ice-pack. The sea ice itself shows δ of + 1.

The most-pronounced difference is between the ice formed on the plateau and that formed on the continental slope. The variation of δ in the 300 km separating the coast from the mountains is as great as the variation over the whole of the polar plateau. This corresponds to the increasing spacing of the curves of equal elevation, equal temperature and equal accumulation when proceeding from the coast toward the centre of the continent.

It will be important to make a network of measurements of δ of surface snows extending throughout the continent, as well as measurements of δ as a function of the depth at diverse points of the Antarctic ice-cap. These data could provide important information on the large-scale displacements of the ice-cap (see, for example, ref. 10 in reference to Greenland).

We take from the present work two examples of information which can be derived from the application of isotope methods on a more local scale:

(1) The sample of ice *LD* comes from a region of the continental slope where the bare ice is exposed over large areas, at more than 60 km from any rocky outcrops. The origin of these fields of bare ice is still controversial. In this particular case, the isotopic composition ($\delta = -22$) indicates that this ice does not come from the polar plateau, but that it must have been formed at the expense of snow precipitated in the same zone (assuming that it has never experienced strong evaporation).

(2) The entire zone of the Sor-Rondane Mountains shows traces of important glacial recessions. Although most of the glaciers of the northern slopes no longer connect with the plateau, it is probable that in the past the ice-cap ran over the mountain range.

It can be seen (Figs. 1 and 2) that all the samples taken from the northern slope of the range have about the same isotopic composition ($\delta = -30$), whether it is bare ice from the ablation zones, or surface snow representing recent precipitation. These ices, then, were formed from local precipitations, and do not represent possible remainders of the ice-cap, dating from before the recession.

Only the sample *GU* has a clearly more negative δ (-39). This value is in good agreement with the geographical facts. In fact, this sample is the only one which comes from an outlet glacier (the Gunnestadbreen), still in connexion with the plateau and presenting a measurable surface flow (maximum displacement of the order of

Yoredale Cyclothems of Northumberland

IN discussion of Yoredale cyclothems insufficient attention has been paid to the degree of change between successive environments of deposition in thinly bedded sequences. There is general agreement that the study of cyclothemic and cyclical sedimentation is primarily an investigation of the sequence of the environmental changes that take place. If it is accepted that this is so regardless of how long a new environment may persist or how widespread it may be, then the full implications of such a statement must be appreciated. For example, in the case of a sandstone–limestone junction the change from a sandstone to a limestone two feet thick is exactly equivalent to the change from an identical sandstone to an identical limestone thirty feet in thickness. That is to say, the change in environment is of the same degree in both cases and that this change occurred in a distinct period of time. The duration for which the new conditions were maintained is of no consequence in this context since this indicates the history of the rock after the all-important event had taken place.

The Yoredale Series is interpreted as a succession of cyclothemic units each of which approaches, or can be related to, an 'ideal' or 'complete' cyclothem in which the beds succeed one another in a series from limestone, through shale, sandstone, and seat-earth to coal. To illustrate the difficulties encountered in attempting to interpret the Yoredale sediments of Northumberland in terms of such a concept an example is taken from the section of Middle Limestone Group strata at Beadnell (*National Grid*, ref. 46 236293) on the Northumbrian coast. In Fig. 1, a plot is made above the mid-horizontal line of the various rock types arranged in succession from one environmental extreme to the other in accordance with the standard cyclothem, and the changes of environment as inferred from the succession of rock types are consecutively numbered 1–28 along the top of the diagram. Below the mid-horizontal line the thicknesses of the beds are indicated by vertical lines. It would appear that this sequence can be interpreted in several different ways as detailed here:

(1) The traditional interpretation would be to consider the beds from 1 to 27 as a single cyclothem; this same sequence might more recently be referred to as a 'major' cyclothem.

(2) Two cyclothems may be distinguished, from beds 1–11 and 12–27 respectively, that is, beginning a new cyclothem with each limestone that follows a change of high degree in environment.

(3) Three cyclothems may be recognized, from beds 1–11, 12–17, and 18–27, if the fossiliferous calcareous sandstone is interpreted as a marine horizon.

(4) Four cyclothemic units from beds 1–11, 12–17, 18–23, and 24–27, may be recognized, if in addition to the last case beds 24–27 are considered to represent a cyclothem with the calcareous member missing.

In the first of the interpretations made here, all the sediments from one thick limestone to the next are grouped as a single cyclothem in the traditional manner. Such a disordered grouping cannot be accepted as a cyclothemic unit. In recent years[1], distinction has been made between 'major' and 'minor' cyclothems, whereby relatively thin or minor cyclical repetitions of strata are conceded near the top of a larger and embracing major cyclothem. This interpretation is equally difficult to accept since the thin limestones of the 'minor' cyclothems should be regarded as equally significant environmentally as the thick limestone which defines the 'major' cyclothem. Any grouping of beds 1–27 in terms of a cyclothem, 'major' or otherwise, is identified only by the presence of thick limestones; thick limestones are named, are important commercially, are conspicuous in the field, are important stratigraphical marker horizons, but they do not represent especially important units in a cyclical series.

The three remaining subdivisions of the sequence shown in Fig. 1 form a series recognizing in turn a thin limestone, a fossiliferous calcareous shale, and finally the position where a marine horizon might have occurred, as logical points in the succession to define the limits of cyclothemic units. Such interpretations realize the overall importance of the changes which occur in the environment and are not primarily subject to considerations of thickness. However, following this line of argument, further cyclothems might be recognized wherever

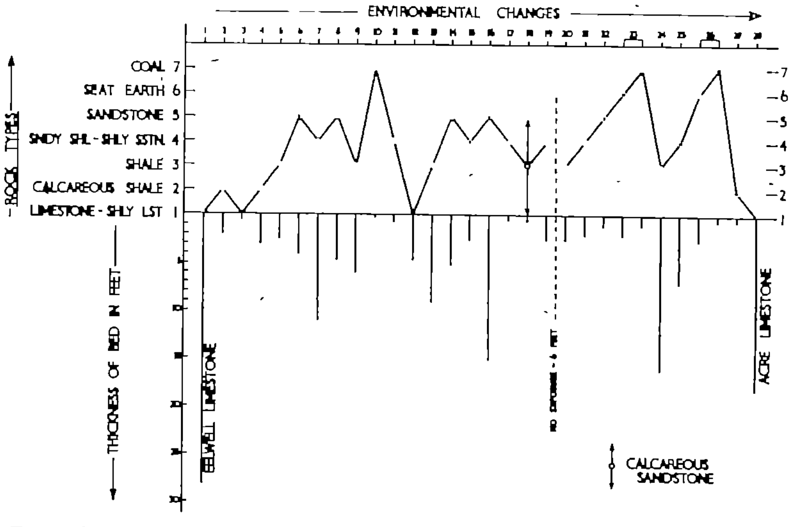

Fig. 1. Sequence from the Belwell to the Acre limestones at Beadnell, Northumberland

there is an interruption of the 'ideal' gradual change. It is clear that once cyclothems are referred to with certain members 'missing' or 'absent' then a process is begun which if taken to its logical conclusion fragments the sequence to the point of meaninglessness. Nevertheless, in the literature to-day, cyclothems are described as 'modified' or 'reduced'; beds are referred to as 'missing', 'restricted', 'absent', etc. Reference is made to 'typical' or 'usual' and 'unusual' cyclothems in which the standard taken is the 'ideal' sequence and in no sense is this a comparison with an actual rock sequence or an 'average' rock sequence. Repeatedly authors point out the inadequacy of their successions to realize theoretical conceptions and so one is led to the conclusion that attempts to apply the cyclothem hypothesis to such successions might mistakenly distinguish sequences of rock types as equatable or comparable entities by admitting variation in 'detail' from an ideal, instead of realizing the full implication of the actual existence of such 'modified' sequences. That is to say, perhaps in certain cases it is not the successions which are 'inadequate' but that the application of such 'ideals' is inappropriate.

METEOROLOGY

A Secondary Source of Water Vapour in the Upper Atmosphere

The early pioneering work of Dobson, Brewer and Cwilong with frost point hygrometers indicated that over South England the water-vapour content of the stratosphere between 12 and 15 km is extremely small in all seasons, being about 2 mg/kg (frost point temperature being about − 80°). Subsequent measurements of humidity between the same levels over a geographical region extending from Norway to equatorial Africa revealed the interesting fact that in all seasons and in most of the locations the moisture content of the lower stratosphere is very small. On the basis of such observations, which led to the concept of a uniformly dry stratosphere, Dobson *et al.*[1] postulated the existence of a meridional circulation in the stratosphere involving the poleward movement of very cold saturated air near the equatorial tropopause and its descent over high latitudes. This theory has been amplified further by Ramanathan[2] and Murgatroyd and Singleton[3]. On the other hand, a large number of observations made over the North American continent and Greenland during 1959 and 1960 using automatically registering frost point hygrometers indicated a very wide range of frost point temperatures from − 67° to − 80° C (refs. 4, 5). Similar observations made over Japan indicate that on many occasions the water-vapour mixing ratio increases with height in the stratosphere[6]. Rohrbough[7], using a balloon-borne sampling system, has recently reported high humidity mixing ratio of 320 mg/kg at a height of 30 km over the United States, this height being a record for the determination of humidity. These recent observational results, which indicate a rather complex distribution of water-vapour, suggest that the earlier concept of a uniformly dry stratosphere needs re-examination.

Quite apart from the data provided by individual soundings involving elaborate equipment, no routine climatological data on humidity in the stratosphere were available until very recently. The monthly mean humidity data (based on at least ten individual observations each month) of a large number of stations from the U.S.S.R. and a few from Sweden for levels up to 100 mb have been given in the *Monthly Climatic Data for the World* published by the U.S. Weather Bureau. An analysis of these data covering the period January 1961–May 1962 reveals the following interesting features:

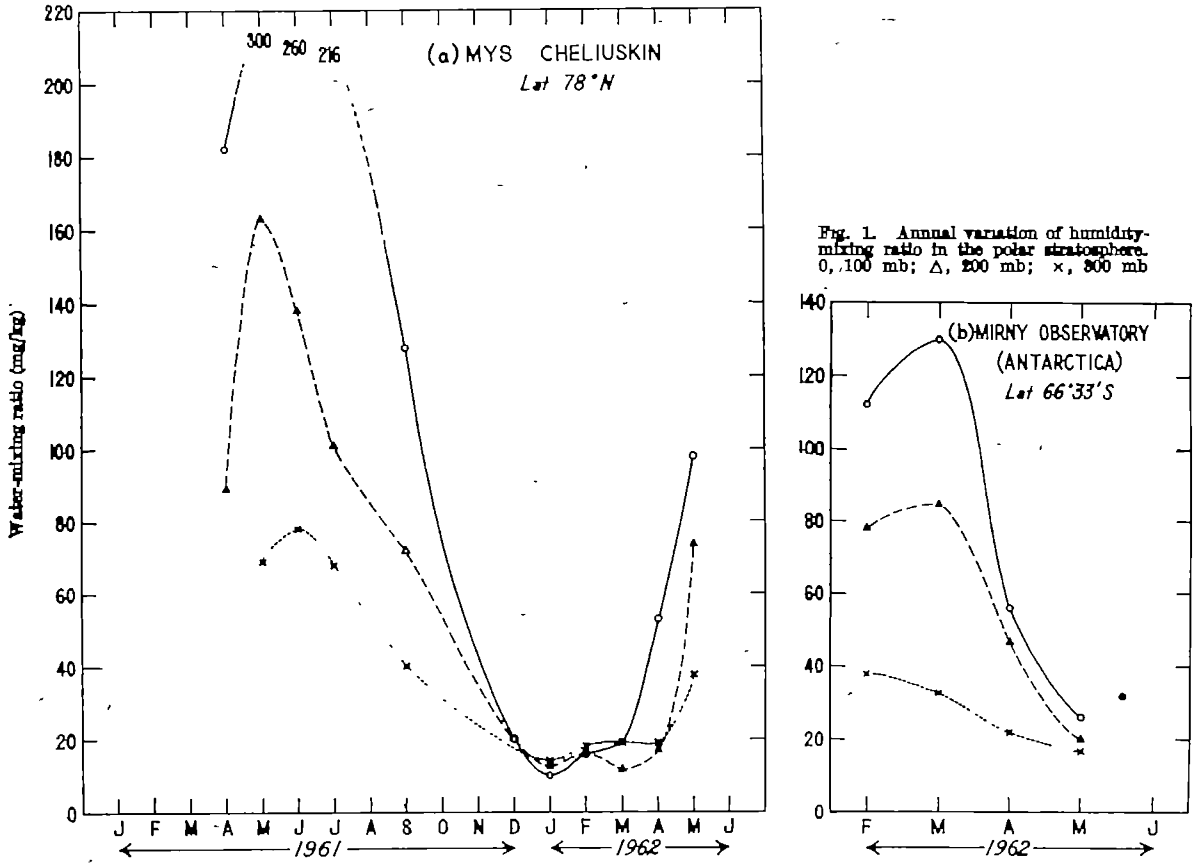

Fig. 1. Annual variation of humidity-mixing ratio in the polar stratosphere. O, 100 mb; △, 200 mb; ×, 300 mb

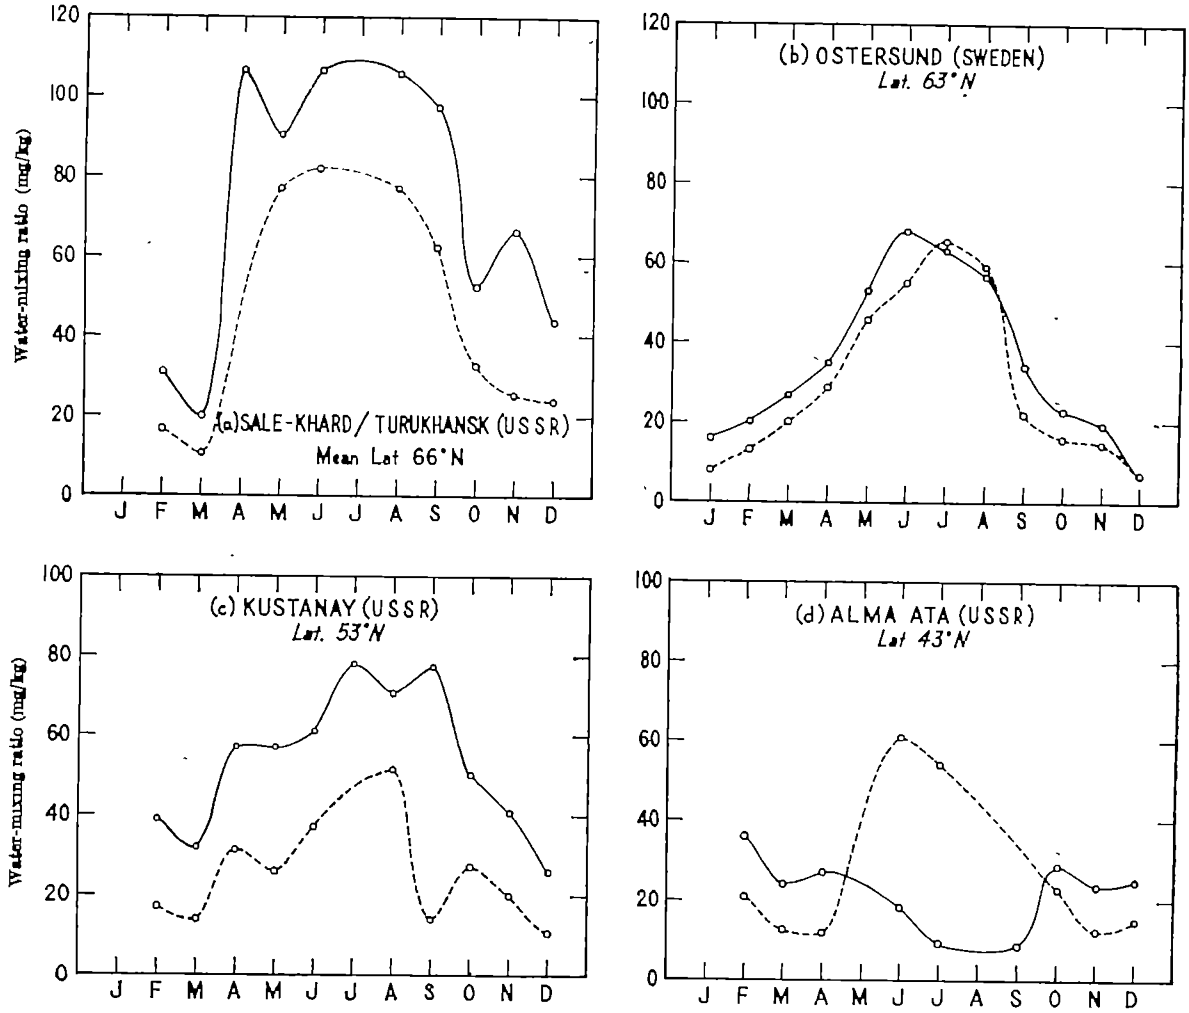

Fig. 2. Annual variation of humidity-mixing ratio at four stations at different latitudes (1961). ——, 100 mb; – – –, 200 mb

(1) The highest concentration of water-vapour in the lower stratosphere is found near the summer pole and attains values of about 200–300 mg/kg at the 100-mb level (16 km).

(2) There is a systematic annual cycle in the water-vapour concentration at all stations to the north of lat. 45° N. with a maximum in summer and a minimum in winter.

(3) The amplitude of the annual variation is the highest near the summer pole and decreases with decreasing latitude.

(4) Water-vapour mixing ratio increases with height for the greater part of the year at the high-latitude stations.

(5) The annual cycle of mixing ratio in the Antarctic stratosphere is similar to those in the Arctic in the appropriate season.

(6) At stations to the south of about lat. 45° there is a reversal in the phase of the annual cycle.

Fig. 1*a* shows the annual variation of the monthly mean mixing ratio at Mys Cheliuskin (77° 43′ N., 104° 17′ E.) during the period April 1961–May 1962 for three different levels, 300, 200 and 100 mb. The summer values of mixing ratio amounting to more than 300 mg/kg at 16 km in May is the highest ever reported anywhere in the lower stratosphere and is about 100 times greater than the value in the early British observations. Independent confirmation of the summer increase of humidity is afforded by Fig. 1*b*, which illustrates the data of Mirny Observatory, Antarctica (60° 83′ S., 93° 00′ E.), where summer conditions prevail in January and February. The decrease of annual amplitude with latitude is illustrated by Fig. 2, which shows the results in respect of 4 different stations covering the latitude range 66° N. to 43° N. It is interesting to find that at Ostersund (Sweden), where instruments of different makes are used, the annual pattern is the same as at the Russian stations to the north of lat. 45° N. At latitudes less than 45° N. the annual variation seems to follow a different pattern, as would be seen from Fig. 2*d*, which pertains to Alma Ata (43° 14′ N., 76° 56′ E.). The mixing ratio at 100 mb is a minimum during July–September whereas that at 200 mb is a maximum in the same period.

The features in respect of Alma Ata can be explained broadly in terms of the known features of upper air climatology of the Asian region together with some kind of meridional circulation. But the other observed features cannot be accounted for by the prevailing concept that the whole of the water-vapour in the lower stratosphere has its ultimate source in the Earth's surface. A clue to a possible secondary source of water-vapour in the upper atmosphere is afforded by the recent theory put forward by de Turville[illegible] that the entire hydrogen content of the Earth's oceans could be of solar origin. According to this, the protons contained in the solar wind get trapped by the Earth's magnetic field and after a process of accretion throughout the estimated age of the Earth finally get oxidized as water. Frith[illegible], following up this theory further. has suggested that the water-vapour formed at high levels could be transported downwards by turbulence. In support of this, it has been cited by him that the noctilucent clouds found in the mesosphere at 80 km as well as the mother-of-pearl clouds found occasionally in the middle stratosphere (25 km) could both be formed by the condensation of water-vapour carried downwards from the higher levels. Such a concept involving a secondary source of water-vapour in the upper atmosphere could qualitatively account for some of the new features revealed by the recent data on stratospheric humidity. Since relatively large values of humidity occur only to the north of lat. 60° and only during the sunlit period of the year, it is tempting to suggest a photochemical origin for the water-vapour in accordance with the equation:

$$\mathrm{OH} + \mathrm{H} \rightleftharpoons \mathrm{H_2O}$$

From available data on the spectrum of the night airglow, there is evidence for the presence of OH radical at about 70 kilometres where there is an appreciable amount of atomic hydrogen also. The dominant circulation in the upper stratosphere and the lower mesosphere during summer is a vast circumpolar anticyclone of great persistence[10]. The subsidence associated with this anticyclone might be effective in transporting the water vapour downwards from the mesosphere to the lower stratosphere.

Barometer and Wind Fluctuations in North-West Europe, 1796–1950

Barometric series from manuscript and printed sources were recently utilized for the preparation of maps of annual anomalies. From these maps it was possible to determine the pressure at the Wash (53° N., 0½° E.) since 1706 and pressure gradients (since 1796) between positions 400 km south-south-west and north-north-east and 400 km east-south-east and west-north-west (corresponding to west and south calculated components of surface wind). In Fig. 1 the mean values for ten-year periods of pressure and pressure gradients are shown. The 'SW wind' is a measure of the closeness of the isobars directed west-south-west to east-north-east, and the 'NW wind' relates to a component of pressure gradient at right angles to this. The latter component is small. Indeed, the variation in direction from one thirty-year period to another of the prevailing wind, as shown in Fig. 1 (for example, 224°), is much smaller than has hitherto been supposed.

Wind observations of north-west Europe since 1635 were likewise combined into components, as explained in a recent issue of *Geografiska Annaler* (44, 303; 1962). The apparent mean wind in any decade, determined without taking velocity differences into account, was found to be directed along the isobars, on the average from west-south-west, with frequency components of the order of 18 per cent from west and 8 per cent from south. The 'true' surface wind at a typical land station comes from the south-west, not west-south-west. The vector anomalies of the wind, if one year is compared with another, were nevertheless found to follow Buys Ballot's law in the usual way, and are directed from the west-south-west when the isobaric anomaly lines lie west–east. Using empirical relationships with the wind components in percentages, it was possible to 'calibrate' the pressure gradient curve as indicated at the right-hand part of Fig. 1, and to determine the pressure-gradient fluctuations quantitatively in the seventeenth and eighteenth centuries.

St. David's College,
Beckenham, Kent.

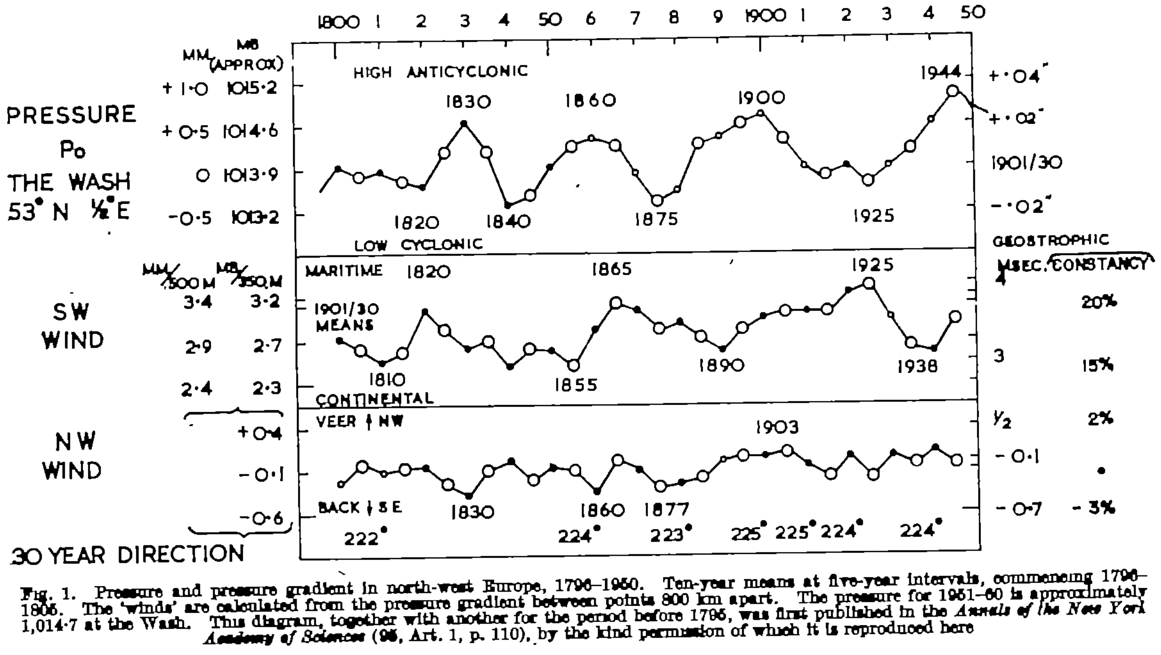

Fig. 1. Pressure and pressure gradient in north-west Europe, 1796–1950. Ten-year means at five-year intervals, commencing 1796–1805. The 'winds' are calculated from the pressure gradient between points 800 km apart. The pressure for 1951–60 is approximately 1,014·7 at the Wash. This diagram, together with another for the period before 1795, was first published in the *Annals of the New York Academy of Sciences* (95, Art. 1, p. 110), by the kind permission of which it is reproduced here

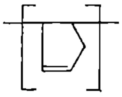
RADIATION CHEMISTRY

Radiation-induced Ionic Reactions: *Cyclo*pentadiene Polymerization

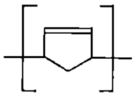
Recent investigations[1–3] on the radiation-induced polymerization of certain monomers have provided evidence for the production of ionic as opposed to radical initiation. The polymerization of such monomers can be initiated by Friedel–Crafts catalysts, and *cyclo*pentadiene[4] falls into such a class. Pure, rigorously dried (silica-gel treated) *cyclo*pentadiene was irradiated with cobalt-60 γ radiation (dose-rate $2\cdot27 \times 10^{17}$ eV g^{-1} min^{-1}). At $-78\cdot5°$ C a gel was formed after conversion of 1·6 per cent of the monomer to polymer. The results of carbon, hydrogen analysis fitted an empirical formula of C_5H_6. The gelling dose was $8\cdot5 \times 10^{17}$ eV g^{-1}, and the subsequent increased rate of polymer formation corresponded to the removal of $17{,}760 \pm 1{,}521$ (*S.D.*) monomer molecules per 100 eV. This was linear with dose up to at least 40 per cent conversion. At 0° C the yields were lower and suffered a high degree of irreproducibility (G(-monomer) range of 1,518–12,750). At 22° C a dimer impurity could not be excluded owing to its spontaneous thermal formation[4], but polymerization did ensue in one experiment with an overall G(-monomer) yield of 10,600 at 15 per cent conversion. In the absence of silica-gel drying the yields were substantially reduced. The efficiency of the reaction at low temperature, and the necessity for rigorous drying[9] to attain high yield are criteria for the non-participation of radical processes.

The infra-red spectrum of the radiation-induced polymer in a potassium bromide disk was similar to that of polymer prepared by stannic chloride catalysis in chloroform at −5° C (ref. 5). The repeating unit of the latter polymer has been formulated as:



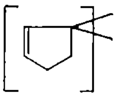
(I)

or



(II)

Nuclear magnetic resonance analysis of a solution of a sample of catalysed material in carbon tetrachloride favours structure I. A similar analysis of a radiation-produced sample which formed a swollen gel in the solvent suggests a structure:

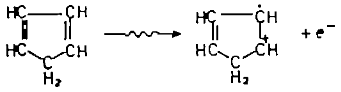


(III)

Owing to line-broadening, hyperfine structure was not observed so that the assignments must be regarded with some reserve.

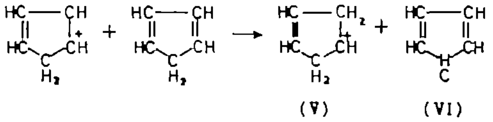
In formulating a mechanism for a radiation-induced polymerization it is primarily necessary to explain the modes of charge separation and stabilization. The production of a stable carbonium ion from an initial radical-ion has been accounted for by proton transfer[6], ion-molecule reactions[3] or ion re arrangements[2]. Capture of the conjugate electron on solid sub-microscopic particles[6,7] is one favoured postulate for production of a stable negatively-charged entity. Carbanion formation[2,8] has also been proposed as a possibility, and in the case under discussion such a negative ion can be envisaged in the following possible scheme.

The primary process is:



(IV)

followed by an ion-molecule reaction with monomer:



(V) (VI)

Afterwards VI captures the electron on its return to the neighbourhood of the positive ion to form the very stable *cyclo*pentadienyl ion which acts as the counter-ion. V or a re-arranged form then initiates propagation more readily than it undergoes neutralization. The energy requirements for charge separation may be derived from the energetic primary event and from the contribution of polarization forces. The rapid gelation and insolubility of the whole polymer in solvents suggests a cross-linked structure arising from branching during propagation[8]. This might result from hydride-ion transfer between propagating chains or between such chains and formed polymer[9]; an alternative would be the occurrence of proton transfer to the remaining double bond in a repeating unit of a neighbouring chain.

I thank Mr. T. L. Jones and Dr. R. K. Webster for carrying out the nuclear magnetic resonance analysis, and acknowledge an initial suggestion by Dr. T. F. Williams and the encouragement and advice of Dr. W. G. Burns and Dr. W. Wild.

CHEMISTRY

Improved Efficiency in Gas Chromatography by Molecular Sieve Flour

IT has been demonstrated that columns packed with 5*A* molecular sieve flour dispersed on conventional 'Chromosorb' support perform better than columns packed with crushed molecular sieve pellets[1]. This is illustrated in Fig. 1 by the chromatograms showing the separation of air. Curve *A* was produced with a 2 m × ¼ in. column packed with 60/80 mesh 5*A* molecular sieve. Curve *B* was produced with an equal-dimension column packed with 28 per cent molecular sieve flour coated on 60/80 mesh red 'Chromosorb'. The molecular sieve column provides only 97 plates compared with 562 plates for the mixed column. Expressed as height equivalent to a theoretical plate, this represents a decrease from 20·6 mm to 3·5 mm and a six-fold increase in efficiency. Separations were at room temperature with flow-rates near 50 ml./min of helium. The sample was 2 ml. of air.

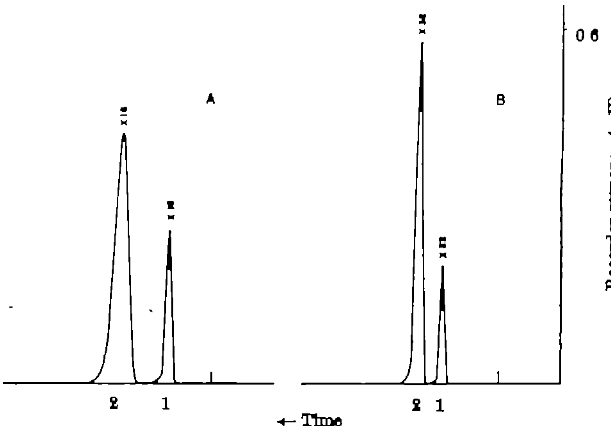

Fig. 1. Chromatogram showing the separation of oxygen (1) and nitrogen (2). *A*, Molecular sieve 60/80 mesh; *B*, molecular sieve flour coated on 'Chromosorb'

The mixed 'flour' column worked effectively with light hydrocarbons as well as with permanent gases.

The −200 mesh 5*A* molecular sieve flour was obtained from Chrom-Line Laboratories, Kansas City. It was dispersed on 'Chromosorb' by mixing two parts 'Chromosorb' with one part molecular sieve flour. The mixture was rolled in a cylindrical container for 18 h and then screened. The material which passed a 60 but was retained on an 80- mesh screen was used as the column packing. Of the original 33 wt. per cent added to the mixture, 28 wt. per cent of the flour was retained on the 'Chromosorb'.

Electron Paramagnetic Resonance Spectrum of the Acetyl Radical

THE electron paramagnetic resonance (EPR) spectrum of the acetyl radical, CH_3CO, has been detected during and after photolysis of biacetyl at 77° K. Small (100 mg) samples of biacetyl were distilled into thin-walled quartz tubes and degassed. The samples were placed in the *V*-4546 quartz Dewar accessory of a Varian *V*-4500 spectrometer, and irradiated under liquid nitrogen with a low-pressure mercury arc.

A typical spectrum, recorded after 90 min irradiation, is reproduced in Fig. 1. This spectrum was analysed in terms of two radical species each exhibiting hyperfine interaction with three equivalent protons. The wider spectrum, in which the proton hyperfine interaction is 66 ± 5 Mc/s, was attributed to the methyl radical, since the observed hyperfine splitting and *g*-value (2·0027 ± 0·0008) are in excellent agreement with previous work[1,2] on the methyl radical. The features of the spectrum due to the methyl radical decreased slowly in intensity when the lamp was turned off, reaching half-intensity in approximately 15 min. The remaining spectrum, which is believed to be that of the acetyl radical, did not decay significantly after switching off the lamp, but on warming to approximately 140° K in a *V*-4547 variable temperature accessory, it decreased rapidly in intensity without change in shape. The hyperfine interaction is that of three protons with equal couplings of 47 ± 5 Mc/s, appreciably less than that to be expected from equivalent protons β to a π-electron radical centre[3]. Acetyl, which has not previously been detected spectroscopically, is a σ-electron radical analogous to the formyl radical reported recently[4]. The *g*-value of the acetyl spectrum was found to be 2·0055 ± 0·0008 and the comparatively high maximum-slope line-width of 15 Mc/s probably reflects a small anisotropy in the coupling constants, rather than in the *g*-value, since the spectrum of acetyl was quite accurately centro-symmetric.

The presence of both acetyl and methyl radicals in irradiated, condensed biacetyl is consistent with the mechanism of Noyes *et al.*[5,6], who proposed the primary decomposition step at 2700 Å to be:

$$CH_3COCOCH_3 + h\nu \rightarrow 2\alpha CH_3CO^* + (2-2\alpha)CH_3CO \qquad (1)$$

where CH_3CO^* decomposes almost immediately into $CH_3 + CO$. Their evidence suggested that α was 0·5, and therefore (1) was kinetically indistinguishable from:

$$CH_3COCOCH_3 \rightarrow CH_3COCO + CH_3 \qquad (2)$$

followed immediately by:

$$CH_3COCO \rightarrow CH_3CO + CO \qquad (3)$$

In our experiments the observed concentration of acetyl radicals was at least five times that of the methyl radicals, and even allowing for the disappearance of methyl radicals during irradiation, an upper limit of 0·25 can be placed on α of reaction (1). Therefore under our conditions reaction (2) cannot be the only primary decomposition step.

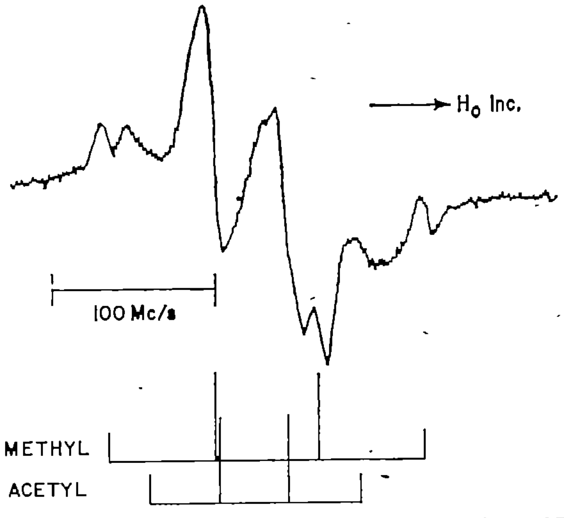

Fig. 1. EPR spectrum of ultra-violet-photolysed biacetyl at 77° K

If the acetyl radical concentration were sufficiently high, a methyl radical could be formed on absorption of a second quantum of energy by an acetyl radical:

$$CH_3CO + h\nu \rightarrow CH_3 + CO \qquad (4)$$

However, the build-up of methyl radicals on irradiation of biacetyl is simultaneous with that of the acetyl radicals, so that absorption by acetyl radicals cannot be the (sole) precursor to methyl radical formation.

If, as is generally believed, radical recombination reactions have very low or zero activation energies, the persistence of acetyl radicals in biacetyl at 77° K indicates that these radicals are rigidly held in the matrix. In contrast, the methyl radicals are presumably free to migrate. Further work to determine the fate of the methyl radicals is in progress, and the investigation is being extended to include higher ketyl radicals.

We thank Dr. R. J. Cvetanović for his interest.

Estimation of Small Amounts of Sulphate by Precipitation with Radioactive Barium

IN the course of work on the metabolism of sulphur amino-acids in malnourished infants it was necessary to measure total sulphate concentration in large numbers of urine samples. The urine from these patients is very dilute, so that to obtain accurate results by the classical gravimetric or titrimetric methods it would be necessary to use large volumes. This is inconvenient, since for the oxidation of organic sulphur the urines have to be digested with concentrated acid. By precipitating with barium chloride containing radioactive barium, and measuring the radioactivity in the precipitate, the estimation could be made on 0·1–0·5 ml. urine.

To a sample of 0·5 ml. containing 0·5–20 μM sulphate are added 1–2 ml. of barium chloride reagent. 1 ml. of the reagent is enough for quantities of sulphate up to 5 μM; for quantities between 5 and 20 μM 2 ml. should be added. The reagent consists of 0·03 M barium chloride in 1 N hydrochloric acid and 60 per cent ethyl alcohol. To this is added $^{133}Ba\,Cl_2$, about 0·05 μc./ml., depending on the sensitivity of the counter. The alcohol is added to reduce the solubility of the barium sulphate[1]. If the solution is not acid, precipitation is incomplete. After this was done it was found that an excess of acid significantly increases the solubility of barium sulphate[2]. In practice, however, the effect seemed to be negligible, and is allowed for if sulphate standards are included in each batch of measurements.

The sample and barium chloride reagent are mixed by shaking, allowed to stand for 1 h, and centrifuged at 4,500 r.p.m. for 10 min. The supernatant is decanted and the tube allowed to drain. The sides of the tube and the surface of the precipitate are then rinsed with 1 ml. of non-radioactive barium chloride reagent. It was found that washing the precipitate decreased the recovery and made the results more irregular. In one experiment the amount of supernatant trapped in the precipitate was measured by precipitating sulphate with a solution of non-radioactive barium chloride containing radioactive silver nitrate. The activity trapped in the precipitate was negligible.

After rinsing, the activity of the precipitate is counted in a scintillation counter with a well crystal. The whole operation is carried out in one tube, so that the possibilities of loss are minimal. The amount of barium-133 added to the reagent is adjusted to give a count-rate of about 2,000 c.p.m./μM sulphur.

In 21 consecutive measurements of 2–10 μM sulphate the mean difference between duplicates was 1·4 per cent (max. 3·8 per cent). In 8 consecutive measurements of 0·5–2 μM sulphate the mean difference was 3·0 per cent, or 1·5 per cent if one aberrant pair of readings, differing by 12 per cent, is excluded.

In 3 experiments to test linearity, the results shown in Table 1 were obtained.

Table 1

μM SO_4 present	No. of samples	Counts per min	Percentage of counts at 0·5 μM	Percentage error
0·5	4	1,028	100	—
1·0	6	2,068	200	0·1
2·0	6	4,162	404	1·0
4·0	2	7,945	772	4·0

In acid solution the other constituents of urine did not interfere with the precipitation of sulphate. 8 samples of infants' urine were taken at random, and aliquots of 0·5 ml. added to 0·5 ml. of standard solutions containing 10 and 20 μM sulphate per ml. The mean recovery was 101 per cent.

It appears, therefore, that by this method amounts of sulphate down to 0·5 μM can be estimated with an accuracy of ± 2 per cent.

Tetrahedral Co-ordination in *Bis-N*-isopropyl Salicylaldiminato Nickel II

SACCONI *et al.*[1] have recently reported that preliminary investigations indicate a tetrahedral arrangement of ligands about the nickel atom in the paramagnetic *bis-N*-isopropyl salicylaldiminato nickel II. This was based on the isomorphism of this compound with the cobalt and zinc analogues, and the large (~ 7 Å) distance between nickel atoms, which precludes a polymeric octahedral structure such as found for acetylacetonato nickel II (ref. 2), or *bis*-dimethylglyoximato nickel II (ref. 3).

We have since collected three-dimensional data by the equi-inclination Weissenberg technique and have proceeded with structure determination. We are still refining the structure and at this stage $R = 0·064$. The arrangement of the ligands about the nickel atom is a distorted tetrahedron.

Current bond distances about the nickel atom are:

Average Ni—O distance is 1·90 Å
Average Ni—N distance is 1·97 Å
N_1—Ni—O_1 angle is 94·0°
N_2—Ni—O_2 angle is 94·9°
N_1—Ni—O_2 angle is 112·6°
N_2—Ni—O_1 angle is 111·7°
N_1—Ni—N_2 angle is 121·0°
O_1—Ni—O_2 angle is 125·1°

The two salicylaldimine residues are essentially planar, the mean deviation of atoms from the least square planes of the two being about 0·025 Å. The angle between the planes is 81°.

Apparent Molecular Weight of Insulin in Dilute Acid Solution

THE molecular weight of the smallest unit of the insulin molecule occurring in dilute acid solution has been in doubt for some time. Most data from experimental methods, such as ultracentrifugation[1], light scattering[2] and osmometry[3], indicate a minimum value of about 12,000. Some evidence, however, has accumulated for the existence of an insulin molecule of molecular weight of about 6,000 under acidic conditions[4]. This corresponds to the insulin unit the molecular weight of which obtained from the amino-acid sequence is 5,750 (ref. 5). A number of investigators have indeed observed such a value in non-aqueous solvent/water mixtures[6], in media favourable to dissociation[7] and in aqueous solution at alkaline *p*H values[8].

We have measured the apparent molecular weight of insulin in acid solution over a range of concentrations from approximately 0·8 to 0·02 g/100 ml. using the technique of sedimentation equilibrium. A Spinco model *E* ultracentrifuge, equipped with a Rayleigh interference optical system and both 12-mm and 30-mm cells, was used.

The results of our study are shown in Fig. 1, which refers to four different insulin solutions. The insulin was a crystalline preparation containing an unknown amount of zinc, prepared by the Commonwealth Serum Laboratories (batch number *A3*). The solvent in all cases was an aqueous glycine–hydrochloric acid–sodium chloride buffered solution of ionic strength 0·1 and *p*H 2·00. Solutions 1, 2, 3 and 4 had initial concentrations of approximately 0·5, 0·2, 0·1, and 0·05 g/100 ml. respectively and were centrifuged at speeds of 17,980, 17,980, 29,500 and 29,500 r.p.m., respectively, until equilibrium was reached. Since column heights of only 2–3 mm were used equilibrium was reached in less than 18 h. The temperature of the rotor was held constant at 25·0 ± 0·2° C. The four solutions were prepared from a concentrated (1 g/100 ml.) stock solution of insulin that had previously been dialysed for 72 h against a hundred times its volume of buffer with a change of buffer at 48 h. After dialysis the *p*H of both insulin solution and diffusate was 2·04. The refractive index increment of the stock solution compared with the diffusate was determined by means of the refractometer described by Cecil and Ogston[9].

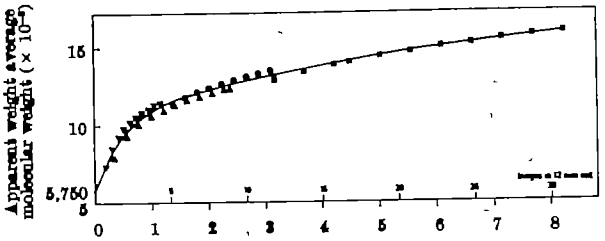

Fig. 1. Apparent weight average molecular weight of insulin as a function of insulin concentration at pH 2·04 and 25° C. ■, Solution 1; ●, solution 2; ▲, solution 3; ▼, solution 4

The four solutions for centrifugation were prepared by weight dilution of portions of the stock solution with diffusate. Diffusate was placed in one compartment of the double sector ultracentrifuge cell. Dow-Corning '555' silicone oil was added to the solution compartment to provide a curved bottom. The equilibrium Rayleigh patterns were photographed and the plates measured on a toolmakers' microscope. Schlieren photographs at 90° bar angle were also taken to facilitate determination of the positions of meniscus and cell bottom. From these results and knowledge of the refractive increment, the equilibrium concentration distribution of solute in the cell was calculated in terms of fringe number (J). By means of a least squares procedure, a quadratic expression for the dependence of $\ln J$ on r^2 was obtained. (r = distance in the cell from the centre of rotation, in cm.) Substitution into the first derivative of the latter expression allowed calculation of the apparent molecular weight for a series of r values and thus for a series of concentrations by means of the expression[10]:

$$M_{\text{app}} = \frac{2RT\text{d}\ln J}{(1 - \bar{v}\rho)\omega^2\text{d}r^2}$$

taking a value of 0·72 (ref. 11) for $\bar{v}$, the partial specific volume.

For a thermodynamically ideal polydisperse system of uncharged macro-molecules for which the refractive index increment depends linearly on the concentration of solute, this equation would yield a weight average molecular weight. These conditions do not strictly hold for insulin and we can consider that M_{app} is only an approximate measure of the weight average molecular weight.

It is apparent from Fig. 1 that over the concentration range studied the apparent weight average molecular weight of insulin is strongly dependent on concentration, ranging from about 7,500 at 0·02 g/100 ml. to about 16,000 at 0·85 g/100 ml. This behaviour is consistent with the belief that under the conditions of our experiments insulin exists in a state of dynamic association. It also appears that in the limit of zero concentration a molecular weight of about 6,000 would be obtained.

Marcker[12] has suggested that the insulin dimer (of molecular weight 12,000), which is the predominant form of the molecule in acid solution at moderate concentrations, is formed by means of a double disulphide bridge between two monomer (of molecular weight 6,000) units, with a disulphide exchange reaction allowing rapid equilibrium between monomer and dimer to occur. He also suggested that the reaction is mediated by mercaptide ions. The results presented here would seem to disagree with the disulphide exchange reaction explanation since the concentration of mercaptide ions would be very low at pH 2·04, yet a rapid, reversible equilibrium appears to exist under these conditions. Furthermore, in experiments with mixtures of cystine and oxidized glutathione at pH 2 Spackman[13] *et al.* have found no evidence for disulphide exchange between these model compounds.

We thank Dr. E. T. Adams, jun., of the University of Wisconsin, for discussing his results with us prior to publication, and Prof. D. O. Jordan, of the University of Adelaide, for his advice.

BIOPHYSICS

Examination of Optically Excited Amino-acids by Electron Spin Resonance at Very Low Temperature

INVESTIGATIONS carried out in our laboratory[1] on the optical behaviour of serum-albumin protein and of its main constituents have not given any serious evidence of the photo-conductor behaviour of the protein. Things are exactly as if each amino-acid, taking off a fraction of the quantum it absorbs selectively, reacted independently from its partners. The time of radiative deactivation by slow fluorescence is the only factor varying with the association process and the chemical purity of the aggregate.

Combining electron spin resonance with optical excitation, Allen and Ingram recently demonstrated the existence of a metastable state that they considered characteristic of the condensed state of their compound (semiconductivity of hydrated proteins irradiated by ultraviolet at low temperature)[2].

Now combining electron spin resonance and optical excitation we experimented again: we wanted to see whether, under certain conditions, it was possible to obtain a signal for the amino-acid alone. The uniformity of the quantic behaviour observed during the purely optical experimentation then occurred again.

Samples of phenylalanine and tryptophan, in microcrystalline form, were placed in quartz tubes which were vacuum-tapered. Irradiation at temperatures close to that of liquid nitrogen was made directly in the cavity of the 100 kc/s Varian spectrometer for times varying from a few minutes to 1 h, the sources being mercury steam arcs at low pressure (emission maximum at 2537 Å) and at high pressure (emission maximum at 3650 Å). Interferential or chemical filters were added to determine more accurately the spectral zone chosen for examination.

The main results, mostly qualitative, were as follows: (1) Radiations centred on 2537 Å produced a progressive narrow electron spin resonance signal, not yet explained. of a factor g close to 2 (Fig. 1). This signal, obtained at liquid nitrogen temperature, remained after the end of the optical excitation and of the resulting radiative deactivation. It was thermostable and seemed to proceed from a non-reversible radiation damage, analogous to that producing ionizing radiations[3]. Under the conditions of our experiment, the signal was only produced by optical excitation at very low temperatures. Consequently, it seemed to result from the photochemical evolution of excited electronic states, artificially accumulated.

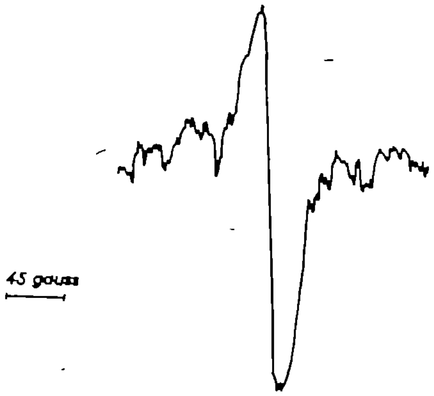

Fig. 1. Irradiation of phenylalanine (λ = 2537 Å)

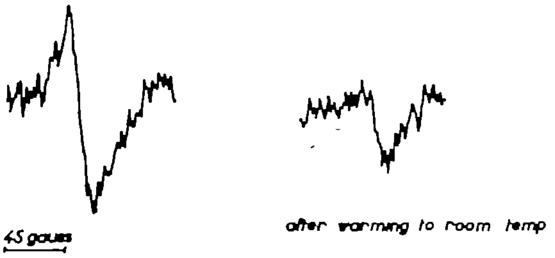

Fig. 2. Irradiation of tryptophan (λ = 3650 Å)

(2) Radiations centred on 3650 Å produced an electron spin resonance signal, similar to the first, conditions being equal. It could be imputed to the intervention of shorter wave-length radiations, insufficiently filtered. But its intensity now varied with temperature: if we heated the sample up gradually, a sharp decline occurred from −150° C. After heating up to normal temperature, a new measurement at −196° C revealed the existence of a residual signal expressing quite certainly an irreversible radiation damage (Fig. 2).

Indeed the chemical purity of our samples could be challenged: the primary importance of this factor in electron spin resonance is well known and especially when the spectrometer was used, as in this case, at a high degree of sensitiveness. But this restriction could be reduced by the reproducibility of the results with amino-acids of different origin and particular care given to the manufacturing of the quartz tubes.

To avoid radiation damage of the experiment with radiations centred on 3650 Å, we tried to improve their selection in limits possible within the sensitivity of the spectrometer.

If, as we hope, the electron spin resonance signals already obtained were specific for amino-acid molecules or for their crystalline state, the following conclusion can be drawn: radiations centred on 3650 Å produce a metastable dynamic configuration, different from the excited configurations producing quick radiative deactivation ineluctibly at −196° C, and also different from thermostable configurations resulting from the photochemical evolution of the preceding ones.

This conclusion accords with the theories inspired by the optical behaviour of amino-acids referred to at the beginning of this communication.

BIOCHEMISTRY

Actomyosin-like Protein in Mitochondria of the Mouse Liver

Incubation of mitochondria isolated from normal cells or cancer cells liberate two substances into the medium—a lipoprotein and adenine nucleotide. When separated from the mitochondria and added to the soluble cell fraction, these have been found to exert a highly stimulating effect on glyoolysis[1,2]. In the case of mitochondria from normal cells, liberation of both these factors has been shown to depend on reversible changes in configuration of mitochondrial membranes. Pre-incubation of mitochondria with adenosine triphosphate, magnesium ions or ethylenediamine tetraacetic acid—that is, agents provoking shrinkage of mitochondria—proved to diminish or to prevent liberation of the stimulating factors and their retention within the mitochondria. On the contrary, pre-incubation with inorganic phosphate, calcium ions or potassium chloride, known to cause membrane relaxation and swelling of mitochondria, increased the release of the stimulating factors into the medium[1,2].

This evidence led to the assumption that release of glycolysis-stimulating factors within the cell was related to functioning of the enzymatic contractile system of mitochondrial membranes[1,2]. On the other hand, it had been suggested by Lehninger that intermediate enzymes of the coupled mechanism of respiratory phosphorylation, occurring in mitochondrial membranes, represented 'mechanoenzymes', similar to actomyosin[4]. This prompted our attempt to isolate actomyosin from mitochondria, the origin of which was not muscle tissue.

After mechanical disruption, mouse liver mitochondria were extracted with Weber's solution at 0° for 24 h. The extracted protein displayed considerable ATPase activity, increasing on the addition of dinitrophenol, magnesium ions or flavin adenine dinucleotide. The Weber extract was used in experiments with polymerization of actomyosin. Owing to the protein content and viscosity being low in the extract, we proceeded to determine the presence of actomyosin on the addition of extraneous myosin *A* as 'primer'. Rabbit muscle myosin *A*, added to the Weber extract of liver mitochondria, caused a drastic increase of viscosity (more than 5-fold). Fig. 1*A* shows viscosity of the resulting complex to be much higher than the total viscosity of its components. Addition of ATP to the solution caused the complex to dissociate and protein viscosity to diminish. Dissociation of the complex proved to be reversible, so that demonstration of the polymerization–dissociation reaction could be repeated with the same solution (Fig. 1*B*). When the actomyosin formed had been dropped into water, the addition of ATP produced a different mechanical effect—intense retraction of the gel and extrusion of water, apparent to the naked eye (Fig. 2). Addition of muscle actin to the extract from mitochondria failed to raise its viscosity.

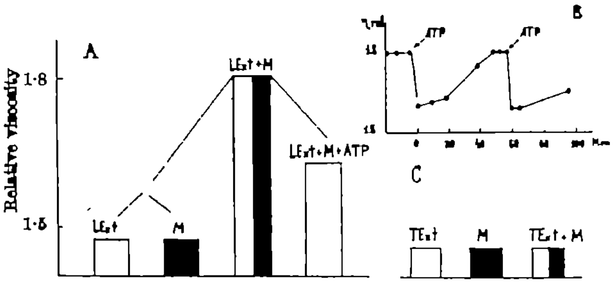

Fig. 1. Variations in relative viscosity with actomyosin polymerization dissociation. *A*, Extract from liver mitochondria (*LExt*), myosin *A* (*M*) and their mixture. Protein content: *LExt* 1 78 per cent; *M*, 0 062 per cent; KCl, 0·6 M; pH, 7 0; temperature, 22° C. *B*, Same; arrows indicate addition of ATP, 1 mM. *C*, Extract from cancer cell mitochondria

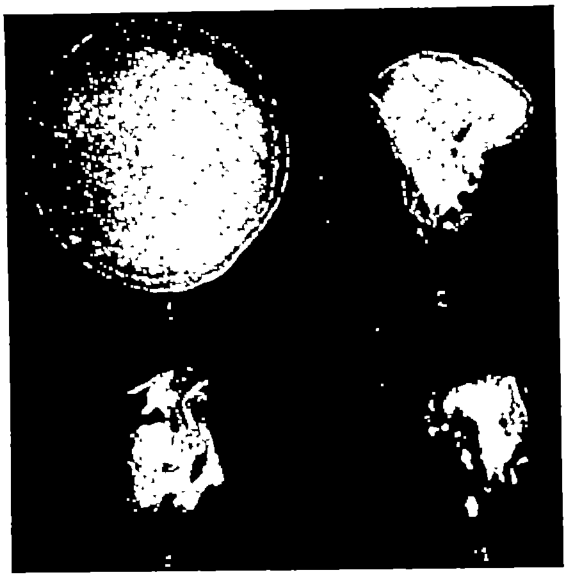

Fig. 2. Synaeresis of actomyosin–water gel exposed to ATP (× c. 4·5)

Although the actomyosin complex has only been revealed on addition of exogenous myosin *A*, it seems reasonable to consider the complex to be performed within the mitochondria, as: (*a*) polymerization occurs on the addition of myosin *A* in a very small quantity insufficient for forming a complex even with muscle actin; (*b*) the structural protein, extractable from mitochondria, displays ATPase properties, being activated by the same substances as the ATPase from actomyosin.

The presence of an actomyosin like protein in liver mitochondria must play a part of outstanding importance in their functioning. Owing to the reversibility of changes in configuration of actomyosin molecules, interaction between actomyosin and ATP may be accompanied by two correlated processes in mitochondrial membranes. In the first place respiratory energy coupling intermediate enzymes assume a kinetically favourable spatial distribution, promoting high rate of synthesis of ATP. On the other hand, this may affect regulation of the release from mitochondria of the glycolysis-stimulating factors and in all probability of other agents as well. When the ATP-level within mitochondria is high, stimulating factors are maintained by the actomyosin bond preventing their release from mitochondria, so that glycolysis fails to occur. As the ATP-level decreases, the configuration of the actomyosin molecule changes, the stimulating factors are released from the bond and liberated into the hyaloplasm, glycolysis sets in, resulting in restoration of a normal intracellular ATP-level.

Attempts to detect the actomyosin-like protein in mitochondria from cancer cells have failed (Fig. 1*C*), although tumour cell mitochondria display marked contractility. It may be assumed that, in tumour cells, mitochondrial membranes, as well as external membranes[5], have a genetically determined abnormal structure, their permeability being independent of contractility.

Interaction of Œstrogens labelled with Carbon-14 with Pyridine Nucleotide in the Presence of Peroxidase

THE discovery by Stotz *et al.*[1,2] that the injection of physiological doses of œstrogens into ovariectomized rats produces large increases in the activity of uterine peroxidase and that several tissues with high rates of cell renewal also have high peroxidase activity has aroused interest in the possible role of this enzyme in cellular proliferation and growth. In work[3,4] on horseradish peroxidase, it has already been shown that this enzyme could catalyse the interaction between œstrogens and certain amino-acids and proteins under aerobic conditions, and this communication deals with a similar reaction involving the pyridine nucleotides.

(16–^{14}C) œstrone (310,000 c.p.m. in 10 μg) dissolved in 5 ml. phosphate buffer *p*H 7·4 was incubated under oxygen with DPNH (5×10^{-4} M), manganese chloride (10^{-4} M) and horseradish peroxidase (10 μg), for 24 h at 37° C, and the amount of radioactivity remaining in the aqueous medium after extraction with ether was determined. This was repeated under various experimental conditions and with different compounds. In addition, each ethereal fraction was examined for œstrone or its metabolites by chromatography followed by autoradiography as described previously[5]. The anaerobic incubation was carried out in an evacuated Thunberg tube.

The results in Table 1 show that horseradish peroxidase in the presence of DPNH or TPNH is able to convert œstrone (and other phenolic œstrogens) into water-soluble, ether-insoluble compounds in relatively high percentage yields. The ether extracts contained several unidentified radioactive metabolites and virtually none of the added œstrogen remained intact. No products of either kind were formed if the reduced pyridine nucleotides were omitted, showing that DPNH and TPNH are directly involved in the reaction and are not merely acting as water-soluble carriers.

Table 1. PERCENTAGE CONVERSION OF ^{14}C-ŒSTRONE TO WATER-SOLUBLE ETHER-INSOLUBLE PRODUCTS BY PEROXIDASE IN THE PRESENCE OF PYRIDINE NUCLEOTIDES UNDER VARIOUS EXPERIMENTAL CONDITIONS

Experimental conditions	Percentage of added radioactivity remaining in aqueous medium after extraction with ether
Normal incubation*	39·0 43·5
DPNH omitted	1·1
